Education attainment. Table 4 shows that early educational treatment, the home environment, and the Treatment × Home interaction significantly predicted education attainment. Additionally, there was a significant indirect effect of risk on educational attainment as mediated by the home environment. This indirect effect is conditional because the Treatment × Home interaction term was significant. Consequently, we followed up this finding with post hoc analyses of simple indirect effects by estimating the mediation model separately for the control and treated samples. These post hoc tests of simple indirect effects indicated that the home environment mediated the relation between risk and education attainment for participants in the control group (effect = −0.36, *SE* = 0.13, CI = −76, −0.11) but not for the treated group (effect = −0.04, *SE* = 0.05, CI = −21, 0.04). That is, for the control group, increases in education attainment were associated with increases in HOME scores ($B = 0.83$, $SE = 0.23$, $p < .000$), but not with child risk levels ($B = 0.01$, $SE = 0.14$, $p = .96$). For the treated group, education attainment was significantly related neither to HOME scores ($B = 0.19$, $SE = 0.19$, $p = .31$) nor to child risk levels ($B = -0.14$, $SE = 0.17$, $p = .41$).

Figure 3 depicts the Treatment × Home interaction effect on education attainment. For children with lower quality home environment scores (1 *SD* below the mean), those in the treatment group attained on average 2 more years of education than did children in the control group ($p < .001$). Treatment was not associated with a significant increase in education attainment for children with average-quality home environments ($p = .25$) or higher quality home environments (1 *SD* above the mean; $p = .24$).

High school graduation. As seen in Table 4, only the home environment accounted for high school graduation in this sample. The home environment, in turn, was predicted by children's risk index.

Table 4
Moderated Mediation: Educational Outcomes

	Educational attainment			High school graduation		
	Coefficient	*SE*	95% CI	Coefficient	*SE*	95% CI
Effect on outcome						
Education treatment	.68**	0.24	0.22, 1.16	.06	0.26	−0.43, 0.62
Risk	−.06	0.11	−0.27, 0.17	−.09	0.12	−0.32, 0.13
Home environment	.51**	0.15	0.22, 0.79	.30*	0.12	0.05, 0.51
Treatment × Home	−.57*	0.27	−1.02, −0.02	−.41	0.26	−0.95, 0.05
Effect on home environment						
Risk	−.33***	0.07	−0.48, −0.22	−.33***	0.06	−0.49, −0.23
Indirect effect

**p* < .05. ***p* < .01. ****p* < .001.

Thus, the effect of risk on high school graduation was significantly mediated by the home environment. However, there was no evidence of moderated mediation.

Employment. As seen in Table 5, as children's risk levels increased, their likelihood of being employed at the time of the young adult interview decreased, but no evidence that this risk was mediated through its effects on the early home environment was found. Conversely, higher home environment scores were directly associated with greater likelihood of employment in young adulthood.

Table 5
Moderated Mediation: Employment

	Coefficient	*SE*	95% CI
Effect on employment			
Education treatment	.30	0.24	−0.24, 0.72
Risk	−.23*	0.12	−0.45, −0.01
Home environment	.25*	0.12	−0.01, 0.46
Treatment × Home	.07	0.24	−0.42, 0.51

Risk	−.33***	0.06	−0.49, −0.23
Indirect effect			
Indirect effect	−.08	0.04	−0.17, −0.00

**p* < .05. ****p* < .001.

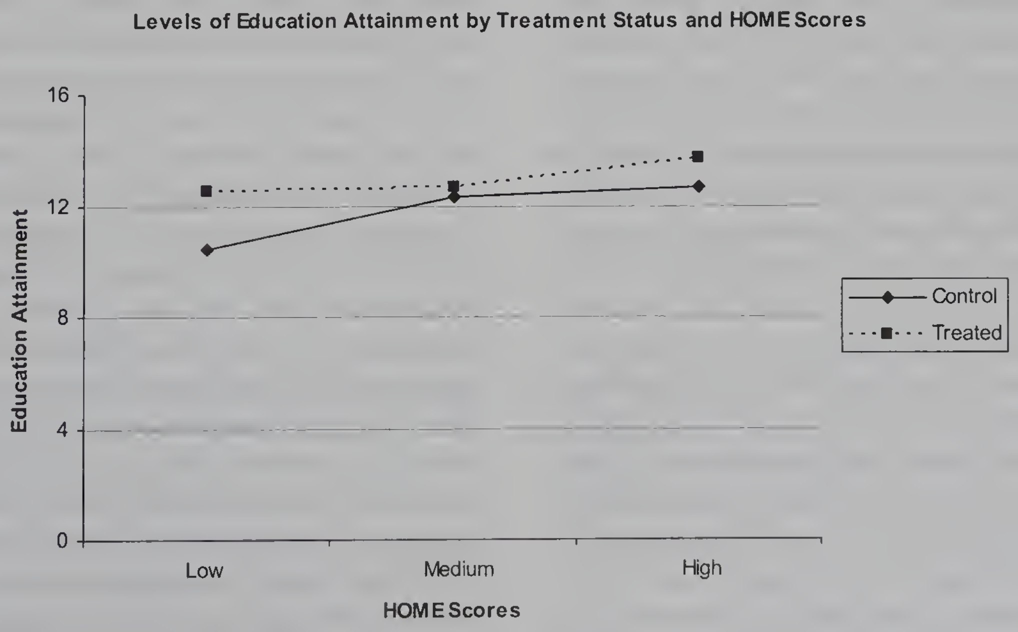

Figure 3. Years of education attainment by treatment status and Home Observation for Measurement of the Environment (HOME) scores.

Teen parenthood. Given the simultaneous estimation of effects, there was no evidence that the likelihood of having a child while a teen was related to risk level, the home environment, early education, nor an interactive effect of early education and the home environment.

Discussion

The first goal of the study was to examine the very long term effects of early cumulative risk over and above any effects of early intervention and to learn whether early intervention and early risk interacted when predicting the selected outcomes. As previously reported (Campbell et al., 2008), for the combined Abecedarian and CARE samples, early educational intervention was significantly associated with educational attainment in general, attending a 4-year college or university specifically, and obtaining skilled employment. The present analyses showed, in addition, that a prospective measure of cumulative risk summed across the first 5 years of life negatively predicted overall educational attainment, high school graduation specifically, and being employed as a young adult. Unexpectedly, early intervention was not found to moderate associations between early risk and young adult outcomes within this sample.

The second goal of this study was to examine a moderated mediation hypothesis: whether the quality of the early home mediated the found effects of early cumulative risk on later outcomes and whether early educational intervention moderated the effects of the early home environment on these outcomes. The results suggest that the home environment did mediate the effects of early risk for high school graduation but not for being employed or teen parenthood. Support for the moderated mediation hypothesis was found only for education attainment in general: The early home environment appeared to mediate the association between early risk and this outcome for the control group but not the treated group.

This study found associations between early risk and young adult accomplishments, a longer time span than is typical in the literature. The finding that early risk significantly predicted overall educational attainment and high school graduation specifically confirms as well as extends earlier work showing increased early cumulative risk to be associated with poor concurrent and shorter term academic outcomes (Brody et al., 2003; Forehand et al., 1998; Gutman et al., 2002; Gutman et al., 2003; Prelow & Loukas, 2003). The finding that higher early risk was associated with an increased likelihood of teen parenthood adds to previous work showing how individual risk factors are associated with teen parenthood (Cairns & Cairns, 1994; Haveman, Wolfe, & Wilson, 1997; Ludtke, 1997; Miller-Johnson, Winn, Coie, Malone, & Lochman, 2004). The current finding is modified by the fact that, within this sample, teen parenthood was no longer significantly predicted by risk when models simultaneously examined early risk, the early home environment, and early treatment.

The present findings suggest that when early cumulative risk and intensive early education in a child-care setting are considered simultaneously, higher level accomplishments in young adulthood were affected by early educational intervention whereas more basic-level accomplishments were associated with early risk. High school graduation, being employed as a young adult, and teen parenthood were all predicted by early cumulative risk irrespective of early intervention, whereas going to college and having a skilled-level job in young adulthood were predicted by early treatment, irrespective of early risk. Perhaps early risk added little to the prediction of going to college because it was at the earlier stage of completing high school that risk did the most harm, precluding the possibility of going to college. This is consistent with the report by Teachman, Paasch, Day, and Carver (1997) that family poverty appears to exert its greatest impact on high school graduation rather than on college attendance. Thus, within a high-risk sample, those experiencing the higher levels of risk find it harder to achieve some of the basic accomplishments of young adulthood, such as graduating from high school or getting any job. Early intervention, however, may provide the boost needed for higher levels of success, such as attending college or obtaining skilled employment.

A key finding from the present analyses is that treatment moderated the mediation of risk through the quality of the home environment. This effect emerged when predicting to the linear measure of young adult education attainment. For children in the control group, early cumulative risk was associated with a poorer quality home environment, which in turn was associated with lower levels of education attainment in young adulthood. This was consistent with our hypotheses. In contrast, our analyses found no evidence of such mediation for the treated group. Having the 5 years of educational intervention in a high-quality child-care setting appeared to be protective; that is, it buffered treated children against the long-term effects of a poor-quality early home environment on later educational attainment. This finding is consistent with other work suggesting that early intervention may moderate the effects of the early home environment (Bradley et al., 2001). Previous research involving the effects of child care on shorter term outcomes with high-risk samples has found evidence that child-care quality serves as a protective factor for some outcomes but not others. Burchinal et al. (2006) in their study of African American children in kindergarten through third grade found quality child care to be protective for math scores and behavior problems, but not for reading. Thus, different protective factors may be important for different outcomes (Gutman et al., 2003). The results here suggest that the effect for treatment was larger for those from poor-quality home environments than for those from higher quality early home environments. This implies that high-quality child care may be more effective for children whose parents are less responsive and provide less stimulating home environments than for other children.

Although evidence was found that early home environment mediated the effects of risk for educational outcomes, no evidence of such mediation was found for being employed or teen parenthood. The HOME, the measure used to assess the quality of the early home environment, has previously been shown to be associated with cognitive development and academic outcomes (Bradley, Caldwell, & Rock, 1988). Given this, its association with later educational outcomes in the present sample is consistent with the literature. One mechanism to explain the significant mediation findings is suggested by the work of Brody et al. (2003), who studied young African American adolescents growing up in single-mother homes in rural settings. These investigators found that cumulative risk was associated with parenting practices, which were in turn associated with youth self-regulation. Self-regulation was in turn associated with academic achievement. Heckman, Stixrud, and Urzua (2006) have suggested that noncognitive factors, as well as cognitive factors, strongly predict educational attainment. The environment provided by one's parents, combined with inherited ability and early intervention all play a role (Heckman et al., 2006). However, in the present study, the links between the early home environment and later educational attainments appear to be different from those that influence being employed and adolescent parenthood. The decision to become sexually active is complex (Michels, Kropp, Eyre, & Halpern-Felsher, 2005). Concurrent peer relationships and other adolescent circumstances undoubtedly play crucial roles in decisions made about parenthood when an adolescent is faced with such a life-altering experience. Young adult employment is subject to concurrent employment opportunities as well as personal characteristics influencing one's desire to seek work. Thus, the effects of early cumulative risk on employment and teen parenthood outcomes need further study; the links may be direct, as found here, or mediated through other early or concurrent factors not assessed in this study.

The hypothesis that increased early risk would be positively associated with illegal activity was not confirmed within this sample. In the present study, crime was represented by the young adults' self-reported convictions for misdemeanors and felonies and use of illegal drugs. A large body of research links risk and concurrent behavior problems. For example, using an index of cumulative risk, Furstenberg, Cook, Eccles, Elder, and Sameroff (1999) found that urban adolescents with 8 or more risk indicators (out of 10 possible) showed a 40% rate of behavior problems, compared to only 7% of those with 2 risk factors. However, these authors were examining current rates of problem behavior compared with current risk circumstances. Perhaps concurrent risk is more predictive of these outcomes than cumulative risk experienced much earlier in the life span.

No evidence was found that early educational intervention and early risk directly interacted to influence young adult outcomes. This finding was unexpected. It is noteworthy in this regard that the present sample consisted entirely of individuals who were drawn from high-risk backgrounds. Whether children exposed to more risk gain more from quality child care is a research question pertinent to policies regarding preferential entrance into public child-care programs, such as Head Start and prekindergarten, many of which use a high-risk index to determine who is recruited. Prior observational studies have found quality child care to be a stronger predictor of positive outcomes for children exposed to more social risk during early childhood (Burchinal et al., 2006; Burchinal, Peisner-Feinberg, Bryant, & Clifford, 2000; Caughy, DiPietro, & Strobino, 1994; Hubbs-Tait et al., 2002; Peisner-Feinberg & Burchinal, 1997; Peisner-Feinberg et al., 2001; Schliecker, White, & Jacobs, 1991; Vandell, 2004). This sample, however, consisted of individuals all considered high risk due to poverty and most considered at high risk due to minority ethnic status. This homogeneity within the present sample could have precluded detection of the expected interaction between risk and treatment.

Some limitations should be considered in interpreting the findings of the study. First, the sample was limited to individuals born into low-income families almost all of whom were African American, and thus the findings generalize to that demographic group and may apply to other groups in unknown ways. As noted earlier, being minority ethnic status is a variable that in and of itself has been found to be a risk factor. In addition to being more likely to be of low income (Denavas-Walt, Proctor, & Lee, 2006) and to experience other stressors that European Americans (Evans, 2004), discrimination and racism experienced by ethnic minority families may also negatively influence development (Murry, Brown, Brody, Cutrona, & Simons, 2001; Prelow, Danoff-Burg, Swenson, & Pulgiano, 2004). That is, as Murry, Brown, et al. (2001) found, although a lack of income and other resources is a significant factor in families' stress and functioning, ''simply being Black in America'' (p. 917) also played a critical yet sometimes unacknowledged role affecting maternal psychological functioning, thus influencing the quality of relationships and interactions in the home environment.

A second caveat is that the sample size was small, which may have reduced the power to detect smaller relationships and interaction effects (McClellan & Judd, 1993). This may have been especially problematic when considering the data on illegal activity. The total sample size was relatively small, and the proportion of young adults who self-reported lawbreaking was smaller still. Admission of a misdemeanor occurred in only 17% of the sample, and only 10% admitted a felony. Power may also have been limited by the fact that most of the outcomes considered here were dichotomous rather than continuous variables.

Another limitation of this work, one generally shared by the literature in this area, is that some of the risk factors that may have contributed to outcomes were not assessed and thus were not included in the cumulative risk index. Within the literature on this topic, wide variety exists concerning this issue. For example, Brody et al. (2003) included 7 possible factors, Sameroff et al. (1993) had 10, and Evans (2003) listed 9. This diversity among risk factors makes it difficult to compare findings across studies. An alternate approach to studying the question of risk might be to combine risk variables empirically using factor analyses as was performed by Deater-Decker et al. (1998). Burchinal, Roberts, et al. (2000) compared three approaches to analyzing risk—testing individual risk factors, creating risk factor scores using factor analyses, and calculating a cumulative risk index—and found that similar, but not identical, conclusions could be drawn using each approach. Given sufficient sample sizes, considering domains of risk, rather than simply summing indicators, may be more appropriate for different outcomes. However, longitudinal studies often consist of small sample sizes, for which a cumulative risk index may be most appropriate (Burchinal, Roberts, et al., 2000).

Similarly, the models in the current analyses did not include protective factors (beyond early educational intervention) that may have been related to outcomes, nor did they include how the adolescents and young adults interpreted the early risk factors. Future research could include these variables to gain a better understanding of the effects of early risk as well as pathways to competence in the context of adversity (Masten et al., 1999).

Another caveat concerns generalizations that can be made about the effects of child care. Although the treatment took place in a full-time child-care setting, the educational intervention was not typical of the early child-care experience for most young children. Moreover, although the treatment and control groups differed by the fact that one received the systematic early treatment and the other did not, many children in the control group did experience out-of-home care before the age of 5. Different types were used by this group including relative care, family day care homes, and state-licensed center care, as determined by family circumstances. Thus, the group comparisons are between those who did and did not receive early educational intervention in a child-care setting, not between those who did and did not experience out-of-home child care.

Despite the limitations, several strengths of this study increase confidence in the findings. These strengths include the study's longitudinal nature, which provided prospective data on early risk, and the very long span of time covered by the data collection, from birth to young adulthood. This permitted early risk to be summed across early childhood, capturing the natural variation that occurred within individual lives as experienced at the time. As noted by Gerard and Buehler (2004), one of the strengths of cumulative risk models is ''their potential to capture the natural covariation of risk factors'' (p. 1833). In addition, both the Abecedarian and CARE studies had low rates of attrition, increasing investigator confidence in long-term outcomes. Confidence in the conclusions pertaining to early educational intervention is increased by the fact that both Abecedarian and CARE were randomized studies. This degree of experimental control allows for the interpretation of early treatment's contribution to the outcomes with more confidence than would be possible in a naturalistic study where self-selection into treatment could have biased the findings.

These findings have implications for public policymakers considering how to allocate limited resources. Given that the effects of early cumulative risk can be very long-lasting and impact important basic young adult outcomes, resources are needed to help protect high-risk children from the effects of such multiple stressors. Increased early risk may have a particularly negative effect on some of the basic-level accomplishments society requires for minimal self-sufficiency. Early intervention, however, moderated the effects of less optimal home environments on educational attainment and was promotive for the important outcomes of college attendance and obtaining skilled employment in this high-risk sample. These findings affirm the allocation of resources to provide early childhood programs for high-risk children.

Manuscripts Accepted for Publication

Lying and Truth-Telling in Children: From Concept to Action, Fen Xu, Xuehua Bao, Victoria Talwar, and Kang Lee.

Preschoolers' Implicit and Explicit False-Belief Understanding: What Are the Relations With Complex Syntax? Jason Low.

Mother–Infant Interaction During the First 3 Months: The Emergence of Culture-Specific Contingency Patterns, Joscha Kärtner, Heidi Keller, and Relindis Yovsi.

Not Doing What You Are Told: Early Perseverative Errors in Updating Mental Representations via Language, Patricia A. Ganea and Paul L. Harris.

The Rise in Cortisol in Family Day Care: Associations With Aspects of Care Quality, Child Behavior, and Child Sex, Megan Gunnar, Erin Kryzer, Mark J. Van Ryzin, and Deborah A. Phillips.

"My Way or Mom's Way?": The Bilingual and Bicultural Self in Hong Kong Chinese Children and Adolescents, Qi Wang, Yi Shao, and Yexin Jessica Li.

The Significance of Insecure Attachment and Disorganization in the Development of Children's Externalizing Behavior: A Meta-Analytic Study, Pasco Fearon, Marian Bakermans-Kranenburg, Marinus Van IJzendoorn, Anne-Marie Lapsley, and Glenn Roisman.

Children's Sensitivity to the Conventionality of Sources, Gil Diesendruck, Nurit Carmel, and Lori Markson.

When Do Children Exhibit a Yes Bias? Mako Okanda and Shoji Itakura.

Children Monitor Individuals' Expertise for Word Learning, David Sobel and Kathleen Corriveau.

Developmental Patterns in Decision-Making Autonomy Across Middle Childhood and Adolescence: European American Parents' Perspectives, Laura Wray-Lake, Ann C. Crouter, and Susan M. McHale.

Bridging Theory of Mind and the Personal Domain: Children's Reasoning About Resistance to Parental Control, Kristin Lagattuta, Larry Nucci, and Sandra Leanne Bosacki.

The Dynamics of Free Recall and Their Relation to Rehearsal Between 8 and 10 Years of Age, Martin Lehmann and Marcus Hasselhorn.

The Tuning of Human Neonates' Preference for Speech, Athena Vouloumanos, Marc D. Hauser, Janet F. Werker, and Alia Martin.

Early Gesture Predicts Language Delay in Children With Pre- or Perinatal Brain Lesions, Eve Sauer, Susan C. Levine, and Susan Goldin-Meadow.

Coercive and Prosocial Fathering, Antisocial Personality, and Growth in Children's Postdivorce Noncompliance, David S. DeGarmo.

Parent Discipline Practices in an International Sample: Associations With Child Behaviors and Moderation by Perceived Normativeness, Elizabeth Gershoff, Andrew Grogan-Kaylor, Jennifer E. Lansford, Chang Lei, Arnaldo Zelli, Kirby Deater-Deckard, and Kenneth A. Dodge.

The Complex Relation Between Bullying, Victimization, Acceptance, and Rejection: Giving Special Attention to Status, Affection, and Sex Differences, René Veenstra, Siegwart Lindenberg, Anke Munniksma, and Jan Kornelis Dijkstra.

Who Said You Could Wear My Sweater?: Adolescent Siblings' Conflicts and Associations With Relationship Quality, Nicole Campione-Barr and Judith G. Smetana.

Categorization in 3- and 4-Month-Old Infants: An Advantage of Words Over Tones, Alissa Ferry, Susan Hespos, and Sandra Waxman.

Family Socioeconomic Status and Consistent Environmental Stimulation in Early Childhood, Robert Crosnoe, Tama Leventhal, R. J. Wirth, Kim Pierce, and Robert Pianta.

Defining Best Practice in Care and Protection of Children in Crisis-Affected Settings: A Delphi Study, Alastair Ager, Lindsay Stark, Bree Akesson, and Neil Boothby.

Inconsistency With Prior Knowledge Triggers Children's Causal Explanatory Reasoning, Cristine H. Legare, Susan A. Gelman, and Henry M. Wellman.

Children's Tattling: The Reporting of Everyday Norm Violations in Preschool Settings, Gordon Ingram and Jesse Bering.

Conversation, Development, and Gender: A Study of Changes in Children's Concepts of Punishment, Patrick Leman and Marina Bjornberg.

Integrating Different Perspectives on Socialization Theory and Research: A Domain-Specific Approach, Joan Grusec and Maayan Davidov.

Children's Sleep and Adjustment Over Time: The Role of Socioeconomic Context, Mona El-Sheikh, Ryan J. Kelly, Joseph A. Buckhalt, and J. Benjamin Hinnant.

Antecedents and Correlates of the Popular-Aggressive Phenomenon in Elementary School, Philip Rodkin and Glenn I. Roisman.

The Effects of the 1999 Turkish Earthquake on Young Children: Analyzing Traumatized Children's Completion of Short Stories, Elif Celebi Oncu and Aysegul Metindogan Wise.

Individual and Peer Group Normative Beliefs About Relational Aggression: Developmental Changes and Prediction of Relational Aggression, Nicole E. Werner and Laura G. Hill.

Gender, Values, and Occupational Interests Among Children, Adolescents, and Adults, Erica Weisgram, Rebecca S. Bigler, and Lynn S. Liben.

Children's Understanding of Social-Cognitive and Social-Communicative Aspects of Discourse Irony, Eva Filippova and Janet Wilde Astington.

The Head Bone's Connected to the Neck Bone: When Do Toddlers Represent Their Own Body Topography? Celia A. Brownell, Sara R. Nichols, Margarita Svetlova, Stephanie Zerwas, and Geetha Ramani.

Connecting Cues: Overlapping Regularities Support Cue Discovery in Infancy, Sarah Sahni, Mark Seidenberg, and Jenny Saffran.

Mexican-Heritage Children's Attention and Learning From Interactions Directed to Others, Katie G. Silva, Maricela Correa-Chávez, and Barbara Rogoff.

The Development of Social Essentialism: The Case of Israeli Children's Inferences About Jews and Arabs, Dana Birnbaum, Inas Deeb, Gili Segall, Adar Ben-Eliyahu, and Gil Diesendruck.

Parent Involvement and Children's Academic and Social Development in Elementary School, Nermeen El Nokali, Heather J. Bachman, and Elizabeth Votruba-Drzal.

Do Effects of Early Child Care Extend to Age 15 Years? Deborah Vandell, Jay Belsky, Margaret Burchinal, Laurence Steinberg, Nathan Vandergrift, and NICHD Early Child Care Research Network.

I Like Me If You Like Me: On the Interpersonal Modulation and Regulation of Preadolescents' State Self-Esteem, Sander Thomaes, Albert Reijntjes, Bram Orobio de Castro, Brad J. Bushman, Astrid Poorthuis, and Michael J. Telch.

An Eye for Detail: An Event-Related Potential Study of the Rapid Processing of Fearful Facial Expressions in Children, Petra Vlamings, Lisa M. Jonkman, and Chantal Kemner.

Experience-Based and On-Line Categorization of Objects in Early Infancy, Marc Bornstein and Clay Mash.

On the Progression and Stability of Adolescent Identity Formation, Wim Meeus, Rens van de Schoot, Loes Keijsers, Seth J. Schwartz, and Susan Branje.

Dogs, Bogs, Labs, and Lads: What Phonemic Generalizations Indicate About the Nature of Children's Early Word-Form Representations, Erik Thiessen and Meagan N. Yee.

Investigating the Development of Core Cognitive Skills in Autism: A 3-Year Prospective Study, Elizabeth Pellicano.

Home Media and Children's Achievement and Behavior, Sandra Hofferth.

The Effects of Maltreatment and Neuroendocrine Regulation on Memory Performance, Dante Cicchetti, Fred A. Rogosch, Mark L. Howe, and Sheree L. Toth.

Interracial and Intraracial Contact, School-Level Diversity, and Change in Racial Identity Status Among African American Adolescents, Tiffany Yip, Eleanor K Seaton, and Robert M. Sellers.

Child Care and the Development of Behavior Problems Among Economically Disadvantaged Children in Middle Childhood, Elizabeth Votruba-

Drzal, Rebekah Coley, Carolina Maldonado Carreno, Christine Li-Grining, and P. Lindsay Chase-Lansdale.

Children's Classroom Engagement and School Readiness Gains in Prekindergarten, Nina C. Chien, Carollee Howes, Margaret Burchinal, Robert Pianta, Sharon Ritchie, Donna Bryant, Richard Clifford, Diane Early, and Oscar Barbarin.

Early Elementary School Adjustment of Maltreated Children in Foster Care: The Roles of Inhibitory Control and Caregiver Involvement, Katherine Pears, Philip A. Fisher, Jacqueline Bruce, Hyoun K. Kim, and Karen Yoerger.

Children's Understanding of Ordinary and Extraordinary Minds, Jonathan Lane, Henry Wellman, and E. Margaret Evans.

What Paradox? Referential Cues Allow For Infant Use of Phonetic Detail in Word Learning, Christopher Fennell and Sandra R. Waxman.

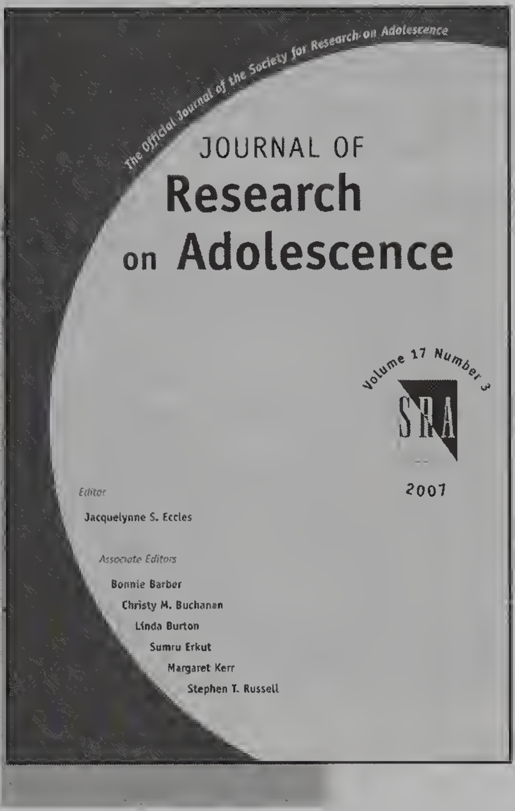
Contagious Yawning in Autistic and Typical Development, Molly Helt, Inge-Marie Eigsti, Peter J. Snyder, and Deborah A. Fein.

Tolerance of Practices by Muslim Actors: An Integrative Social-Developmental Perspective, Maike Gieling, Jochem Thijs, and Maykel Verkuyten.

Structure and Strategies in Children's Educational Television: The Roles of Program Type and Learning Strategies in Children's Learning, Deborah L. Linebarger and Jessica Taylor Piotrowski.

Bridging the Gap: Solving Spatial Means–Ends Relations in a Locomotor Task, Sarah Berger, Karen E. Adolph, and Alisan E. Kavookjian.

Sex Categorization Among Preschool Children: Increasing Utilization of Sexually Dimorphic Cues, Kerri Johnson, Leah Lurye Murphy, and Louis G. Tassinary.



The Official Journal of the Society for Research on Adolescence

Multidisciplinary and international in scope, the ***Journal of Research on Adolescence (JRA)*** significantly advances knowledge in the field of adolescent research. Employing a diverse array of methodologies, this compelling journal publishes original research and integrative reviews of the highest level of scholarship. Featured studies include both quantitative and qualitative methodologies applied to cognitive, physical, emotional, and social development and behavior. Articles pertinent to the variety of developmental patterns inherent throughout adolescence are featured, including cross-national and cross-cultural studies. Attention is given to normative patterns of behavior as well as individual differences rooted in personal or social and cultural factors.

Notice to Contributors

Child Development publishes empirical, theoretical, review, applied, and policy articles reporting research on child development. Published by the interdisciplinary Society for Research in Child Development (SRCD), the journal welcomes relevant submissions from all disciplines. Further information is available at http://www.srcd.org/cd.html.

Types of Articles

Child Development considers manuscripts in formats described below. Inquiries concerning alternative formats should be addressed to the Editor prior to submission. All submissions are expected to be no more than 40 manuscript pages, including tables, references, and figures (but excluding appendices). Authors should provide a justification if the submission is substantially longer. Unless the editor finds that justification compelling, the submission will be returned to the author for shortening prior to editorial review.

Empirical articles comprise the major portion of the journal. To be accepted, empirical articles must be judged as being high in scientific quality, contributing to the empirical base of child development, and having important theoretical, practical, or interdisciplinary implications. Reports of multiple studies, methods, or settings are encouraged, but single-study reports are also considered. Empirical articles will thus vary considerably in length, but should be no longer than 40 manuscript pages; text and graphics should be as concise as material permits. All modes of empirical research are welcome.

Empirical reports are reserved for short cutting-edge empirical papers that are no longer than 4,000 words in length (including text, tables, footnotes, appendices), which advance research and knowledge in an area through noteworthy findings and/or new methods. For manuscripts that require longer descriptions of methods and results, authors should use the Empirical article format.

Reviews focus on past empirical and/or on conceptual and theoretical work. They are expected to synthesize or evaluate a topic or issue relevant to child development, should appeal to a broad audience, and may be followed by a small number of solicited commentaries.

Essays describe original concepts, methods, trends, applications, and theories; these may also be accompanied by solicited commentaries.

Child Development and ... are articles that provide readers with tutorials about some new concept or academic specialty pertinent to research in child development. These papers should review the major definitions, methods, and findings of the concept or specialty and discuss past or potential links to child development.

From another perspective is a format in which papers on a focal topic, written by different authors, are published simultaneously. Papers represent diverse perspectives (e.g., authors whose work represents different populations; different disciplines; different theories, methods, or analytic tools). In some cases, calls for submissions on particular topics will be disseminated through SRCD (via e-mail or SRCD publications), and submissions will undergo normal editorial review. In some cases, a submitted manuscript (e.g., an empirical article) may be selected as a lead article for this format, with invited commentaries providing additional perspectives. The editors also welcome suggestions from readers for topics for this format.

Manuscript Submission

Child Development invites for consideration manuscripts that are neither identical to nor substantially similar to work published or under review elsewhere. In the submission cover letter, please provide details about other published or submitted papers having substantial overlap (including data sets) with the new CD submission to enable editors to judge whether the new submission is sufficiently distinct from other work to warrant consideration. Please note if the paper is posted on a website, see http://www. srcd.org/web posting. html. Editors retain the right to reject manuscripts that do not meet established ethical standards for research or dissemination.

Manuscripts should be submitted electronically to the Child Development Online Submission Site at www.srcd.org /CDsubmit/ as a Word or WordPerfect file. Please also submit a cover letter that contains the name(s) of the author(s) and affiliation(s), and the street address, telephone, fax, and electronic mail address of the corresponding author. A corresponding author's submission to *Child Development* implies that all coauthors have agreed to the content and form of the manuscript and that the ethical standards of SRCD have been followed (see the *Child Development* website or pp. 283–284 of the 2000 SRCD Directory). Any financial interest or conflict of interest must be explained to the Editor in the cover letter. The corresponding author is responsible for informing all coauthors, in a timely manner, of manuscript submission, editorial decisions, reviews, and revisions. Please note that if your submission (or its revision) is accepted for publication, each author must submit a signed Exclusive License Form (http://www.srcd.org/Documents/Publications/CD/cdcopyright.pdf) before the manuscript can enter production. Planning ahead to meet this requirement is especially important for manuscripts with multiple authors.

The manuscript file should be formatted with double-spaced, 12-point type, and should include a single paragraph abstract of 100-120 words. Please follow all guidelines on format, style, and ethics provided in the Publication Manual (5th ed.) of the American Psychological Association. Figures included with initial submissions will not be returned. Therefore, please submit only electronic files or copies of figures. If color artwork is submitted, and the authors believe color art is necessary to the presentation of their work, the submissions letter should indicate that one or more authors or their institutions are prepared to pay the substantial costs associated with color art reproduction. Authors should keep a copy of all correspondence, files, and figures to guard against loss.

Manuscript Review

If you have any questions about your submission, please inquire at cdev@srcd.org or call (734) 926-0615. Each manuscript is handled by the Editor or an Associate Editor who consults with one or more Consulting Editors and/or ad hoc reviewers who have relevant expertise. To ensure blind review, cover sheets are removed before review; authors should avoid including any other information about identity or affiliation in submissions. Copies of the submission and associated correspondence are retained in the SRCD archives. For accepted manuscripts, authors are required to prepare a 300-500 layperson's summary for public dissemination purposes. Details are provided to authors as part of final processing.

There is no charge for publication in *Child Development* unless tabular or graphic materials exceed 10% of the total number of pages. Charges are also levied for changes in proofs other than correction of printer's errors. Any inquiries relating to charges or business matters (including reprint orders) should be addressed to Wiley-Blackwell, *Child Development*, Production Coordinator, 350 Main Street, Malden, MA 02148, (781) 388-8200.

Inquiries and suggestions regarding editorial policy may be addressed to: Dr. Jeffrey J. Lockman, Editor, *Child Development*, Department of Psychology, Tulane University, 2007 Percival Stern Hall, New Orleans, LA 70118-5698, lockman@tulane.edu. *Please do not send electronic or paper manuscripts to the above address.* Doing so will delay the processing of your manuscript.

Note to NIH Grantees

Pursuant to NIH mandate, Society through Wiley-Blackwell will post the accepted version of Contributions authored by NIH grantholders to PubMed Central upon acceptance. This accepted version will be made publicly available 12 months after publication. For further information, see www.wiley.com/go/nihmandate.

MONOGRAPHS OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT

Recent

A DYNAMIC CASCADE MODEL OF THE DEVELOPMENT OF SUBSTANCE-USE ONSET
- *Kenneth A. Dodge, Patrick S. Malone, Jennifer E. Lansford, Shari Miller, Gregory S. Pettit, and John E. Bates* (Serial No. 294, 2009).

FLEXIBILITY IN EARLY VERB USE: EVIDENCE FROM A MULTIPLE-*N* DIARY STUDY
- *Letitia R. Naigles, Erika Hoff, and Donna Vear* (Serial No. 293, 2009).

MARITAL CONFLICT AND CHILDREN'S EXTERNALIZING BEHAVIOR: INTERACTIONS BETWEEN PARASYMPATHETIC AND SYMPATHETIC NERVOUS SYSTEM ACTIVITY
- *Mona El-Sheikh et al.* (Serial No. 292, 2009).

THE EFFECTS OF EARLY SOCIAL-EMOTIONAL AND RELATIONSHIP EXPERIENCE ON THE DEVELOPMENT OF YOUNG ORPHANAGE CHILDREN
- *The St. Petersburg–USA Orphanage Research Team* (Serial No. 291, 2008).

UNDERSTANDING MOTHER-ADOLESCENT CONFLICT DISCUSSIONS: CONCURRENT AND ACROSS-TIME PREDICTION FROM YOUTHS' DISPOSITIONS AND PARENTING
- *Nancy Eisenberg et al.* (Serial No. 290, 2008).

DEVELOPING OBJECT CONCEPTS IN INFANCY: AN ASSOCIATIVE LEARNING PERSPECTIVE
- *David H. Rakison and Gary Lupyan* (Serial No. 289, 2008).

THE GENETIC AND ENVIRONMENTAL ORIGINS OF LEARNING ABILITIES AND DISABILITIES IN THE EARLY SCHOOL YEARS
- *Yulia Kovas, Claire M. A. Haworth, Philip S. Dale, and Robert Plomin* (Serial No. 288, 2007).

THE PRESERVATION OF TWO INFANT TEMPERAMENTS INTO ADOLESCENCE
- *Jerome Kagan, Nancy Snidman, Vali Kahn, and Sara Towsley* (Serial No. 287, 2007).

CHILDREN'S QUESTIONS: A MECHANISM FOR COGNITIVE DEVELOPMENT
- *Michelle M. Chouinard* (Serial No. 286, 2007).

BEST PRACTICES IN QUANTITATIVE METHODS FOR DEVELOPMENTALISTS
- *Kathleen McCartney, Margaret R. Burchinal, and Kristen L. Bub* (Serial No. 285, 2006).

FOUNDATIONS OF SELF-AWARENESS: AN EXPLORATION THROUGH AUTISM
- *R. Peter Hobson, Gayathri Chidambi, Anthony Lee, and Jessica Meyer* (Serial No. 284, 2006).

OUR CHILDREN TOO: A HISTORY OF THE BLACK CAUCUS
OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT, 1973–1997
- *Diana T. Slaughter-Defoe, Aline M. Garrett, and Algea O. Harrison-Hale* (Serial No. 283, 2006).

PARENTAL SUPPORT, PSYCHOLOGICAL CONTROL, AND BEHAVIORAL CONTROL:
ASSESSING RELEVANCE ACROSS TIME, CULTURE, AND METHOD
- *Brian K. Barber, Heidi E. Stolz, and Joseph A. Olsen* (Serial No. 282, 2005).

BEING HURT AND HURTING OTHERS: CHILDREN'S NARRATIVE ACCOUNTS
AND MORAL JUDGMENTS OF THEIR OWN INTERPERSONAL CONFLICTS
- *Cecilia Wainryb, Beverly A. Brenl, and Sonia Matwin* (Serial No. 281, 2005).

CHILDHOOD SEXUAL ASSAULT VICTIMS: LONG-TERM OUTCOMES AFTER TESTIFYING IN CRIMINAL COURT
- *Jodi A. Quas, Gail S. Goodman, Simona Ghetti, Kristen Weede Alexander, Robin Edelstein, Allison D. Redlich, Ingrid M. Cordon, and David P. H. Jones* (Serial No. 280, 2005).

THE EMERGENCE OF SOCIAL COGNITION IN THREE YOUNG CHIMPANZEES
- *Michael Tomasello and Malinda Carpenter* (Serial No. 279, 2005).

TRAJECTORIES OF PHYSICAL AGGRESSION FROM TODDLERHOOD TO MIDDLE CHILDHOOD:
PREDICTORS, CORRELATES, AND OUTCOMES
- *NICHD Early Child Care Research Network* (Serial No. 278, 2004).

CONSTRAINTS ON CONCEPTUAL DEVELOPMENT: A CASE STUDY OF THE ACQUISITION OF
FOLKBIOLOGICAL AND FOLKSOCIOLOGICAL KNOWLEDGE IN MADAGASCAR
- *Rita Astuti, Gregg E. A. Solomon, and Susan Carey* (Serial No. 277, 2004).

ORIGINS AND EARLY DEVELOPMENT OF HUMAN BODY KNOWLEDGE
- *Virginia Slaughter, Michelle Heron, Linda Jenkins, and Elizabeth Tilse* (Serial No. 276, 2004).

MOTHER–CHILD CONVERSATIONS ABOUT GENDER: UNDERSTANDING THE ACQUISITION OF ESSENTIALIST BELIEFS
- *Susan A. Gelman, Marianne G. Taylor, and Simone P. Nguyen* (Serial No. 275, 2004).

THE DEVELOPMENT OF EXECUTIVE FUNCTION IN EARLY CHILDHOOD
- *Philip David Zelazo, Ulrich Müller, Douglas Frye, and Stuart Marcovitch* (Serial No. 274, 2003).

Child Development

CHILD DEVELOPMENT (ISSN 0009-3920), one of three publications of the Society for Research in Child Development, Inc., is published bimonthly by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to *CHILD DEVELOPMENT*, Journal Customer Services, John Wiley & Sons Inc., 350 Main Street, Malden, MA 02148-5020.

Information for Subscribers: *Child Development* is published in six issues per year. Institutional subscription prices for 2010 are: Print & Online: US$670 (US), US$938 (Rest of World), €608 (Europe), £479 (UK). Prices are exclusive of tax. Asia- Pacific GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www3.interscience.wiley.com/aboutus/journal_ordering_and_payment.html#Tax. The price includes online access to the current and all online back files to January 1st 1997, where available. For other pricing options, including access information and terms and conditions, please visit www.interscience.wiley.com/journal-info.

Delivery Terms and Legal Title: Prices include delivery of print journals to the recipient's address. Delivery terms are Delivered Duty Unpaid (DDU); the recipient is responsible for paying any import duty or taxes. Legal title passes to the customer on despatch by our distributors.

For more information about Wiley-Blackwell journals, including online access information, terms and conditions, and other pricing options, please visit www.interscience.wiley.com or contact our customer service department, tel: (800) 835-6770 or +1 (781) 388-8598 (Americas); +44 (0) 1865 778315 (Europe, Middle East, and Africa); or +65 6511 8000 (Asia Pacific). Subscription in 2010 includes three issues of *Monographs of the Society for Research in Child Development* and three issues of *Child Development Perspectives.* Single issues from current and recent volumes are available at the current single issue price from csjournals@wiley.com. Earlier issues may be obtained from Periodicals Service Company, 11 Main Street, Germantown, NY 12526, USA. Tel: +1 518 537 4700, Fax: +1 518 537 5899, Email: psc@periodicals.com. Volumes 37 to date are available in microfilm from ProQuest Information and Learning, Serials Customer Service Department, 300 North Zeeb Road, Ann Arbor, MI 48106; telephone: (800) 521-0600 x2873.

Electronic Access: The *Child Development* website can be found at www.srcd.org. Abstract information for this journal is electronically available at www.blackwellpublishing.com/cdev. This journal is available online at Wiley InterScience. Visit www3.interscience.wiley.com to search the articles and register for table of contents e-mail alerts.

Access to this journal is available free online within institutions in the developing world through the HINARI initiative with the WHO. For information, visit www.healthinternetwork.org

Journal Customer Services: For ordering information, claims and any enquiry concerning your journal subscription, please go to interscience.wiley.com/support or contact your nearest office:

Quality of Care

The quality of the attachment relationship between a child and parent is important to children's development, but past research into the link between attachment and children's development has been inconsistent. **Fearon, Bakermans-Kranenburg, van IJzendoorn, Lapsley, and Roisman** (p. 435) carried out a meta-analysis, looking at 69 studies involving almost 6,000 children on the effect of the quality of child–mother attachment on children's behavior problems. Attachment insecurity is significantly associated with a higher level of children's behavior problems, particularly in boys, in clinical samples, and in studies that used observational assessments of behavior problems. Their analysis suggests that the effects of attachment are relatively persistent over time. More specifically, children who seem unable to maintain a coherent strategy for coping with separation are at greatest risk for later behavior problems and aggression.

The Helping Hand of Language

Although infants typically produce their first words sometime around their first birthdays, long before this milestone occurs they are learning a lot about language and establishing links between the language they hear and the objects and events they see. To learn how early these links emerge in infancy, **Ferry, Hespos, and Waxman** (p. 472) asked whether 3- and 4-month-olds are better able to notice categories of objects if the objects were introduced with words. Infants who heard nonsense words provided evidence of categorization, but those who heard tone sequences didn't. This tells us that even this early in development, words exert an influence on how we categorize objects that's distinct from that of nonspeech. The study provides the earliest evidence to date of a link between words and concepts; in so doing, it reinforces the guidance that parents talk to their babies, because from early on, the little ones are listening and learning.

Language allows us to learn about any topic without directly experiencing it. When new information is provided verbally about an object that isn't visible, we update our knowledge. **Ganea and Harris** (p. 457) sought to determine at what age young children do this. They found that by 19 months—almost at the onset of language production—toddlers can update based on verbal information. Even at 23 months, the updating process is error prone, but not at 30 months. This suggests that toddlers search for the object at the original location when they've been *told* about an item being moved instead of seeing it for themselves. Moreover, the children didn't make the mistakes because they couldn't encode the new information; they encoded the new information about the item's new location but failed to use it to guide their search. In showing that the ability to acquire information from words is a major cognitive advance, the study sheds light on how children use language to guide their search behavior.

Sibling Fighting and Classroom Bullying

A lot of research into fighting between siblings has focused primarily on younger children. In a study on adolescent siblings, **Campione-Barr and Smetana** (p. 464) used a new measure to examine what teens fight about and how different types of conflicts affect their relationships. The bottom line: Teen siblings argue most often about invasion of personal space (''Who said you could wear my sweater?'') and also about issues of equality and fairness (''It's my turn to sit in the front seat of the car!''). Their conflicts are frequent but not intense. Those who quarrel most often about personal space issues have poorer relationships with their siblings, with less trust and communication. The study—of more than 100 mostly White, middle-class pairs of siblings ages 13 and 15—extends our understanding of fighting between older brothers and sisters.

Veenstra, Lindenberg, Munniksma, and Dijkstra (p. 480) tackle fighting from a different perspective—bullying. They ask: Are bullies children who can't control their aggressive impulses? Not likely, according to this large-scale Dutch study. For most bullies, the pursuit of status (in this case, the desire to dominate classmates) and affection

(that is, acceptance and lack of rejection) seems to foster strategic control of bullying behavior. The study, of almost 500 elementary-school children, finds that bullies generally choose to gain status by dominating their victims, but at the same time they try to reduce the chances that they'll end up on the outs with other classmates by choosing victims who are weak and not well liked by others. Gender also plays a role, with bullies being rejected by the children of the gender for whom they're a potential threat; for example, boys are rejected by boys when they bully boys and by girls when they bully girls. This study helps us understand the complex nature of bullies and victims in the elementary years.

How Divorced Dads Parent

Studies on divorced dads have found that when fathers who don't live with their children make time to be involved with them, it cuts down on problem behaviors in the youngsters. But in a new longitudinal study, **DeGarmo** (p. 503) finds that characteristics of the dads' behavior play a role in how the children do. The study took a look at 230 families with children from 4 to 11 to determine how divorced dads' parenting practices affected their children's likelihood of obeying or disobeying them, specifically taking into consideration dads' levels of social and antisocial behavior—their likeliness to have stolen, engaged in fights, be suspended from school, and so forth. For both girls and boys, when dads were antisocial, the positive effects of their monthly contact with their children were significantly reduced. The study has implications for prevention programs.

Speech Versus Nonspeech Sounds

Are infants' early listening biases for the sounds of language (as opposed to nonspeech sounds) specifically tuned to speech, or do they extend more broadly to other primate vocalizations such as rhesus monkey calls? **Vouloumanos, Hauser, Werker, and Martin** (p. 517) presented newborns and 3-month-olds with nonsense speech and the vocalizations of rhesus monkeys. Surprisingly, given that newborns have shown a preference for speech over nonspeech sounds, they found monkey calls as interesting as speech. However, the babies did prefer both monkey calls and speech to synthetic sounds. In contrast, 3-month-olds listened more to speech than to monkey vocalizations. This shows that people are born with a more broadly tuned preference that minimally includes speech and monkey vocalizations. And over the first 3 months of life, infants' listening preferences are sharpened, resulting in a species-specific preference for speech.

Brain Lesions and Language

Children with brain lesions before or around the time of birth often take longer to reach early language milestones; these delays normalize for many but persist for some. To identify which children will continue to have language delays, **Sauer, Levine, and Goldin-Meadow** (p. 528) examined whether vocabulary delays can be predicted by looking at how 18-month-old children with brain lesions used gestures such as pointing or waving good-bye when they weren't saying a lot, comparing them with typically developing children of the same age. (Gesture has been found to be a good predictor of later language abilities in typically developing children.) The children's language comprehension was tested when they were 30 months old. Findings of this longitudinal study: Gesturing at 18 months (but not early speech) predicted which children with lesions had vocabulary delays a year later, suggesting that gesture may be a tool for diagnosing persistent language delay in children with brain lesions.

Cultural Differences: Early Interaction, Self, and Discipline

Intuitively, mothers react to infants' signals quickly, normally in less than a second. This part of intuitive parenting, called contingent responsiveness, has implications for infants' later development. Earlier studies have found differences in the way mothers from different cultures react to their 3-month-olds. In a longitudinal cross-cultural study, **Kärtner, Keller, and Yovsi** (p. 540) looked at video-recorded interactions between moms and their infants prior to 3 months of age from German families (whose culture stresses independence) and from the Nso, an ethnic group in Cameroon (whose culture emphasizes interdependence). Moms in the two groups were similar in the amount of contingent responsiveness. But differences in how they reacted across their children's first 3 months suggest that moms' culture-specific beliefs and behavioral standards interact with developments in their babies' abilities to communicate (such as, for example, maintaining eye contact for longer periods). These culture-specific patterns emerged during the infants' 2nd and 3rd months of life. The results have implications for mother–child counseling programs and for those working in the field of early mother–infant interaction.

Wang, Shao, and Li (p. 555) looked at language as a representational system of culture and find that the language children speak shapes how they view themselves. They asked 125 bilingual children and adolescents (ages 8–14) from Hong Kong to recall events from their lives and describe themselves, then asked how they felt about Chinese interdependent or Western independent values. Compared with children interviewed in Chinese, children interviewed in English gave more detailed accounts of themselves and their personal experiences, focused more on unique personal attributes and qualities in describing themselves, and talked more about their own roles and perspectives in past events. Children interviewed in Chinese gave less elaborate and more socially oriented descriptions of themselves and their memories, and agreed more with Chinese interdependent values and less with Western independent values. Thus, the use of a particular language influenced whether children supported a particular cultural belief system and also shaped how they defined themselves and remembered their personal experiences. The findings offer new insights into the dynamic relations between language, culture, and the self.

Gershoff et al. (p. 487) took a cross-cultural look at discipline. Disciplining children has been studied a lot in the United States but less so in the rest of the world. Previous research has found that the meaning and effects of different forms of discipline vary by their cultural context. But this study, which sought to determine whether certain disciplinary techniques are linked with more or less child aggression regardless of the country in which the family lives, finds that disciplining children harshly is associated with negative outcomes everywhere. It also finds that for children who live in a culture in which harsh discipline is normal, the effects may not be as strong. The authors collaborated with colleagues in China, India, Italy, Kenya, the Philippines, and Thailand to look at almost three hundred 8- to 12-year-olds and their mothers. In shedding light on methods of discipline around the world, the study suggests that there's more universality in the use of particular techniques and in their associations with child behavior than previously thought.

The "Ayes" Have It

In prior research, 2- and 3-year-olds have shown a "yes" bias, that is, a tendency to say "yes" to yes–no questions pertaining to their knowledge. **Okanda and Itakura** (p. 568) looked at more than 100 Japanese 3- to 6-year-olds, finding that the reason this happens is because of both social factors (the social pressures of compliance, for example) and cognitive factors (such as that they cannot control their answer or cannot understand the conversation), and that each factor plays an important role depending on age. For example, 3-year-olds might show a yes bias automatically due to underdeveloped cognitive ability, while for older children, social reasons (such as sensitivity to interviewers' intentions) might explain their yes answers. Given that yes–no questions are the most common method used in developmental psychology, the findings suggest that researchers consider alternate methodologies for preschoolers.

Telling Lies and Falsehoods

We tend to view children as blunt truth tellers lacking in the rules of social grace, but a study of Chinese children suggests there may be something else going on. **Xu, Bao, Fu, Talwar, and Lee** (p. 581) examined whether one hundred twenty 7-, 9-, and 11-year-olds would tell lies to be polite when they received a gift they didn't like and whether children's behaviors were related to their moral understanding of lie and truth telling in a situation that called for politeness. All the children categorized untruthful statements as lies and truthful statements as the truth, regardless of whether the lies were told for prosocial or nonprosocial purposes. However, the older the children, the more they saw others' lying in polite situations less negatively and the more likely they were to tell lies in such situations themselves. Contrary to previous findings, children's moral knowledge about lying was strongly related to their actual behavior.

Low (p. 597) looked at false belief, which happens when individuals recognize that other people can have beliefs about the world that are wrong. The study looked at more than 100 preschool-age Pakeha (New Zealanders of European descent). Findings: The 3- and 4-year-olds accurately gazed in anticipation of where the main character of a story would mistakenly go to look for an object that had been moved, despite giving an incorrect verbal answer in a false-belief task. This differentiation between verbal and nonverbal responses suggests that young children have an early implicit understanding of belief before they show a mastery of certain forms of grammar that are involved in talking about the mind. In short, thought, in some core form, can exist without complex language.

Youth Autonomy

Children and adolescents identify clothing, friendship, and leisure activities as issues within the personal domain; we know that having some degree of choice over these decisions is important for both a sense of identity and mental health. **Lagattuta, Nucci, and Bosacki** (p. 616) looked at 4- to 7-year-olds' beliefs about how children would act in situations in which a parent forbids them to take part in a desired activity. Findings: From ages 4 to 7, children's predictions that characters would comply with moral rules (such as prohibitions against stealing) and feel good about doing so rose significantly, suggesting that between these ages, children showed increasing awareness of the limits to legitimate disobedience. In stark contrast, children of all ages predicted that the characters would frequently break parents' rules that intruded on the personal domain and that this disobedience would feel good, particularly when the desired activities were described as essential to the character's sense of identity. The findings suggest that children make important distinctions between different kinds of rules when reasoning about decisions and emotions.

Wray-Lake, Crouter, and McHale (p. 636) examined decision making within the family, an important way in which young people gain independence and responsibility. This longitudinal study spanning 9 years asked parents in about 200 White, European American families about their teens' decisions. They find that young people's input into decisions increased gradually from ages 9 to 14 and then surged from ages 15 to 20. Also, young people had more input into decisions about appearance, activities, schoolwork, and social life than about chores, health, and curfew. And girls, youths whom parents said were easy to supervise, and youths with better educated parents had more decision-making autonomy. Importantly, there wasn't a single, universal pattern in the development of decision making; rather, decision-making autonomy, a reflection of the development of youths' independence and responsibility, depended on what kinds of decisions youngsters faced and on their personal characteristics and family circumstances.

Trusted Sources

By age 3, children adapt their expectations about what people know about things based on their experience with others. **Diesendruck, Carmel, and Markson** (p. 652) find that children are more likely to presuppose that others share their knowledge when people have shown that they know the names of familiar objects or how they're used than when they have shown that they don't know these familiar items. Children acquire a lot of information about the world by observing and listening to others; as some of this information isn't directly taught to children but rather must be inferred by them, this study suggests that the kind of inferences preschoolers draw about the meaning of new words or functions varies depending on how knowledgeable the source of the information is. The research, of more than 100 Israeli 3- and 4-year-olds, has implications for our understanding of how children communicate with others, but also for how children learn.

Sobel and Corriveau (p. 669) considered how children learn new information, a process in which they have to rely on others as sources of information. Prior research suggests that children recognize and make inferences based on how reliable individuals are as sources of knowledge. In this study, the researchers asked whether young children register these different kinds of expertise and use that knowledge judiciously. Results: 4-year-olds gave more weight to the information provided by speakers who had information about the hidden properties of objects than to those who had more superficial knowledge. This suggests that by the time children are 4, they can pick up on cues given by speakers to decide whether the speaker is a credible source of information.

The Significance of Insecure Attachment and Disorganization in the Development of Children's Externalizing Behavior: A Meta-Analytic Study

R. Pasco Fearon

Marian J. Bakermans-Kranenburg
and Marinus H. van IJzendoorn
University of Leiden

Anne-Marie Lapsley
Barnet, Enfield & Haringey Mental Health NHS Trust

Glenn I. Roisman
University of Illinois at Urbana-Champaign

This study addresses the extent to which insecure and disorganized attachments increase risk for externalizing problems using meta-analysis. From 69 samples (N = 5,947), the association between insecurity and externalizing problems was significant, d = 0.31 (95% CI: 0.23, 0.40). Larger effects were found for boys (d = 0.35), clinical samples (d = 0.49), and from observation-based outcome assessments (d = 0.58). Larger effects were found for attachment assessments other than the Strange Situation. Overall, disorganized children appeared at elevated risk (d = 0.34, 95% CI: 0.18, 0.50), with weaker effects for avoidance (d = 0.12, 95% CI: 0.03, 0.21) and resistance (d = 0.11, 95% CI: −0.04, 0.26). The results are discussed in terms of the potential significance of attachment for mental health.

Although the significance of the parent–child relationship was recognized by scientists and clinicians since the earliest days of formal psychological inquiry (e.g., Baldwin, 1895; Freud, 1908; James, 1890), two major advances occurred in the 1960s and 1970s that created lasting legacies for the study of human development. John Bowlby's (1969) theory of parent–child attachment was revolutionary in the way it integrated evolutionary, biological, developmental, and cognitive concepts into a unified account of human attachment behavior. This remarkable achievement paved the way for the scientific study of attachment, largely because it created a conceptual framework for developing testable hypotheses about causal influences, developmental processes, and expected long-term consequences of attachment for mental health (Bretherton, 1997). Critical among these novel contributions were the clear characterization of the proximal behavioral functions associated with attachment and their interplay with other biologically significant behavioral systems, the use of comparative evidence as crucial sources of theory-development, and the concept of an internal working model as a framework for understanding continuities in attachment behavior across context and over time. The notion that the quality or organization of attachment behavior in early infancy or childhood might have implications for later socioemotional development and mental health is arguably one of attachment theory's most well-known and contested predictions (Lamb, Thompson, Gardner, Charnov, & Estes, 1984; Rutter, 1995). Nowhere is this issue more significant than in the domain of aggression and externalizing behavior problems, where the social costs are substantial (Loeber & Hay, 1997).

Researchers working in the attachment field, following Bowlby and others, have considered a number of mechanisms that might explain why attachment experiences in early life might be associated with later adaptation and mental health. Several theorists have suggested that the role of attachment may center on the way in which

children respond to sources of threat and challenge, and the extent to which children are able to draw on parental support and comfort as a means of coping (Kobak, Cassidy, Lyons Ruth, & Ziv, 2005). Secure children, it is maintained, have had repeated experiences of a caregiver who is responsive when support and proximity are needed and expect the caregiver(s) to be available and comforting when called upon. In contrast, children with insecure attachment relationships may have had experiences in which bids for proximity have been discouraged, rejected, or inconsistently responded to and rely more heavily on secondary coping processes to deal with stress and challenge.

Developmental continuities between the organization of the attachment relationship and functioning beyond it (in time or space) have generally been conceptualized with reference to the internal working models construct. This important conceptual heuristic is thought of as a set of organized cognitive–affective psychological structures that organize thinking, feeling, and behavior vis-à-vis the attachment figure as a potential haven of safety and comfort in times of stress (Bretherton, 1995; Main, Kaplan, & Cassidy, 1985). These models are thought to become generalized over time and influence functioning in wider interpersonal relationships across the life span and form the basis of a generalized sense of the self as worthy of love and care and others as available and responsive (Cassidy, 1988; Sroufe, Egeland, Carlson, & Collins, 2005a). In addition to this primary explanatory construct, several other factors (possibly related to internal working models) have been discussed as potential mediators between a secure attachment relationship and lowered risk for mental health problems generally and externalizing problems more specifically, such as (a) a developing sense of self-confidence through repeated experiences of support and comfort and through effective exploration of the environment (Goldberg, 1997), (b) generalized positive social expectations (as opposed to mistrust and perceived hostility; see Dodge & Coie, 1987), (c) the socialization of moral emotions and values within a secure attachment relationship (Kochanska, 1997; van IJzendoorn, 1997), (d) modeling of prosocial behavior by a sensitive caregiver (Guttmann-Steinmetz & Crowell, 2006), (e) continuity in the quality and supportiveness of ongoing parental care (Lamb et al., 1984), and (f) the capacity for effective emotion regulation (e.g., Cassidy, 1994). Other possibilities exist that have been given less attention, such as the social modulation of biological systems mediating stress and arousal regulation (e.g., Suomi, 2003; Weaver et al., 2004).

Although Bowlby's work was highly influential, the development of a standardized procedure for the systematic study of attachment behavior, as observed in a naturalistic setting, was a major further step forward in the establishment of an empirical knowledge base concerning the developmental significance of attachment (Ainsworth, Blehar, Waters, & Wall, 1978; Sroufe, 1983). Ainsworth et al.'s (1978) Strange Situation procedure (SSP) has become one of the most widely used—if not the most widely used—standardized lab assessment of early childhood behavior based on direct observation and represents a paradigm example of how to systematically study naturally occurring behavior in quasi-naturalistic contexts. The identification of individual differences in patterns of reunion behavior following separation in the SSP triggered a program of research studies aimed at uncovering their developmental antecedents and sequelae (Belsky & Isabella, 1988; Schneider-Rosen & Rothbaum, 1993). Despite the accumulation of an impressive volume of data over the years, the picture that unfolded regarding the developmental consequences of attachment has proved complex and often contradictory, particularly in the domain of mental health and psychopathology (Goldberg, 1997).

One of the earliest and most influential longitudinal studies of the psychosocial outcomes of children observed in the SSP in infancy was launched in Minnesota by Byron Egeland, Alan Sroufe, and colleagues (see Sroufe, Egeland, Carlson, & Collins, 2005a, 2005b). Erickson, Sroufe, and Egeland (1985) followed their relatively large sample of high-risk infants from 12 months to preschool and collected extensive assessments of children's behavior using observer and teacher ratings of social competence, ego control, peer confidence, and externalizing behavior problems in the school setting. Most importantly for the current purposes, secure children scored lower than insecure children on assessments of behavior problems and avoidant children stood out as being particularly at risk, a finding echoed in several later studies (Burgess, Marshall, Rubin, & Fox, 2003; Goldberg, Gotowiec, & Simmons, 1995; Munson, McMahon, & Spieker, 2001). Interestingly, a later report from the Minnesota study at Grades 1–3 (Renken, Egeland, Marvinney, Mangelsdorf, et al., 1989) found associations between attachment insecurity and externalizing problems in boys but not girls (see also Lewis, Feiring, McGuffog, & Jaskir, 1984).

In a manner that was to become somewhat characteristic of the topic, the first reports of these findings were followed immediately by a nonreplication. In the same monograph, Bates, Maslin, and Frankel (1985) reported on a longitudinal follow-up of 120 infants who had previously been observed in the SSP at 12 months and found no association between attachment security and parent reports of externalizing behavior problems at age 3. Any number of methodological factors could be considered when interpreting these early, apparently contradictory findings. Notably, Erickson et al.'s (1985) study excluded cases that were not stable in terms of attachment classifications between 12 and 18 months, while Bates et al. (1985) only collected attachment data at 12 months. There are obvious reasons why the stability of attachment might be a factor in its predictive power. Furthermore, Sroufe et al.'s study was drawn from a substantially more impoverished population than the Bates et al. study, which was predominantly middle class. A number of authors have argued that attachment security should be thought of as an interactive risk factor that is more significant when other psychosocial stressors are present in the family ecology (Belsky & Fearon, 2002; Kobak et al., 2005). The two studies also employed different outcome measures (teacher vs. parent report), which in turn may index contextual differences in the expression of externalizing behavior or in the validity of the assessments.

Thus, even in the earliest phase of research into the longitudinal outcomes of attachment security and insecurity, positive findings, negative findings, and interactions emerged in almost equal measure. A similar mix of results emerged from later studies conducted in the 1980s and early 1990s. With such a complex pattern of study outcomes, narrative reviews took diverging positions regarding the status of the evidence for an association between attachment and children's behavior problems (see Belsky & Nezworski, 1988).

The identification of disorganized attachment (Main & Solomon, 1986, 1990) led to renewed interest in the potential for attachment to predict robustly externalizing behavior problems (Carlson, 1998; Lyons Ruth, Alpern, & Repacholi, 1993; Moss, Cyr, & Dubois Comtois, 2004). These seemingly inexplicable, contradictory, and fragmentary behaviors observed during the SSP are considered by many to represent relational processes at special risk for psychopathology, particularly in the domain of childhood aggression (Liotti, 1992; Lyons Ruth, Zeanah, & Benoit, 2003; Main & Morgan, 1996; Moss, Cyr, et al., 2004). Several authors have outlined hypotheses regarding the mechanisms by which disorganized attachment may lead to aggression, with considerable attention focusing on states of emotional dysregulation and dissociative processes that may block the person's awareness of his or her violent actions (e.g., Fonagy, 2004; Liotti, 1992; Solomon & George, 1999). Subsequently, a sizable body of evidence emerged that was consistent with the view that disorganized attachment may be associated with increased risk for externalizing behavior problems and aggression. A meta-analysis of 12 studies carried out in 1999 (van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999) showed that this association was robust, with a mean effect size of $r = .29$ ($N = 734$). Nevertheless, since 1999 a significant number of new studies have been conducted, including the largest ever longitudinal study of attachment (with more than 1,000 participants), the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care and Youth Development, which failed to find strong evidence of greater externalizing behavior problems in disorganized children (Belsky & Fearon, 2002; NICHD Early Child Care Research Network, 2006).

The question of whether attachment insecurity plays a causal role in the development of externalizing psychopathology is a vital one for the field, but there is clearly little case for causality if there is no association. With the sheer volume, range, and diversity of studies that have examined the association between attachment security and children's externalizing behavior problems, it has become virtually impossible to provide a clear narrative account of the status of the evidence concerning this critical issue in developmental science. Given that sample variability around an effect of zero can lead to false positives, and sampling variability around a positive effect can lead to false negatives, the question of whether the existing evidence is consistent with positive association is critical for a full appreciation of the predictive significance of attachment for later externalizing behavior problems. Meta-analysis provides a structured, principled methodology for resolving—within limits—these essential scientific questions. In the current study, we analyzed over 60 independent studies that have conducted assessments of attachment security and insecurity using standardized observational tools and related them to measures of children's externalizing behavior problems. In line with expectations derived from the literature, we set out to test several hypotheses, namely, that (a) attachment insecurity, in particular avoidant attachment, would be significantly associated with externalizing behavior problems; (b) stronger effects would be found in low-socioeconomic-status (SES) samples than high-SES samples; (c) stronger associations would be found in boys than in girls; and (d) attachment disorganization would predict externalizing problems more strongly than avoidance or insecurity generally. We added to these a focus on whether effects of attachment-related variation were moderated by age of assessment of externalizing problems. The claim that early attachment has enduring—rather than merely transient—effects on development requires that the magnitude of such associations are not reduced to nil over time. Finally, we also examined a range of relevant methodological factors that might account for systematic between-study variability in effect sizes, including the method of assessment of attachment and the type and context of outcome measurement.

Method

Literature Search

We systematically searched the electronic databases PsychInfo, Web of Science, MEDLINE, Science Citation Index Expanded, Social Sciences Citation Index, and Art & Humanities Citation Index with the key words externalizing, aggressi*, conduct, psychopathology, opposition*, competence, social functioning, prosocial, antisocial, anti-social, behavior problem*, behaviour problem* in the title or abstract (the asterisk indicates that the search contained the word or word fragment). This large set was narrowed down by adding the constraint that the papers must also contain the word attachment and child* or infan* in the title or abstract. This search returned over 1,200 articles in each of the databases. Two further separate search-narrowing strategies were adopted, which yielded two partially overlapping study sets. In one search, we targeted empirical studies by requiring the abstract to contain the words sample or *N*. In another, we required that at least one of the words secur*, avoidan*, resistan*, or disorgani* appeared in the title or abstract. In each case, this reduced the former search by around 60%. When these two sets of search results were merged, this resulted in 856 candidate articles. These were subjected to abstract review in the first instance, from which a large number of clearly irrelevant articles were discarded (e.g., nonempirical papers, studies not involving children). A further 115 articles remained. These were examined individually by the authors according to criteria described next. Second, the reference lists of the collected empirical papers and influential reviews were searched for relevant studies (e.g., Kobak et al., 2005). Third, data sets available to the authors since they were in the public field (NICHD Study of Early Child Care and Youth Development) or part of their ongoing research (SCRIPT; Van Zeijl et al., 2006) were analyzed with regard to the associations between attachment and externalizing behavior.

Studies were included if they reported on the relation between attachment and externalizing or aggressive behavior in children 12 years of age or younger. Externalizing behavior was defined as aggression, oppositional problems, conduct problems or hostility (either alone or in combination), as indicated in the descriptions provided in the method sections of the respective articles. Studies that did not differentiate between externalizing and internalizing problems (e.g., just total problems score of the CBCL) were excluded. Externalizing or aggressive behavior was assessed using observation (e.g., Matas, Arend, & Sroufe, 1978; Turner, 1991), questionnaires (CBCL, PBQ) or clinical interviews (e.g., Speltz, DeKlyen, & Greenberg, 1999), completed by parents (e.g., Aviezer, Sagi, Resnick, & Gini, 2002), teachers (e.g., Egeland & Heister, 1995), or clinicians or trained observers (e.g., Turner, 1991). We restricted the review to studies using observational measures of attachment, such as the SSP (Ainsworth et al., 1978), the Cassidy & Marvin Preschool Attachment system (Cassidy, Marvin, and The MacArthur Working Group on Attachment, 1989), the Attachment Q-Sort (AQS; Waters & Deane, 1985), and the Main and Cassidy system (Main & Cassidy, 1988). In cases where more than one attachment assessment was employed (e.g., the SSP followed by Cassidy & Marvin at a later age), the earliest attachment assessment was selected. We did not include studies that reported on representational measures of attachment (e.g., Attachment Story Completion Task; Verschueren & Marcoen, 1999). When intervention studies were identified, we only included data from the non-treated control sample (e.g., Lieberman, Weston, & Pawl, 1991). Only one study that met our entry criteria also reported on outcome data for father–child attachment security (Aviezer et al., 2002). As this would not allow a meaningful comparison of effect sizes between mother and father attachment, this study was excluded. The meta-analyses reported herein therefore only pertain to mother–child attachment. Also noteworthy is the fact that only four studies were based on samples from predominantly minority-ethnic communities.

Several studies presented data on (partly) overlapping samples, such as Shaw and colleagues (Shaw, Owens, Vondra, Keenan, & Winslow, 1996; Shaw & Vondra, 1995) and the studies reported by Moss and colleagues (Moss, Bureau, Cyr, Mongeau, & St Laurent, 2004; Moss, Cyr, et al., 2004; Moss, Parent, Gosselin, & Rousseau, 1996). Because participants cannot be included in a meta-analysis more than once, the papers that reported on the largest groups of participants were included in our meta-analysis (e.g., Moss, Bureau, et al., 2004). In total, after excluding reports involving overlapping samples, we found 53 studies that yielded 69 independent samples that could be included in our meta-analyses, with sample sizes ranging from 26 to 1,075 (see Table 1). In many cases, outcome statistics were only presented for the avoidant and resistant classifications combined, or indeed for the resistant, avoidant, and disorganized cases combined. Consequently, we focused our primary analyses on the overall contrast between security and insecurity, with insecurity represented by the avoidant, resistant and (in the cases where disorganization had been coded) disorganized classifications. In these analyses, we also tested whether it made a difference to the overall effect size for security if disorganization had been coded. In addition, a number of studies used the AQS to measure attachment security, which does not yield data on the different subtypes of insecurity. As a result, these studies only appear in the meta-analyses involving the overall contrast between security and insecurity. Subsequently, we also extracted more focused contrasts targeting specific insecure categories from the smaller set of studies where these could be identified. The numbers of studies involved in these subanalyses are indicated in the text.

Coding System

We used a structured coding system for assessing the characteristics of the samples and their study designs. The measurement of attachment was coded straightforwardly, as all studies included one of several well-known attachment assessments (SSP, AQS, Preschool Attachment Assessment, Cassidy & Marvin; Main & Cassidy). In each case, the coder extracted effect sizes at the level of the individual attachment classification where possible (i.e., A, B, C, and D). In addition to a number of background variables like year of publication and data source (journal, book chapter, unpublished data), we coded several important potential moderators related to the sample: gender (% male), SES (high/middle vs. low), and clinical status (clinical-child, clinical-parent, nonclinical). Where the gender composition of the sample was not precisely reported we assumed a 50% split. Furthermore, when SES was not noted, a default of high/middle class was recorded (this occurred in five cases). Clinical status was recorded if either the parent or the target child was identified as having a clinical diagnosis or if they had been selected using a clinical cutoff score on a validated instrument. In addition to the measure used to assess attachment, four other design characteristics were coded: (a) age of attachment assessment, (b) age of externalizing assessment, (c) type of outcome measure, and (d) observer or reporter of externalizing behavior. When measurements of externalizing problems at different points in time were reported, we selected the first measurement. When measurements at different points in time were in some way merged (averaged or a trajectory extracted), we recorded the midpoint of the range as the age of the externalizing assessment (e.g., Keller, Spieker, & Gilchrist, 2005). To assess intercoder reliability, 20 randomly selected studies were coded by two coders. The agreement between the coders across the moderator variables was 97% (correlations between continuous moderators were > .95).

Meta-Analytic Procedures

A number of studies reported results separately for boys and girls and four studies reported on samples involving only boys or only girls. In these cases, we calculated separate effect sizes for each gender, and the subsamples were treated as independent outcomes in the analyses. When multiple measures of aggression or externalizing behaviors were used within one study (e.g., Solomon, George, & De Jong, 1995), we selected the outcome for externalizing behavior for the primary set of studies. In a separate set of meta-analyses, we tested whether outcomes were different when aggression outcomes were selected (see the following).

Statistical Analyses

Four sets of meta-analyses were conducted, one for the relation between attachment insecurity and externalizing or aggressive behavior, one for the relation between avoidance and externalizing or aggressive behavior, one for the relation between resistance and externalizing or aggressive behavior, and one for the relation between attachment disorganization and externalizing or aggressive

behavior. The meta-analyses were performed using the Comprehensive Meta-Analysis (CMA) program (Version 2; Borenstein, Rothstein, & Cohen, 2005). For each study, an effect size (*d*) was calculated as the standardized difference between the two pertinent groups (e.g., secure vs. insecure). In those cases where continuous attachment scores were correlated with externalizing scores (e.g., when the study reported on the AQS), we recomputed the statistic into Cohen's *d* (see Mullen, 1989; Mullen & Rosenthal, 1985, chap. 6, for the formulae for transformation of various statistics into Cohen's *d*). Effect sizes indicating a positive relation between externalizing behavior and insecurity, avoidance, and disorganization, respectively (higher levels of externalizing behavior in the insecure, avoidant, or disorganized group compared to the reference group), were given a positive sign. Thus, a positive combined effect for the set of studies comparing disorganized children with secure children on externalizing behaviors would mean that across these studies the level of externalizing behaviors in disorganized children was higher than in secure children. In the main analyses, we compared externalizing behaviors of the children in each attachment classification with all other classifications combined. In an additional analysis on a smaller set of studies with pertinent data, we also compared each classification with the secure classification as the most "pure" reference category.

Using CMA, combined effect sizes were computed. Significance tests and moderator analyses were performed through fixed or random effects models, depending on the homogeneity of the study outcomes. Fixed effects models are based on the assumption that effect sizes observed in a study estimate the corresponding population effect with random error that stems only from the chance factors associated with subject-level sampling error in that study (Lipsey & Wilson, 2001; Rosenthal, 1991). This assumption is not made in random effects models (Hedges & Olkin, 1985). Random effects models allow for the possibility that there are random differences between studies that are associated with variations in procedures, measures, and settings that go beyond subject-level sampling error and thus point to different study populations (Lipsey & Wilson, 2001). To test the homogeneity of the overall and specific sets of effect sizes, we computed Q statistics (Borenstein et al., 2005). In addition, we computed 95% confidence intervals (CIs) around the point estimate of each set of effect sizes. When the set was homogeneous, CIs were based on fixed estimates. In cases where there was heterogeneity across studies, we based CIs on random estimates. Q statistics and p values were also computed to assess differences between combined effect sizes for specific subsets of studies grouped by moderators. Again, fixed effects model tests were used in the case of homogeneous sets of outcomes, and more conservative random effects model tests were used in the case of heterogeneous outcomes. In the present study, random models were tested unless otherwise specified. Contrasts were only tested when at least two of the subsets consisted of at least four studies (Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2003).

When the children in two sets of studies (partially) overlapped (e.g., some studies reported both aggression and externalizing, and we wanted to compare the combined effects for aggression and externalizing), it was impossible to compare directly effect sizes across these sets. We computed 85% CIs for the point estimates of the combined effect sizes in the two sets: Nonoverlapping 85% CIs indicate a significant difference between combined effect sizes (Bakermans-Kranenburg et al., 2003). This approach of comparing 85% CIs served as a conservative significance test (Goldstein & Healy, 1995). We used the "trim-and-fill" method (Duval & Tweedie, 2000a, 2000b) to calculate the effect of potential data censoring (or publication bias) on the outcome of the meta-analyses. Using this method, a funnel plot is constructed of each study's effect size against the sample size or the standard error (usually plotted as $1/SE$, or precision). It is expected that this plot has the shape of a funnel because studies with smaller sample sizes (larger standard errors) have increasingly larger variation in estimates of their effect size as random variation becomes increasingly influential, whereas studies with larger sample sizes have smaller variation in effect sizes (Duval & Tweedie, 2000b; Sutton, Duval, Tweedie, Abrams, & Jones, 2000). The plots should only be shaped like a funnel if no data censoring is present. However, as smaller or nonsignificant studies are less likely to be published (the "file-drawer" problem; Mullen, 1989), studies in the bottom left-hand corner of the plot are often omitted (Sutton et al., 2000). In our meta-analyses, the k right-most studies considered to be symmetrically unmatched were trimmed. The trimmed studies can then be replaced and their missing counterparts imputed or "filled" as mirror images of the trimmed outcomes. This then allows for the computation of an adjusted overall effect size and CI (Gilbody, Song, Eastwood, & Sutton, 2000; Sutton et al., 2000).

For each meta-analysis, we also calculated the number of studies with average sample size and nonsignificant outcome that would be required to bring the combined effect size of the meta-analysis to a nonsignificant level (fail-safe number; Mullen, 1989). Rosenthal (1991, p. 106) suggested that a fail-safe number of more than $5k + 10$ (k = number of studies included) may be considered a general criterion for robustness.

For each study, Fisher's Z scores were computed as well-distributed equivalents for the effect size d, and the Z scores were standardized to test for outliers. No outliers (standardized Z values smaller than -3.29 or larger than 3.29; Tabachnik & Fidell, 2001) were found for study effect sizes.

Results

Is Insecure Attachment Associated With More Externalizing Problems?

The first set of meta-analyses concerned the difference in externalizing behaviors between children rated as secure versus children classified as insecure. In 69 studies including $N = 5{,}947$ participants, the association between attachment security and externalizing behaviors was reported. Any study assessing attachment and externalizing was included in this total set, regardless of type of measures used. If disorganized attachment was assessed, this category was included in the insecure group. In this overall set, we found a significant combined effect size of $d = 0.31$ (see Table 2). Children rated as insecure showed higher levels of externalizing behaviors than children rated as secure. The effect size was modest but robust, as more than 1,700 studies with null results (fail-safe number) would be needed to reduce this effect to nonsignificance. Further support for the absence

of the file-drawer problem was evident through the trim-and-fill approach, showing that only five studies had to be trimmed and filled, with a resulting significant combined effect size of $d = 0.27$ (95% CI: 0.18, 0.36).

As the total set of studies for secure versus insecure attachment was heterogeneous (see Table 3), we looked for significant moderators that might account for between-study variability in outcome. Gender appeared to be a significant moderator (see Table 2). In samples with only girls, the combined effect size was $d = -0.03$ (*ns*), whereas in the samples with only boys and in the mixed samples (i.e., with boys and girls) the combined effect sizes were

significant, $d = 0.35$ and $d = 0.36$, respectively, and significantly different from the null effect in the girls-only samples. Within the mixed samples, the percentage of males in the study tended to be positively related to the magnitude of the attachment-externalizing problems effect size (slope = .013, $p = .11$). Clinical samples also showed a significantly larger combined effect size ($d = 0.49$) than nonclinical samples ($d = 0.26$). This moderator effect was not dependent on gender differences as only two of the clinical samples consisted of boys only (Greenberg, Speltz, Deklyen, & Endriga, 1991; Speltz et al., 1999). Contrary to expectations, SES was not a significant moderator (see Table 2).

The type of assessment of externalizing behaviors and of attachment appeared to make a difference to the effect sizes. When externalizing behavior was observed directly (seven studies) or was indexed by a clinical diagnosis (six studies), the combined effect sizes were larger than in cases where a parent or teacher rated the level of externalizing behaviors. The group of studies based on observations of externalizing behavior was homogeneous. Its combined effect size of $d = 0.58$ was therefore an adequate estimate of the average effect, which amounted to a quite strong association between attachment security and externalizing behavior. The way in which attachment security was assessed also made a significant difference. In particular, studies conducted with the AQS showed the largest effect sizes ($d = 0.70$), whereas studies using the SSP yielded the lowest combined effect size ($d = 0.18$), though this latter effect was nevertheless significant. Because the different attachment measures are typically conducted at different ages, we also conducted a meta-regression analysis with age at the assessment of attachment as a predictor. As expected, the regression was significant (slope = .006, $p = .01$). Notably though, the effect of age was not significant within the SSP, AQS, or Cassidy and Marvin studies, suggesting that age and attachment measure were confounded. Furthermore, the regression with age did not appear to result solely from the larger effects associated with the AQS, as the same regression was significant when AQS studies were excluded (slope = .005, *p* = .03). It is also noteworthy that the overall effect size for security did not vary as a function of whether or not disorganization had been coded (*Q* = 0.10, *p* = .78). Note that this latter analysis excludes AQS studies by definition, as this procedure does not yield a score or classification for disorganized attachment.

Because the SSP is considered to be the gold standard for measuring attachment security, and the set of SSP studies was sufficiently large (*k* = 43), we decided to conduct complementary analyses for secure versus insecure attachment on this subset (see Table 2). In this homogeneous set of studies, we did not find a difference in combined effect size between clinical and nonclinical samples. The difference between samples with only girls versus only boys or mixed samples, however, was significant again, with all-female samples showing no association between attachment security and externalizing problems (*d* = −0.06). Also, we confirmed the larger combined effect size for those SSP studies that included observational measures of externalizing (*d* = 0.61) compared to the other types of assessment.

Interestingly, among the SSP studies the age at which the assessment of externalizing behavior was taken yielded a significant regression weight, with a slope of .002 (*p* = .02), indicating that the association between attachment security and externalizing became stronger with age. Because the SSPs are usually conducted within a small age window of 12–18 months, this significant slope suggested that the prediction of externalizing from attachment security was better with later—not earlier—assessments of externalizing, which is surprising given the longer interval between assessments in these studies.

Is Insecure-Avoidant Attachment Associated With More Externalizing Problems?

In 34 studies involving *N* = 3,675 participants, the insecure-avoidant attachment classifications were differentiated from the other classifications, and in this subset of studies the combined effect size was only *d* = 0.12, which was significant but small in magnitude (see Table 3). Insecure-avoidantly attached children displayed somewhat more externalizing behaviors than comparisons. With one study trimmed and filled the resulting significant effect size was *d* = 0.11, but the fail-safe number of studies needed to bring the effect down below significance was only 24. Because this number is below the Rosenthal (1991) criterion of 5*k* + 10, this outcome should be considered with caution. No significant moderator effects were found. The effect did not vary according to whether or not disorganization had been coded. Within the SSP subset of 25 studies, the combined effect size for insecure-avoidant attachment was *d* = 0.13, and the moderator analyses on this subset converged with the analyses on the total set of studies for avoidance (see Table 3 for those contrasts that could be tested).

Is Insecure-Resistant Attachment Associated With More Externalizing Problems?

In 35 studies involving *N* = 3,568 participants, the insecure-resistant attachment classifications were differentiated from the other classifications. In this subset of studies, the combined effect size was not significant, *d* = 0.11 (see Table 4), and no significant moderator effects were found. Within the SSP subset of 24 studies, the combined effect size for insecure-resistant attachment was only *d* = 0.05, and the contrasts on this subset showed no significant moderators (see Table 4 for those contrasts that could be tested).

Is Disorganized Attachment Associated With More Externalizing Problems?

In 34 studies including *N* = 3,778 participants, a significant combined effect size of *d* = 0.34 (see Table 5) was found for the association between disorganized attachment and externalizing behavior. As expected, disorganized attachment was associated with a higher risk for externalizing behavior later in childhood. However, eight studies had to be trimmed and filled, with a recomputed significant combined effect size of *d* = 0.18 (95% CI: 0.01, 0.34). The fail-safe number amounted to *k* = 407, which was above the Rosenthal criterion, suggesting that the file-drawer problem was not responsible for the association found in the current set of studies.

The set of studies was heterogeneous, and moderator analyses showed that gender was a significant moderator (see Table 5). Remarkably, in the samples with females only the association between disorganized attachment and externalizing behaviors was significantly different from the samples with only boys or with mixed gender, and in fact, the relation was negative; that is, disorganized attachment was associated with less externalizing behavior. However, the combined effect size of the six female samples (*N* = 702) was modest, *d* = −0.20. Clinical status, SES, or type of assessment (for both SSP and externalizing behavior) did not appear to moderate the association

between disorganized attachment and externalizing behavior.

In the set of 24 SSP studies with $N = 3,161$ participants, we found a significant combined effect size of $d = 0.27$, which was similar to the effect size computed for the total set. No other significant moderators were found in this set (see Table 5 for those contrasts that could be tested).

Additional Analyses

The core set of studies on externalizing included assessments of externalizing as well as of aggressive behavior in the case of studies that did not present data on externalizing problems. In order to examine whether the more focused aggression studies would result in higher effect sizes, we decided to conduct two sets of meta-analyses, one for studies with data on externalizing and one for studies presenting aggression data. These two sets of studies partially overlapped (as some studies reported both), and it was therefore impossible to compare directly effect sizes across these sets (see the Method section). We computed 85% CIs for the point estimates of the combined effect sizes and compared these intervals across the two sets of studies: Nonoverlapping 85% CIs indicated a significant difference in combined effect sizes (Bakermans-Kranenburg et al., 2003). For the association between secure versus insecure attachment and externalizing behavior ($k = 65$), a combined effect size of $d = 0.32$ ($p < .01$; 85% CI: 0.26, 0.38) was found. The comparable combined effect size for the aggression outcomes ($k = 32$) was $d = 0.24$ ($p < .01$;

*$p < .05$. **$p < .01$.

85% CI: 0.13, 0.35). For the association between avoidant versus nonavoidant attachments and externalizing ($k = 33$), the combined effects size was $d = 0.12$ ($p < .01$; 85% CI: 0.06, 0.21), and for the aggression outcomes ($k = 20$) the combined effect size amounted to $d = 0.28$ ($p < .05$; 85% CI: 0.08, 0.49). For the association between resistant versus nonresistant attachments and externalizing ($k = 34$), the combined effects size was $d = 0.10$ ($p > .05$; 85% CI: −0.01, 0.21), and for the aggression outcomes ($k = 22$) the combined effect size was $d = 0.05$ ($p > .05$; 85% CI: −0.10, 0.21). Finally, for the association between disorganized attachments and externalizing ($k = 33$), the combined effect size was $d = 0.37$ ($p < .01$; 85% CI: 0.25, 0.49), whereas for the aggression outcomes ($k = 16$) this combined effect size was $d = 0.12$ ($p > .05$; 85% CI: −0.06, 0.30). The 85% CIs did overlap for each of these comparisons, indicating that study outcomes with externalizing behavior or with aggression did not result in significantly different effect sizes.

Because the various comparisons (secure vs. insecure, avoidant vs. nonavoidant, and disorganized vs. nondisorganized) were based on varying numbers of studies and participants, we also selected a core set of 19 studies that provided data on all four comparisons. For the association between attachment security and externalizing, the combined effect size was $d = 0.27$ ($p < .01$; 85% CI: 0.15, 0.39). For avoidance, this combined effect size amounted to $d = 0.06$ ($p > .05$; 85% CI: −0.01, 0.13), for resistance it was $d = 0.11$ ($p < .05$; 85% CI: 0.03, 0.19), and for disorganization the combined effect size was $d = 0.29$ ($p < .01$; 85% CI: 0.13, 0.45). The 85% CIs of the combined effect sizes for attachment security and disorganization did not overlap with the 85% CI of the combined effect size for avoidance, but for the other comparisons the 85% CIs overlapped. Resistant attachment did not show a different combined effect size compared to all other attachment classifications. Insecure and disorganized attachments thus implicate a higher risk for externalizing behavior than avoidant attachment. We also compared each of the nonsecure classifications with the secure classification. In a core set of 18 studies that provided data on all three comparisons, the combined effect size for the association between avoidance versus security and externalizing was $d = 0.12$ ($p < .05$; 85% CI: 0.04, 0.20). For resistant versus secure attachment, it was $d = 0.19$ ($p < .01$; 85% CI: 0.11, 0.28), and for disorganized versus secure attachment, the combined effect size was $d = 0.27$ ($p < .01$; 85% CI: 0.13, 0.41). For all three comparisons, the 85% CIs overlapped, implying that the effects of the various types of insecurity showed similar associations with externalizing behavior.

Discussion

Since Bowlby's earliest work on attachment and separation, there have been persistent suggestions in the literature that attachment insecurity may play an important role in the development of aggression and antisocial behavior (Bowlby, 1944; Lewis et al., 1984; Lyons Ruth et al., 1993; Renken et al., 1989; van IJzendoorn, 1997). The body of research that subsequently tested this association is impressive in its sheer size. However, despite an extensive accumulation of data, a clear view on the empirical standing of this important hypothesis has been elusive. Apparently contradictory findings, nonreplications, and a diversity of study designs and sample sizes have created a body of work that is difficult to integrate coherently in narrative reviews.

The central question we thus posed in this meta-analysis was whether attachment insecurity was associated with externalizing behaviors across all the studies conducted to date. The results showed quite clearly that the answer to this question is a firm yes. Drawing from data on nearly 6,000 children tested in standardized observational assessments of mother–child attachment security, the average effect size for the contrast between secure and insecure children was $d = 0.31$ (95% CI: 0.23, 0.40). Over 1,700 studies of average sample size with null results would need to be added to the database to reduce this effect to nonsignificance. For clinical samples, the average effect size amounted to $d = 0.49$ (95% CI: 0.32, 0.66). On the face of it, these robust findings lend direct support to the notion that attachment plays a significant role in the evolution of children's behavior problems, for typically developing children as well as for clinical groups.

It should be noted that for meta-analytic results the evaluation of combined effect sizes in terms of absolute magnitude is problematic (McCartney & Rosenthal, 2000). It is arguably more meaningful to consider the global association between insecurity and externalizing problems in the context of other studies examining similar phenomena and employing similar methodologies (McCartney & Rosenthal, 2000). In that respect, the combined effect size of $d = 0.31$ reported here is of similar magnitude to meta-analytic results concerning the association between aggression and hostile attributional biases ($d = 0.35$; see Orobio de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002) or resting heart rate ($d = -0.38$, Lorber, 2004) and substantially higher than that between aggression and basal cortisol ($d = -0.10$; see Alink et al., 2008). The combined effect found in this analysis gains even greater significance in light of the fact that a majority of the studies included in the analysis were longitudinal investigations, where independent and dependent variables were measured often several years apart (with an intervening period of 25 months on average).

Three perhaps obvious additional points about the effects should be made at the outset. First, there were so few outcome studies that examined father–child attachment security that we were unable to include them in this meta-analysis. There is clearly an urgent need for further research into the contribution of father–child attachment security and insecurity to children's development. Second, the effects reported in this meta-analysis reflect statistical association, not causation and—although they provide evidence relevant to efforts to determine causality and its mechanisms—alone they are mute on this issue. Third, the effects are uncorrected for the influence of relevant third variables. Controls for these could reduce or increase the magnitude of the global meta-analytic effects. Furthermore, the effects represent an average across a potentially large number of moderating relationships that could amplify or attenuate the association between attachment and externalizing problems (e.g., Belsky & Fearon, 2002; NICHD Early Child Care Research Network, 2006). Related to this point, the association for children from nonclinical populations was highly heterogeneous, indicating large between-study differences in effect size, which could have resulted from a number of methodological factors, such as the composition of the populations studied, the length of the follow-up period or the measurement strategies that were adopted. Indeed, the larger effect found in clinical samples ($d = 0.49$) illustrates this point, and at the same time demonstrates the significance of attachment for clinical groups.

Within clear constraints, the analyses reported in this study were able to consider the role of a number of other potentially important moderators that have been highlighted in the literature. Central among these were SES (with low-risk samples anticipated to yield larger effects), gender (insecure boys expected to show more behavior problems), and age of outcome (with effects expected to persist over time). In contrast to our expectations, the magnitude of the association between attachment and behavior problems was relatively consistent across high- and low-SES samples ($d = 0.25$ vs. $d = 0.31$, respectively). SES represents a rather blunt approximation of a number of important proximal psychosocial risk processes that may be more clearly implicated in the association between attachment and children's externalizing problems. Nevertheless, SES does account for a considerable portion of the variance in externalizing problems in childhood (Bradley & Corwyn, 2002), and the absence of moderation in this meta-analysis is a potentially important result. The finding certainly suggests that attachment insecurity is associated with higher levels of behavior problems even in apparently low-risk psychosocial circumstances. However, possible effects of SES should not be ruled out, as a broad division of samples into low versus high or middle class is clearly limited in precision and in several cases the reviewed studies involved mixtures of differing levels of socioeconomic disadvantage that were not captured in our coding scheme.

Turning to gender, the results were consistent with our expectations and the findings of some early longitudinal studies (Lewis et al., 1984; Renken et al., 1989), in that attachment was more strongly associated with externalizing behavior problems in samples of boys than in samples of girls ($d = 0.35$ vs. $d = -0.03$, respectively). The set of studies on girls was homogeneous; therefore, the absence of a significant association was not due to one or a few outlying outcomes in the lower range. Furthermore, within the mixed sample (boys and girls), a metaregression showed a trend for stronger effects in samples with comparatively more boys than girls. Given that the variation in gender composition within this subset reflected a very narrow range, this finding—when combined with those from the single-gender studies—provides quite compelling evidence of the elevated significance of attachment for behavior problems in boys. Nevertheless, the mixed samples, constituting the large majority of the studies, showed equally strong effect sizes as those with only boys, suggesting that the association between attachment and externalizing cannot be ascribed to boys only.

There are a number of plausible ways of interpreting this gender effect. First, on the face of it the effect may not be surprising, given the substantially higher risk of externalizing problems in boys (Loeber & Hay, 1997). However, this broad explanation subsumes several distinct possibilities that are worthy of attention. First, the lower rates of externalizing behavior problems in girls may impose a range restriction on the dependent variable, which in turn would attenuate the effect size (DeKlyen & Greenberg, 2008). On the other hand, the lower rates of externalizing problems may represent a manifestation of a differing set of etiological mechanisms in girls than boys, with attachment processes figuring more significantly in the developmental trajectories of boys. Certainly, some behavior genetic studies have suggested partially independent genetic and environmental contributions to externalizing symptoms (e.g., Vierikko, Pulkkinen, Kaprio, Viken, & Rose, 2003). Furthermore, a number of nongenetic studies have documented distinct risk factors for girls and boys (Cairns & Cairns, 1984; Cummings, Iannotti, & Zahn Waxler, 1989). A further important possibility to consider is that attachment (and indeed other risk factors) may contribute to a common latent process that has distinctive behavioral manifestations, which in turn are more commonly associated with boys than girls. Pertinent candidate examples might include the behavioral and contextual differences between physical and relational aggression (Crick & Grotpeter, 1995) or overt versus covert antisocial behavior (Loeber & Schmaling, 1985). To the extent that these behavioral processes are measured by different instruments, are evident in different contexts, or are weighted differently by different observers, we may expect differential associations by gender. A further important possibility to consider, which may not be independent of the possibilities described earlier, is that insecurity in girls is more associated with internalizing problems rather than externalizing problems (see DeKlyen & Greenberg, 2008).

In light of claims made by many in the field that attachment has persistent effects on future development, we also expected the association between attachment and behavior problems to be evident in studies with relatively long-term follow-up periods. Consistent with this expectation, we found that the age of the child at the point when externalizing problems were assessed was not significantly associated with the magnitude of study effect sizes. Even more intriguingly, among studies employing the SSP ($k = 43$ studies), applied within a small time window, effect sizes appeared to increase significantly over time.

In addition to these a priori hypotheses, method of measurement proved a significant factor that distinguished studies with relatively small and large effects in two distinct ways. First, different assessments of attachment appeared to be associated with reliable differences in the magnitude of the attachment-behavior problems association. Broadly speaking, the SSP produced smaller effect sizes than the other attachment assessments and the AQS produced comparatively larger effect sizes. Critically, however, it was not possible to disentangle entirely the role played by measurement type (e.g., SSP vs. other assessments) from the age at which the assessment was conducted (infancy or later), as these were essentially confounded. Notably, age was not a significant regressor within the SSP studies or within the non-SSP studies, so a substantial portion of the overall effect came exclusively from the difference between the SSP studies on the one hand and the other assessment types on the other. Although the AQS evidenced the strongest effect sizes by some margin ($d = 0.70$), the metaregression of age on effect size remained significant even when the AQS was removed from the analysis. Thus, while it was clear that security assessed by the AQS was rather more strongly associated with behavior problems than that derived from the SSP, later assessments of attachment beyond the SSP also appeared to yield stronger effect sizes. On that basis, it was not possible to determine whether the critical factor was some methodological or coding variation that distinguishes the SSP from the other attachment assessments, or some factor more closely related to development itself. It is certainly plausible that important developmental changes take place around the beginning of the 3rd year that amplify the link between attachment and externalizing problems.

The second critical measurement factor that emerged from this meta-analysis concerned the measurement of outcome. Studies that assessed externalizing behavior problems via direct observation identified reliably larger effect sizes ($d = 0.58$) than those that relied on questionnaires from parents or teachers ($d = 0.22$ and $d = 0.30$, respectively). This is a potentially important finding from a variety of perspectives. First, the vast majority of the studies that investigated externalizing behavior in relation to attachment reviewed here did not use any objective source of information concerning the outcome. Not only does this strategy limit the conclusions that can be drawn (see Kagan, 2007), it could also partially explain the mixed effects across attachment-outcome studies as a whole. It is noteworthy that the effect sizes cited earlier are apparently positively correlated with the degree of objectivity of the observer.

Nevertheless, although the objectivity of measurement is one potential account of the stronger effect sizes associated with direct observation, it could also be that direct observation reveals qualitatively distinct features of behavior or qualitatively distinct contexts in which behavior takes place. Notably, studies that used observational methods typically focused on the peer setting (e.g., Booth, Rose Krasnor, & Rubin, 1991; Matas et al., 1978; Suess, Grossmann, & Sroufe, 1992) and hence may have been tapping behavior more closely connected with social competence than those that relied on parent or teacher questionnaires. However, these effects are understood, the limited agreement between objective observers, teachers, and parents concerning children's behavior problems creates a strong imperative to use multiple sources of outcome data in future studies of attachment security and its sequelae. At the same time, more data sources per se will not solve this problem. What is arguably needed is a better understanding of the precise circumstances and mechanisms under which aggression and other antisocial acts may be triggered and the contribution that attachment processes make to this. It is hard to imagine that this degree of mechanistic specificity could be achieved without greater reliance on field studies that involve direct and extensive observations in a range of relevant social settings.

Arguments put forward in the literature, and results of an earlier meta-analysis, led us to expect that attachment disorganization would be a stronger predictor of externalizing behavior problems than attachment insecurity generally (van IJzendoorn et al., 1999). However, the findings of the current meta-analysis were only partially supportive of the special status sometimes accorded to disorganized attachment as a precursor of children's externalizing problems. The global effect size for attachment security (*d* = 0.31) was very similar to that for disorganization (*d* = 0.34). It should be noted that these effect sizes do not reflect the outcomes of the same set of studies so direct comparisons are difficult. However, in an analysis of 19 studies where data from all four attachment groups were available the results corresponded to the aforementioned global effects. The effects for security and disorganization were significant and of similar magnitude (*d* = 0.27 and *d* = 0.29, respectively), while the effects for avoidance and resistance were small and in the case of avoidance nonsignificant (*d* = 0.06 and *d* = 0.11, respectively). The 85% CIs for security and disorganization did not overlap with that for avoidance, suggesting significantly stronger effects for insecurity and disorganization than for avoidance. The effect for resistance did not differ from any of the other contrasts, in part because this effect showed marked heterogeneity. Furthermore, in the larger set of studies, resistant attachment was not significantly associated with externalizing problems and showed an effect size numerically similar to that for avoidance. When only studies that provided direct pairwise comparisons between groups were considered, secure children scored lower on measures of externalizing problems than disorganized (*d* = 0.27), avoidant (*d* = 0.12), and resistant (*d* = 0.19) children, and while the CIs for these effects overlapped, disorganized children demonstrated numerically larger effects than the other insecure categories.

Although the effect sizes for disorganization and security compare favorably with other prominent risk factors for externalizing behavior, they also leave room for the possibility that the association may be moderated by other factors. It is highly noteworthy that few if any of the studies reviewed in this study directly addressed questions of mechanism. Arguably, until mediating mechanisms are better understood, we may struggle to find the relevant moderators. Given that an association clearly exists, there is an obvious need for strong theory-driven studies that address mediating processes, particularly those drawing on methods derived from other fields. Some well-studied risk processes worthy of consideration (in addition to the traditional internal working models construct) include impulsivity, negativity emotionality, affect regulation, hostile attributional biases, and physiological hypo-arousal (Belsky, Fearon, & Bell, 2007; Dodge & Coie, 1987; Eisenberg et al., 2001; Raine, Venables, & Mednick, 1997). Risk factors such as these, situated at the biological, cognitive, or affective level may be considered proximal determinants of externalizing behavior, with the quality of the attachment relationship with a primary caregiver conceptualized as a more distal determinant. A crucial question in that context has long been, and remains, the extent to which longitudinal continuities in the effects of attachment represent the ongoing supportive function provided by the attachment relationship as opposed to the early effects of attachment experiences on the emergence of stable psychological structures, such as internal working models. It is notable that Belsky and Fearon's (2002) analysis of the NICHD data at age 1–3 years suggested that the effects of attachment tended to persist primarily when there was continuity in the quality of maternal care. Given the centrality of this issue and the cogent arguments made by several authors on this subject (e.g., Sameroff, 2000; Sroufe et al., 2005a, 2005b), it is unfortunate that few studies have attempted to address this. Related to this, few studies have directly considered the possibility that certain parenting characteristics may be common determinants of both attachment insecurity and externalizing behavior problems. Thus, the extent to which attachment processes per se can be shown to make a specific and causal contribution to children's externalizing problems, either independently of parenting or as a causal mediator of its effects, remains to be seen.

There is also a clear need for a better understanding of causation. In that regard, the absence of studies that have repeatedly assessed both attachment and outcome is a significant barrier. Longitudinal studies that employ cross-lagged panel designs could provide elegant tests of causation by focusing on temporal ordering. However, in order to do this there is an urgent need to establish robust measurement protocols that allow for meaningful repeated assessments of attachment and hence the documentation of change. Of course, causal hypotheses can also be powerfully addressed by intervention studies (Bakermans-Kranenburg, van IJzendoorn, Mesman, Alink, & Juffer, 2008) and in the future these may be critical for determining the role of attachment in children's behavior problems, as well as that of the causal mediators and moderators of its effects.

Not Doing What You Are Told: Early Perseverative Errors in Updating Mental Representations via Language

Patricia A. Ganea
Boston University

Paul L. Harris
Harvard University

This research examined the ability of young ($N = 96$) children to learn about a change in the location of a hidden object, either via an adult's verbal testimony or from direct observation. Thirty-month-olds searched with equal accuracy whether they were told about the change or directly observed it. By contrast, when 23-month-olds were told about the change of location, they often returned to the container where they had last observed the object—even when that container was visibly empty. When interference from prior observational encoding was minimized, 23-month-olds, and even 19-month-olds, successfully updated their knowledge of the object's location on the basis of language. The processing demands of updating experience-based representations from new verbal information are discussed.

A century of research has revealed marked developmental changes in children's ability to update their knowledge of an object's location. We review those developmental changes and then discuss an important gap in our understanding of such updating.

One-year-old infants can watch an object being hidden and search correctly some 5–10 s later (Hunter, 1917). Indeed, they search correctly at successive locations, provided the delay between hiding and search trial is brief (Diamond, 1985; Harris, 1973). In the 2nd year, infants can keep track not just of visible displacements but also of invisible displacements. If an object is carried in a container (Haake & Somerville, 1985; Piaget, 1954), infants search at potential hiding places along the route of the transported object. Toddlers can even decode symbolic information about an object's displacement. For example, if a miniature toy dog is hidden at a particular location in a scale model of a room, 36-month-olds—but not 30-month-olds—treat that information as a representation of where a larger toy dog can be found in a full-size room (DeLoache, 1987, 2004).

Thus, there are major developments in the information that children use to update their knowledge of an object's location: 12-month-olds process an object's visible displacements; 18-month-olds process hidden displacements signaled by movements of a container; 3-year-olds decode the implications of a symbolic displacement—the movement of an object within a scale model. These changes suggest an emerging capacity to entertain more than one mental model of the world. Thus, theorists have proposed that infants entertain a single model but during the 2nd and 3rd years start to process more than one model: They compare successive sightings of a container to infer the hiding place of an object or they map the location of an object within a scale model to its location in a larger space (Perner, 1991; Suddendorf & Whiten, 2001).

Despite these changes, we know little about children's ability to update their knowledge of an object's location via language. Yet children do update on the basis of verbal input well before they use the symbolic information in a scale model. For example, having learned the name for a toy, toddlers went to an adjacent room where they were told that it had undergone a change (become wet). On their return, 22-month-olds, but not 19-month-olds, indicated the wet toy as opposed to a dry exemplar when asked for it by name (Ganea, Shutts, Spelke, & DeLoache, 2007).

We thank the children who participated and their parents. We also thank Jasmine DeJesus, Carina Wind, and the undergraduate research assistants at the Language & Learning Lab at Boston University for their help with data collection and coding.

We modified this paradigm to compare children's ability to update their knowledge of an object's location on the basis of verbal testimony or direct observation. In the testimony condition, we asked if 23- and 30-month-olds who had seen an object placed in location A would search at location B, if they were told—during their brief absence from the room—that the object had been moved from A to B. In the direct observation condition, children observed the change of location for themselves.

We expected toddlers to successfully search for the object at the new location in the observation condition. This corresponds to the classic "A-not-B" search paradigm, which children solve by the middle of the 2nd year. In the testimony condition, by contrast, two possible outcomes were anticipated. Children might update their initial representation of the object's location on the basis of language and correctly search for it at B. Such competence would be consistent with the findings of Ganea et al. (2007).

Alternatively, children might have difficulty with verbal updating, particularly when the revision of a prior, observation-based representation is required (Zelazo, Sommerville, & Nichols, 1999). On this hypothesis, children should initially search at A despite having been told that the object is at B. Only when prompted to search further might children turn from A to B. The executive difficulties faced by infants aged 9–12 months in searching at an object's most recent location, particularly in the face of interference from a prior representation, have long been entertained as an explanation for errors in the A-not-B search paradigm (Aguiar & Baillargeon, 2000; Diamond, 1985; Harris, 1973; Marcovitch & Zelazo, 1999, 2009). We anticipated that such difficulties might re-emerge if information about an object's new location were provided via language rather than direct observation.

Study 1

Method

Participants

Twenty 23-month-olds (9 girls, range = 22.4–24.7, *M* = 23.5) and sixteen 30-month-olds (9 girls, range = 28.3–33.3, *M* = 30.6) were tested. Five children were excluded—for fussiness (4) or lack of English proficiency (1). The majority were White, middle class, and English-speaking.

Materials

Four hiding locations were used: one green pillow on top of a brown couch, a three-drawer cabinet, a blue ottoman (called "chair"), and a wicker basket. For 30-month-olds, the basket was replaced by a beige box with a removable lid, a green cloth bag was placed on top of the ottoman (referred to as "bag"), and the green pillow was replaced with a black pillow. These changes were made because the 30-month-olds were overly interested in the basket during pilot testing and seemed confused when the experimenter called the ottoman a chair.

An opaque curtain was hung in the room to create an inner space (218 × 113 in.) containing the hiding locations and an outer space (34 × 113 in.; see Figure 1). A transparent plastic window was inserted in the curtain (8.5 × 11 in.), 44 in. from the

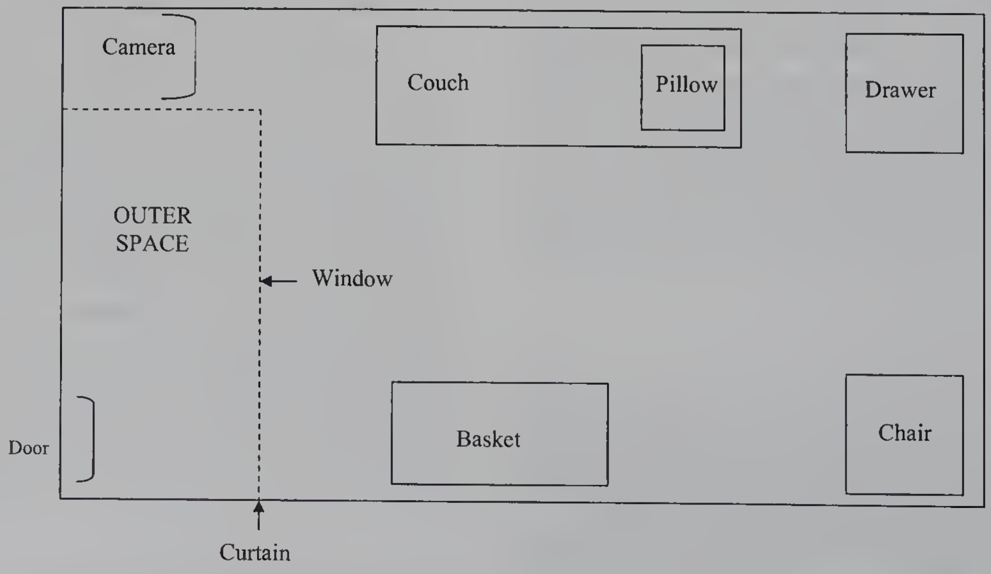

Figure 1. Illustration of experimental room layout.

ground. Children could not see through it unless lifted by an adult. Two stuffed animals served as hiding objects: a black and white puppy and a brown monkey. One camera was placed near the curtain to record the experimental session.

Procedure

The 23-month-olds received the two conditions (testimony and direct observation) in counterbalanced order. The 30-month-olds received the testimony condition first (during piloting children were distracted during the testimony if they had previously watched through the window in the direct observation condition). Each condition was presented following a familiarization phase.

Familiarization phase. Two experimenters sat with the child in the inner space, with the parent in the outer space. The familiarization phase was designed to ensure that children were aware of the four hiding locations and remembered the initial hiding location of the toy. To introduce the child to the hiding locations, the experimenters played a hiding game. One experimenter (E1) hid a toy with the child in one of the four locations (e.g., behind the pillow), while the other experimenter (E2) covered his or her eyes. After the hiding, E1 asked the child to show E2 the location of the toy. This game was repeated for all four locations.

E1 and the child then hid the toy a final time. E1 asked the child to point out each of the four hiding locations (e.g., ''Can you show me the basket?'') and the hidden animal (e.g., ''Can you show me where the puppy is?''). If the child did not indicate the animal's location, E1 showed the child where the animal was, returned it to its location, and asked the child to identify the location again. If the child failed a second time, the session continued but the child's data were excluded. Then E1, the child, and the parent moved behind the curtain for the test phase.

Test phase. The child participated in two conditions—testimony and direct observation. In both conditions, E2 moved the toy from its hidden location diagonally across the room to a new location (e.g., from the pillow to the chair). In the testimony condition, E1 looked through the window and told the child about the change in location: ''Look *E2* is moving the puppy! *E2* is moving the puppy from the pillow to the chair. The puppy is behind the chair. Yeah the puppy is behind the chair!'' In the direct observation condition, the child was lifted up to the window and told: ''Look *E2* is moving the puppy! *E2* is moving the puppy to a new place. Now the puppy is in a new place!'' Note that the verbal information in the direct observation condition did not identify the new location of the toy, only the fact that the toy was moved. For 30-month-olds, E1 used less verbal input during the direct observation condition—''Let's see what *E2* does in there. Do you see her? Look!'' The input given to younger children was judged to be redundant for older children. Then, E1 asked the child to get ready to find the toy and opened the curtain to allow the child to search. If the child did not find the toy on the first try and did not continue to search, she or he was prompted to continue searching (''Do you remember that she moved the puppy? Where is it?'').

The procedure was repeated for the other test condition with the other stuffed animal. As in the previous condition, E1 hid the toy and asked the child to point out the four hiding locations and the location of the hidden toy. After the child identified the toy's location, E1 proceeded with the test phase. The hiding locations for this phase were the remaining two not used in the first trial and the child received the opposite condition from the first trial. Across the three studies reported here, there was no effect of order of conditions on search behavior.

Coding

Films of test sessions for all three studies were coded to identify children's search behavior. Interrater agreement ranged from 94% to 100% (Cohen's kappa = .85–1.00). Disagreements were resolved by another person.

Results and Discussion

We used chi-square or binomial tests to compare children's search in the two conditions with chance levels (for the first response, chance was set at .25 because there were four possible locations to search; when children searched a second time after an error on their initial search, chance was .33).

When children directly observed the change in location, both younger (20 of 20) and older children (14 of 16) searched correctly (binomial tests, $p < .01$; see Figure 2). However, when children were told about the change, few of the younger (4 of 20) but most of the older (12 of 16) children used the verbal information to search correctly ($p < .01$). A chi-square test confirmed that the proportion of children searching correctly in the testimony condition was larger in the older than in the younger group, $\chi^2(1, 36) = 8.77, p < .001$.

Of the 16 younger children who failed to search correctly, most (87%) searched in the initial location

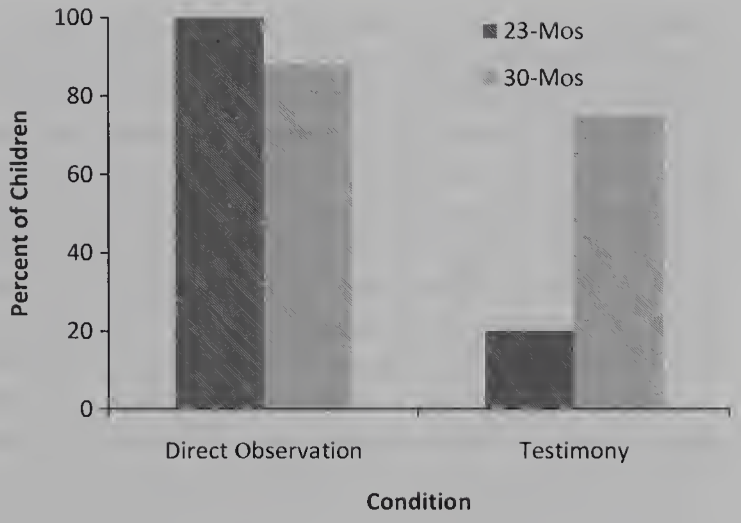

Figure 2. Percentage of children in each of the two conditions who searched correctly in the new location in Study 1.

of the toy ($p < .01$). On their second search attempt, 50% of children searched correctly. Thus, some children may have successfully encoded the new location. However, caution is needed in interpreting this finding because the number of correct second choices was not significantly different from chance, $\chi^2(1, 16) = 2.09$, $p = .14$.

Why did most 23-month-olds not use the verbal information for their initial search? According to the second hypothesis described earlier, toddlers' utilization of verbal information about the new location was prone to interference from the visual representation of the object's initial location. However, children may not have understood the testimony in the first place. This interpretation seems unlikely because Ganea et al. (2007) showed that 23-month-olds can understand verbal information about an invisible change. However, testimony about a location change may be harder to understand than testimony about a state change (i.e., dry to wet).

Study 2 was designed to discriminate between these two interpretations. At the end of the familiarization phase, the toy was left in the middle of the room. If children's utilization of verbal testimony in Study 1 was prone to interference from a prior visual representation of the object's specific location, interference should be reduced in Study 2 because there was no specific prior location. Thus, if children can understand verbal information about a toy's displacement, they should search correctly. However, if children cannot understand information about a location change (as opposed to a state change) they should fail to search correctly.

Because 30-month-olds responded accurately in both the visual and verbal conditions of Study 1, they were not included in Study 2. Instead, to probe the origins of toddlers' updating skills, 19-month-olds were also tested. Recall that the 19-month-olds tested by Ganea et al. (2007) did not respond systematically when given information about a state change.

Study 2

Method

Participants

Sixteen 23-month-olds (9 girls, range = 22.0–24.4, $M = 23.0$) and sixteen 19-month-olds (9 girls, range = 18.3–20.9, $M = 19.4$) were tested. Ten children were excluded—for fussiness (8) or lack of English proficiency (2).

Materials

Materials were the same as in Study 1, except that only two hiding locations were used for the 19-month-olds. The 23-month-olds were tested as in Study 1 with four hiding locations available in the room.

Procedure

Familiarization phase. Children were introduced to the testing locations and asked to identify them as in Study 1. At the end of this phase, E1 left the toy in the middle of the room.

Test phase. After familiarization, E1, the child, and the parent moved behind the curtain. Twenty-three-month-olds then received each of two test conditions—testimony and direct observation. Nineteen-month-olds were tested only in the testimony condition. In both conditions, E2 moved the toy from the middle of the room to a specific location. In the testimony condition, E2 came into the outer space and told the child about the new location: "Guess what? I moved the puppy! I put the puppy behind the pillow. Now puppy is behind the pillow." E1 then reinforced E2's testimony: "Did you hear that? *E2* put the puppy behind the pillow!" In the direct observation condition, E1 simply told the child to watch the change in location through the window in the curtain: "Let's see what *E2* does in there. Do you see her? Look!"

Results and Discussion

The majority of 23-month-olds searched correctly in both the testimony (12 of 16 children, $p < .01$)

and direct observation condition (14 of 16 children, $p < .01$). Thus, when the verbal information about the new location was not vulnerable to interference from visual information about the object's prior location, most 23-month-olds searched correctly. Indeed, most 19-month-olds (13 of 16, $p < .05$) also searched correctly based on testimony.

Study 2 supports two conclusions. First, toddlers can understand and use verbal testimony about an absent object's location. Second, when considered in relation to the perseverative errors observed in Study 1, the findings from Study 2 suggest that 23-month-olds have difficulty acting on testimony that is vulnerable to interference from specific previously encoded visual information. Study 3 was designed to probe this vulnerability.

In Study 3, a new group of 23-month-olds was tested. The initial location of the toy was either an open or a closed container. In the open container condition, children could see that the toy was not in the container upon re-entry.

Study 3

Method

Participants

Twenty-eight 23-month-olds (12 girls, range = 22.0–24.4, $M = 23.3$) were tested. Five children were excluded—because of fussiness (3), lack of English proficiency (1), and parental interference (1).

Materials

The hiding locations were the same as in Study 1, but the box was altered. In the closed box condition, an opaque box with a removable lid was used. In the open box condition, the box had a hole cut in its front panel so that its contents remained visible.

Procedure

With few exceptions, the procedure was the same as for Study 1. First, before the test phase, the initial hiding location of the toy was always in the box (either open or closed, depending on the condition). The location of the box was varied so that in each condition, the box was placed either in the front or in the back of the room, and either on the right or on the left side. Box location was counterbalanced both across trials and across children. Because the box had a different location on each trial and to avoid using the previous location of the box on the next trial, one hiding location was removed. (In this study there were only three hiding locations, bringing the chance level for the first search to .33.) The box was placed on a furniture item (drawer set, couch, ottoman, small table), so that it was at the child's eye level when entering the room.

Children received *testimony* that the toy was moved in both the open and closed conditions, counterbalanced for order. After E2 moved the toy, she told the child about the new location (e.g., "Guess what? I moved the puppy! I moved the puppy from the box to the bag. Now the puppy is in the bag"). E1 reinforced E2's testimony and asked the child to get ready to find the toy. If the child did not find the toy and did not continue to look for it, she or he was prompted to continue searching. The procedure was repeated with the other box (open or closed) and stuffed animal for a second trial.

Results and Discussion

Few children correctly searched in the new location in either the closed (2 of 28) or open box condition (8 of 28). A Fisher exact test confirmed that there was no significant difference in the rate of errors across conditions ($p = .09$). Children who failed to search correctly mostly searched in the old location of the toy: 92% in the closed box condition and 75% in the open box condition, $p < .05$ (chance level .33). Children who failed to update (20) in the open box condition exhibited four types of search: the majority (15) went to the open box and looked inside or searched in it, some (3) approached the open box but halfway switched direction to another location, one child looked at the box upon entry but did not approach it, and finally, one child went straight to an incorrect location without looking at the old location. Of the children who failed to search in the closed box condition (26), the majority (24) went all the way to the box and searched in it, whereas 2 children went to another location in the room.

On their second attempt to find the toy, over half of the children searched correctly (compared to a chance level of .50): 18 of 26 (69%) in the closed box condition, $p < .05$; 14 of 19 (74%) in the open box condition (one child did not search a second time), $p < .05$, indicating that children retained verbal input regarding the new location of the toy despite not searching there immediately. Figure 3 illustrates 23-month-olds' performance across the three studies.

To summarize, 23-month-olds have difficulty in updating their representation of an object's location despite visible evidence that their prior visual encoding is no longer valid. In the open box condition, the majority of children approached the visibly empty container and many searched in it.

General Discussion

Study 1 showed that 30-month-olds were able to search accurately whether they observed the object's change of location or were told about it. Twenty-three-month-olds, by contrast, searched correctly only after observing the change of location. When told about it, they often searched where they last observed the object. Study 2 showed that children could take in verbal information about a new location. When the object was left in the middle of the room, both 19- and 23-month-olds searched correctly when told that it had been moved. Study 3 underlined the lure of earlier observation-based encoding. Twenty-three-month-olds made perseverative errors not only when the initial hiding place was a closed box (replicating the results of Study 1) but also when it was an open box. They could see that the open box was empty yet still approached it, ignoring what they were told about the object's new location. Indeed, many children searched inside the visibly empty box.

The pattern of error displayed by 23-month-olds is reminiscent of the pattern shown by younger infants in the A-not-B paradigm in two notable respects. In that paradigm, infants also return to B even when it is visibly empty (Harris, 1974). Second, when given an opportunity to search after an error, infants display evidence of having encoded the new location. They search there rather than elsewhere (Webb, Massar, & Nadolny, 1972). By implication, children's difficulties in updating on the basis of language are part of a more general difficulty in updating. Nevertheless, the 23-month-old children in this study could update on the basis of visual information. How does language-based updating impose different cognitive demands compared to visually based updating?

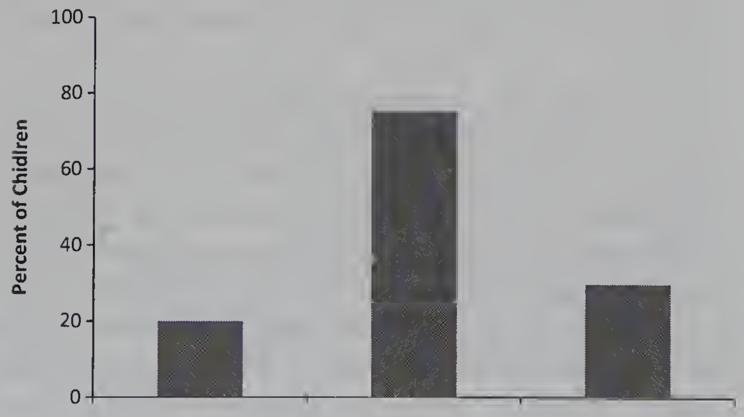

Figure 3. Percent of 23-month-old children in each study who searched in the new location in the testimony condition.

Recent studies with adults suggest that the cognitive mechanisms involved in the perception of action are also involved in processing action descriptions (Yaxley & Zwaan, 2007; Zwaan & Taylor, 2006). Thus, spatial imagery is automatically activated during language processing (Barsalou, Simmons, Barbey, & Wilson, 2003; Bergen, Linday, Matlock, & Narayanan, 2007; Fischer & Zwaan, 2008; Spivey & Geng, 2001; Zwaan, Stanfield, & Yaxley, 2002). Currently, there is little information about the emergence of children's ability to activate such imagery when processing verbal descriptions. Thus, we do not know whether the children tested in our study imagined the transformation of the toy's location when the updating involved language. What our results do indicate is that at 30 months—but not at 23 months—comprehension of action sentences ("The toy was moved from A to B") is equivalent to action observation (seeing the toy moved from A to B).

What changes take place in language-based updating between 23 and 30 months?

First, language-based representation of the new location might increase in strength relative to the visually based representation of the initial location. By analogy, in the classic A-not-B paradigm, infants initiate an action toward the hidden object only when they have a strong representation of the object (Munakata, 2001; Munakata, McClelland, Johnson, & Siegler, 1997). In the current studies, when the basis for updating was visual information, children could form a strong representation of the new location and disregard the initial location. However, when the basis for updating was verbal information, younger children were lured to location A, even when it was visibly empty, suggesting that their visual representation of that location was stronger than the language-based representation of the new location.

A second explanation is that updating in the testimony condition required integration of information from two modalities—visual and verbal. In the direct observation condition, the updating required integration only within the visual modality. In the testimony condition, children had to revise a visual representation on the basis of verbal information. Arguably, younger children's ability to integrate information across different modalities is less efficient than that of older children. One way to test this hypothesis is to manipulate both input (verbal or visual) and initial representation (verbal or visual) for both age groups.

Finally, children's ability to *edit* a prior visually based representation on the basis of subsequent verbal information may change between 23 and 30 months. The editing process may be straightforward when it involves only the addition of new information, as in Study 2 (''The object is now in B'') or as in Ganea et al. (2007; ''Lucy is now wet''), but more demanding if it involves deletion and replacement of specific information as in Studies 1 and 3 (''The object was in location A. Now it is in location B''). In Study 2, children may have stored a generic representation that the toy was ''in the room'' so that subsequently, they only needed to supplement that generic representation. In Studies 1 and 3, the toy was placed in a particular location so that updating called for deletion of that specific initial location and replacement with information about its new location. Developmental differences might be expected, depending on whether updating involves simple addition or deletion and replacement.

In conclusion, toddlers can update on the basis of verbal testimony by 19 months—almost at the onset of language production. Nevertheless, even at 23 months the updating process is error prone. Echoing the difficulties shown by preverbal infants in shifting from one hiding place to another, toddlers display perseverative errors when they have been told about a shift in location instead of observing it for themselves.

"Who Said You Could Wear My Sweater?" Adolescent Siblings' Conflicts and Associations With Relationship Quality

Nicole Campione-Barr
University of Missouri–Columbia

Judith G. Smetana
University of Rochester

A new measure of sibling conflict was used to identify 2 types of conflicts in 115 adolescent sibling pairs (older siblings, $M = 15.59$, $SD = 2.01$ years; younger siblings, $M = 13.02$, $SD = 2.06$ years). Conflicts overall were more frequent than intense and more likely to involve the invasion of the personal domain than conflicts involving equality and fairness, especially by early adolescent older siblings. For both siblings, and with parents' ratings of their relationship with the target child controlled, these conflicts were negatively associated with sibling relationship quality. The implications of the findings for sibling relationships during adolescence are discussed.

Siblings have frequent disagreements during adolescence. Furman and Buhrmester (1985) found that of six major relationships (mothers, fathers, siblings, grandparents, friends, and teachers), early adolescents perceived conflict as occurring most frequently with siblings, perhaps due to the nature of the relationship. Like other family members, relationships with siblings are based on kinship and long histories of interactions; thus, the relationship can withstand conflict without fear of dissolution. However, adolescent sibling conflicts have garnered relatively little research attention.

A meta-analysis has demonstrated that parent–adolescent conflict frequency peaks during early adolescence (Laursen, Coy, & Collins, 1998). Mirroring these results, Buhrmester and Furman (1990) found that among 3rd, 6th, 9th, and 12th graders, conflict with siblings was greatest at 6th grade. This could be due to increases in autonomy seeking, especially as increased sibling conflict was reported mostly by early adolescent younger siblings (Buhrmester & Furman, 1990). Younger siblings may see older siblings as similar to parents in that there is a hierarchy in the relationship. As siblings grow older and developmental differences between them decline, older siblings may hold on to earlier patterns of asymmetry in the relationship, which may be bothersome to younger siblings. Therefore, early adolescents may feel as though some autonomy must be gained from siblings as well as parents to emphasize their maturity.

Buhrmester and Furman (1990) also found that older children reported that their sibling relationships were more egalitarian than did younger children, with adolescents reporting less dominance by their siblings than children. Younger siblings may become more autonomous and no longer allow older siblings to dominate the relationship. However, companionship and affection were also lower in the older age groups. Buhrmester and Furman concluded that sibling relationships become less intense, both positively and negatively, as children move into adolescence. Finally, these researchers found that same-sex sibling dyads felt closer than opposite-sex dyads.

Investigations of specific processes involved in sibling relationships across all age groups, as well as adolescent siblings more generally, have been limited until recently (e.g., Feinberg, McHale, Crouter, & Cumsille, 2003; Kim, McHale, Osgood, & Crouter, 2006). Research on sibling relationships

---

The research described here was conducted in partial fulfillment of the requirements of the Ph.D. degree for the first author at the University of Rochester. We would like to thank Dr. Kenneth Hilton of the Rush-Henrietta School District and the many families who participated in this research. We would also like to thank Denise Gettman, Aaron Metzger, Marina Tasopoulos-Chan, and Myriam Villalobos, as well as our undergraduate research assistants for their assistance with family visits and data entry. We thank the Fetzer Institute for their support of this research.

in early and middle childhood has examined some aspects of sibling conflicts such as resolution strategies (e.g., Howe, Rinaldi, Jennings, & Petrakos, 2002), parental intervention (Ross, Filyer, Lollis, Perlman, & Martin, 1994), and, to a much lesser extent, the content of sibling conflicts (McGuire, Manke, Eftekhari, & Dunn, 2000). McGuire et al. (2000) found that for sibling pairs in middle childhood, the most common issues of conflict involved sharing of personal possessions, and these issues were more common than conflicts over household items. The issues that cause disagreement between adolescent sibling dyads have not been studied, however, and this was one purpose of the present study.

Research from the social domain perspective (see Smetana, 2006) has investigated differences in conflict between parents and adolescents as a function of the topic of the conflict (Smetana & Asquith, 1994). This research shows that parents and adolescents agree that parents should have authority to regulate *moral* (pertaining to others' rights, welfare, or fairness) and *conventional* (contextually relative, arbitrary social norms) issues throughout adolescence, whereas children should have some authority over *personal* issues (pertaining to privacy, control over their bodies, and preferences and choices) well before adolescence (Smetana, 1989; Smetana & Asquith, 1994). However, conflicts are typically over issues that cross the boundaries of different social domains (i.e., issues that adolescents view as infringing on their personal jurisdiction that parents view as conventional or prudential).

The importance of the personal domain during adolescence and McGuire et al.'s (2000) findings for younger sibling pairs suggest that conflicts between siblings also may pertain to personal issues and adolescents' perceptions that their sibling has infringed on their personal domain (e.g., one's personal space or friends). Given the age-related increases in appeals to personal jurisdiction in adolescents' conflicts with parents (Smetana, 1989), sibling conflicts over personal issues may be more frequent and more heated than moral conflicts involving the equality and fairness of household resource distribution (e.g., computer use), which also may occur between adolescent siblings.

The present study examined specific types of conflict among adolescent siblings using a newly developed measure that is similar in structure and response choices to the Issues Checklist (Robin & Foster, 1989), a frequently used measure of adolescent–parent conflict. Previous research has shown that it is important to consider both conflict frequency and its intensity given that they differentially impact relationships and development (Montemayor, 1983). Therefore, both forms of conflict were examined in the present study, and it was hypothesized that issues involving invasion of the personal domain would be more frequent and more intense than those involving moral issues of equality and fairness. Additionally, we investigated the association between the different types of conflicts and sibling relationship quality. Based on previous research showing that adolescents perceived parents to be overly controlling when they tried to regulate adolescents' personal domain (Smetana & Daddis, 2002), we hypothesized that conflicts involving threats to one's sense of self or personal relationships (e.g., copying what the other does, hanging around when the other has friends over) would be associated with lower levels of trust and communication with siblings, whereas conflicts involving equal distribution of resources (e.g., distribution of chores) would be less heated and have less influence on the relationship than conflicts about personal issues. Also, parents' reports of relationship quality with their children were included in these analyses to ensure that significant effects were due to the sibling relationship and not general levels of closeness within the family.

Method

Participants and Sample

Participants were 115 sibling pairs and one of their parents (108 mothers and 7 fathers). The sibling pairs were within one to four grade levels of one another. Older siblings in the dyads ranged in age from 12.03 to 20.38 years ($M = 15.59$, $SD = 1.98$); younger siblings ranged from 8.48 to 16.57 years ($M = 13.07$, $SD = 2.01$). The mean age difference was 2.53 years ($SD = .95$). Initially, 7th- and 10th-grade adolescents were recruited as part of a larger study; half of the students at each grade participated with an older sibling and half participated with a younger sibling. For the present study, sibling pairs were divided into three age cohorts. The preadolescent-early adolescent cohort ($n = 24$) consisted of 7th graders ($M = 10.23$ years, $SD = 1.02$) and their younger siblings ($M = 12.79$ years, $SD = .51$); the early-middle adolescent cohort ($n = 62$) consisted of early ($M = 12.93$, $SD = .75$) and middle ($M = 15.50$, $SD = 0.83$; some of whom were 7th graders with an older sibling, and some of whom were 10th graders with a younger sibling) adolescents. The middle-late adolescent cohort ($n = 29$) consisted of 10th graders ($M = 15.70$, $SD = .450$) and their older siblings ($M = 18.11$, $SD = 0.93$). Due to the small and uneven numbers of sister–sister and brother–brother sibling dyads when examined within the three age groups, we examined sibling sex composition as either same- or mixed-sex dyads ($n_{\text{same-sex}}$: pre-early = 8; early-middle = 35; middle-late = 17, $n_{\text{mixed-sex}}$: pre-early = 16; early-middle = 28; middle-late = 12). Age cohorts did not differ significantly by sex composition, mother's education, or family income; however, middle-late adolescent pairs were more likely than early-middle adolescent pairs to reside in single- or stepparent households.

The sample was primarily European American (88%), with the remaining participants African American (9%) or other ethnicities (3%). Most siblings lived with both biological parents (69%); the remainder resided in stepparent (9%) or single-parent families (21%). Family structure (examined as two-biological parent families vs. all else) and ethnicity (European American vs. all else) did not differ significantly by age cohort. The median yearly family income was between $55,000 and $69,999, and most parents (86%) had some college education. Mothers' and fathers' mean ages were 42.47 and 43.92 years (SDs = 4.69 and 5.65), respectively.

Measures

Sibling conflict. The Sibling Issues Checklist was developed for the present study, based on the format of the Issues Checklist (Robin & Foster, 1989); however, the content of the individual items was selected to be appropriate to siblings. The 20 issues were chosen based on a content analysis with a pilot sample of sixty-five 6th to 9th graders who were demographically similar to the study sample. They gave free responses to the question, "What types of things do you fight about with your brothers or sisters most often?" Responses suggested by more than 20% of the pilot sample were used in the final scale. As found in previous research (Smetana, 1989; Smetana & Asquith, 1994), the conflict topics reported by the pilot sample were mundane, everyday issues. Both older and younger siblings rated how often the issues were discussed (frequency) on a 5-point scale from 1 (*never*) to 5 (*very often*), and how "hot" the discussions got (intensity) on a 5-point scale ranging from 1 (*calm*) to 5 (*very angry*).

Relationship quality. The Trust and Communication subscales of the Armsden and Greenberg (1987) Parent and Peer Attachment Inventory were used to assess relationship quality. These scales have been used previously to assess relationships with mothers, fathers, friends, and romantic partners, but we adapted the questions to assess sibling relationship quality (e.g., My brother/sister accepts me as I am; My brother/sister can tell when I'm upset). As found previously, the Trust and Communication subscales were highly correlated, rs = .69 and .78 for older and younger siblings, respectively. Therefore, the two subscales were combined into a single mean relationship quality score. The scale consisted of 18 items rated on a 5-point scale ranging from 1 (*almost never or never*) to 5 (*almost always or always true*). Cronbach's alphas were .87 for both older and younger siblings' reports. Both siblings reported on their relationships with their participating sibling; sibling reports were moderately correlated, $r(115) = .52$, $p < .001$, suggesting that sibling dyads share some commonalties (but not complete overlap) in their views of their relationship. Finally, parents reported on their relationship with each of their two children using the original version of the inventory (αs = .80 for both).

Procedures

Participants were recruited from a Northeastern U.S. suburban school district. Letters describing the study were sent to parents of 7th- and 10th-grade students, and parents mailed back interest response sheets. Researchers also made presentations to students during their "homebase" classes to encourage their participation. Inclusion criteria were that students have a nontwin sibling less than 5 years older or younger than they were. Older siblings had to be first-born children, and younger siblings could be any later-born status, although most (80%) were second-born. As part of the larger study, families were paid honoraria for participating in a 2-hr visit at the university lab, during which they completed consent and assent forms, questionnaire measures, interviews, and sorting and family interaction tasks.

Results

Preliminary Analyses: Sibling Conflict Factors

The sibling conflict scales were empirically derived. To eliminate dependencies in the data and to determine whether the results replicated across siblings, we analyzed older and younger siblings' reports separately for ratings of frequency and intensity. This resulted in four separate principal components analyses with varimax rotation. Three inclusion criteria (eigenvalues greater than 1.00, scree tests, and meaningfulness and interpretability) were used in determining the number of factors. Variables that loaded .40 or greater on a factor, had low cross-loadings, and loaded highly on the same factor for at least three of the four analyses were retained in the scale.

The two hypothesized factors, Equality and Fairness (7 items: control over TV remote, TV show to watch, computer use, turn in front seat of car, which radio or CD to listen to, phone use, places to go with family), and Invasion of the Personal Domain emerged. Four of the six items loading on this latter scale entailed infringing on one's personal domain (going into other's room, copying what other does, borrowing without permission, and hanging around other's friends), but ''teasing and being mean'' (which pertains to a moral issue) and ''breaking other's things'' unexpectedly loaded on this scale. Seven of the 20 items (whose turn for chores, turn to play video games, rules of playing game, bathroom use, eating other's food, parents' attention, telling other what to do) were dropped from the scales due to cross-loading or inconsistent loading across the two scales (interested readers can write to the authors for the factor loadings and eigenvalues). Mean composites were created separately for younger and older siblings' reports of conflict frequency and intensity for the two types of issues. Alpha coefficients were acceptable for all scales (.77–.81).

Differences in Sibling Conflict by Form, Type of Issue, Dyad Age, and Sex Composition

Although ratings of conflict frequency and intensity were highly correlated, they were examined separately here, as they have been found to have different consequences for adolescent–parent relationships (Montemayor, 1983). A 2 (conflict rating: frequency vs. intensity) × 2 (reporter: older vs. younger sibling) × 2 (type of issue: fairness and equality vs. invasion of personal) × 3 (age cohort) × 2 (sex composition: same vs. mixed) mixed model analysis of variance (ANOVA), with conflict rating and type of issue as within-subjects factors and reporter, age, and sex as between subjects factors, was performed (see Table 1 for means).

Significant main effects of conflict rating, $F(1, 102) = 36.70$, $p < .001$, $\eta^2 = .27$, and conflict type, $F(1, 102) = 11.31$, $p < .001$, $\eta^2 = .10$, were qualified by a significant Rating × Type interaction, $F(1, 102) = 55.23$, $p < .001$, $\eta^2 = .35$; Rating × Reporter interaction, $F(1, 102) = 4.53$, $p < .05$, $\eta^2 = .04$; and a Rating × Type × Reporter interaction, $F(1, 102) = 10.12$, $p = .01$, $\eta^2 = .09$. Overall, conflict frequency ratings were higher than conflict intensity ratings,

Table 1
Means (Standard Deviations) of Conflict Frequency and Intensity by Reporter, Type, Age, and Sibling Gender

	Pre-early pairs		Early-middle pairs		Middle-late pairs	
	Same	Mixed	Same	Mixed	Same	Mixed
Frequency						
Personal						
Older	2.83 (1.20)	2.91 (1.30)	2.58 (0.93)	2.69 (0.80)	2.58 (0.87)	2.55 (0.94)
Younger	2.25 (1.06)	2.15 (1.07)	2.40 (0.84)	2.54 (0.88)	2.22 (0.91)	2.21 (1.06)
Equality						
Older	2.50 (0.83)	2.23 (0.89)	2.86 (0.98)	2.58 (0.77)	2.46 (0.99)	2.57 (0.85)
Younger	2.80 (1.27)	2.36 (0.70)	2.67 (0.86)	2.53 (0.95)	2.21 (1.01)	2.24 (0.86)
Intensity						
Personal						
Older	2.71 (0.98)	2.70 (1.27)	2.43 (0.85)	2.49 (0.84)	1.94 (0.94)	2.27 (1.04)
Younger	2.48 (1.31)	2.38 (0.96)	2.32 (0.91)	2.75 (0.97)	2.12 (0.92)	2.45 (1.20)
Equality						
Older	1.91 (0.67)	1.83 (0.86)	2.18 (0.77)	1.99 (0.72)	2.02 (0.87)	2.18 (0.75)
Younger	2.34 (1.11)	1.89 (0.69)	1.78 (0.66)	2.02 (0.88)	1.97 (1.07)	1.64 (0.74)

Note. Same = same sex; Mixed = mixed sex.

and conflicts were more likely to be over invasion of the personal domain than over equality and fairness. However, conflicts over equality and fairness were more frequent than intense, while there was no difference in rating of conflicts over invasion of the personal domain. Also, older siblings reported greater frequency of conflicts than younger siblings (there was no difference in intensity), and older siblings reported more frequent conflicts over invasion of the personal domain than younger siblings.

Finally, there were two significant three-way interactions with age cohort: Type × Reporter × Age Cohort, $F(2, 102) = 4.30$, $p < .05$, $\eta^2 = .08$, and Rating × Type × Age Cohort interaction, $F(2, 102) = 7.33$, $p < .001$, $\eta^2 = .13$. Older siblings reported more conflicts over invasions of the personal domain than over equality and fairness, but this was significant only in the youngest age cohort of siblings. Also, the finding that equality and fairness conflicts were more frequent than intense was only the case for the younger two age cohorts.

Associations of Type of Issue With Sibling Relationship Quality

To examine the association between conflict types and sibling relationship quality, four separate hierarchical regression analyses were performed on conflict frequency and intensity as rated by older and younger siblings. In the first step of the analyses, age cohort, sibling sex composition, and parental marital status were entered as controls (no other demographic variables were associated with the variables of interest; see Table 2). Additionally, in the first step, parents' report of their relationship with the older or younger child (depending on the analysis) was entered. Given that reports of relationship quality across multiple individuals within the same family are often moderately correlated, we controlled for parent–teen relationship quality so that any significant associations with sibling conflict were specifically associated with the sibling relationship, not the more general family environment. In the second step, the two types of conflict were entered simultaneously.

As shown in Table 3, for both conflict frequency and intensity, older siblings in same-sex pairs reported more trust and communication than those in mixed-sex pairs. Additionally, parents' trust and communication with younger siblings were significantly associated with older siblings' reports of trust and communication with these siblings. Finally, over and above the significant sex composition and parental relationship effects, conflicts over personal domain invasions, but not conflicts over equality and fairness, were negatively associated

with older siblings' reports of relationships with younger siblings (significantly for frequency and approaching significance for intensity). The results of the analyses for younger sibling were similar. Whereas sex composition was not significant in the analysis, parents' reports of better relationships with older siblings were significantly associated with younger siblings' reports of better relationships with older siblings. Also, conflicts over invasion of the personal domain, but not conflicts over equality and fairness, were significantly and negatively associated with younger siblings' reports of relationship quality.

Discussion

The current study demonstrated that sibling conflicts in primarily White, middle-class adolescent dyads could be differentiated into personal domain conflicts or moral conflicts over equality and fairness of shared resources. Interestingly, conflicts over invasion of the personal domain also included a clearly moral issue—teasing and being mean—and a more pragmatic issue of property damage, suggesting that autonomy and space invasions shaded into (moral) concerns with welfare. Previous research by Helwig (2006) has demonstrated that especially in middle childhood and early adolescence, rights are often justified in terms of personal autonomy. Therefore, while conflicts over breaking one's personal possessions or teasing and being mean may pertain to moral rights, the adolescents may interpret these actions as invading their personal space or sense of agency. Nevertheless, conflicts involving the invasion of the personal domain (including psychological harm) were distinct in the factor analysis from moral conflicts over equality and fairness, and they were also more frequent and intense. These differences were most pronounced in early adolescent older siblings. This is somewhat consistent with previous findings by Buhrmester and Furman (1990) that sibling conflict is greater among early adolescents than younger children or older teens. The results also mirror the findings of Laursen et al.'s (1998) meta-analysis demonstrating that parent–adolescent conflict frequency peaks during early adolescence. Given that conflicts in both sibling and parent–adolescent relationships are mostly over personal issues, it is likely that both reflect adolescents' basic needs to claim some issues as outside of legitimate control by others. Claims to personal jurisdiction have been described as essential in establishing a sense of individuality (Nucci & Lee, 1993).

Buhrmester and Furman (1990) found that increased sibling conflict in early adolescence was mostly reported by younger siblings, whereas in the present study, early adolescent *older* siblings reported more conflicts, specifically over personal issues. These findings are consistent with McGuire et al.'s (2000) finding that middle-childhood older siblings reported more conflict over sharing personal items than did younger siblings. Together, these findings indicate the importance of assessing not only the frequency but also the content of sibling disputes. In the present study, early-adolescent older siblings reported having more conflicts over things such as borrowing something of the other's without asking, hanging around when the other has friends over, or copying what the other does than conflicts over issues such as bathroom use or whose turn it is to do chores. These types of conflicts may be more salient to older siblings in early adolescence, who may not want their younger siblings ''tagging along'' while they are trying to engage in more adult-like behaviors. An alternative explanation may be that as early adolescent older siblings begin the process of individuating from their family, they may engage in more conflicts with all family members, and this may be a change for younger siblings and parents, especially if they had previously enjoyed a close relationship.

We also found that for both older and younger siblings, more frequent and intense conflicts over invasion of the personal domain were associated with poorer relationships between siblings. Given that the data are cross-sectional, it is not clear whether this is because more conflicts over personal issues make it difficult to be in a close, trusting relationship, or whether siblings who have poor quality relationships feel free to more frequently invade one another's personal domain. Future research should include longitudinal samples to better understand the causal direction of this association.

Due to the way the sample was recruited, the age cohorts were uneven in size. Additionally, while the different gender constellations were relatively even, the cell sizes were too small to decompose same-sex dyads into male and female pairs or mixed-sex dyads into brother–sister and sister–brother pairs. Therefore, we only examined same sex versus mixed sex. Significant gender effects were found for relationship quality between siblings. Among older siblings, same-sex pairs reported being closer than mixed-sex pairs (there was no effect for younger sibling reports). Exploratory analyses suggested that, consistent with previous research, sister–sister dyads appeared to be closer than brother–brother dyads (*Ms* = 3.45, 3.20).

The present study was an important first step in examining the different types of issues that cause conflict between adolescent siblings and their associations with relationship quality. Although our measure was based on extensive free-response pilot testing, it is possible that we did not tap all of the salient issues in adolescent sibling conflicts. Thus, the measure needs to be validated through further research, particularly among ethnic minority and lower socioeconomic status youth, as well as youth from different cultures. Future research also should include observations of actual conflicts and examine how interactions, negotiation, and conflict resolution differ by the type of issue being discussed. Conflicts can be constructive and provide a context to learn negotiation or conflict resolution skills, but they also may be interpersonally destructive, and further research is needed to determine if this difference is dependent on the content of the conflicts or other aspects.

Categorization in 3- and 4-Month-Old Infants: An Advantage of Words Over Tones

Alissa L. Ferry, Susan J. Hespos, and Sandra R. Waxman
Northwestern University

Neonates prefer human speech to other nonlinguistic auditory stimuli. However, it remains an open question whether there are any conceptual consequences of words on object categorization in infants younger than 6 months. The current study examined the influence of words and tones on object categorization in forty-six 3- to 4-month-old infants. Infants were familiarized to different exemplars of a category accompanied by either a labeling phrase or a tone sequence. In test, infants viewed novel category and new within-category exemplars. Infants who heard labeling phrases provided evidence of categorization at test while infants who heard tone sequences did not, suggesting that infants as young as 3 months of age treat words and tones differently vis-à-vis object categorization.

Questions concerning the relation between linguistic and conceptual organization hold a central position in the cognitive sciences. Most of the research investigating the dawning of this relation has focused on early word learning and has documented that by roughly children's first birthdays, words support the formation of object categories (e.g., Balaban & Waxman, 1997; Fulkerson & Haaf, 2003; Namy, 2001; Waxman & Booth, 2003; Waxman & Braun, 2005; Woodward & Hoyne, 1999). More recent work has identified a link between words and object categories in infants as young as 6 months (Fulkerson & Waxman, 2007). Our goal was to consider this phenomenon in infants at 3 and 4 months.

Background

Waxman and Markow (1995) showed that for infants as young as 12 months of age, providing the same name for a set of distinct objects (e.g., four different animals) highlights commonalities among them and supports the formation of an object category (e.g., animal). For half of the infants in their task, the objects (e.g., the four animals) were introduced in conjunction with a novel noun (e.g., ''See the *fauna*?''); for others, the very same objects were introduced with a general orienting phrase containing no novel word (e.g., ''See here?''). At test, infants viewed two objects: a new member of the now-familiar object category (e.g., another animal) and a member of a novel object category (e.g., a vehicle), and heard, ''See what I have?'' Infants in the word condition showed a reliable preference for the novel object (e.g., a vehicle); those in the no word control condition revealed no preference. These outcomes document an early link between words and object categories in infants just beginning to build a lexicon.

Additional evidence documents the specificity of this phenomenon within the 1st year of life. At 13–14 months, infants distinguish between *kinds* of novel words, mapping novel words presented as nouns (but not adjectives) specifically to object categories (Booth & Waxman, 2009; Waxman & Booth, 2001). But younger infants' expectations about words are less precise. At 11 months, they do not distinguish between kinds of words (nouns and adjectives) in categorization tasks (Waxman & Booth, 2003). Nonetheless, their expectations are not so general as to include novel words under any circumstance: If the *same* novel word is applied to a set of distinct objects, 12-month-olds successfully

form an object category, but if a *different* word is applied to each, they do not (Waxman & Braun, 2005). This indicates that by 12 months, infants successfully cull novel words from the ongoing speech stream, detect whether the same or different words have been applied to a set of objects, and expect that objects named by the same word (but not those named by different words) are members of a shared category.

Importantly, although other kinds of auditory stimuli, including tones and melodic sequences, are engaging to infants, these stimuli do not promote object categorization even when they are consistently applied. Fulkerson and Waxman (2007) compared the influence of novel words and tone sequences on object categorization in infants at 6 and 12 months. Infants viewed pictures of exemplars from the same category (e.g., dinosaurs), presented sequentially. Infants in the word condition heard a naming phrase as they viewed each picture (e.g., "Look at the toma! Do you see the toma?"); those in the tone condition heard a sequence of pure tones, matched precisely to the word condition for timing, duration, and volume. At test, all infants viewed pictures of a new exemplar from the familiar object category (e.g., a new dinosaur) and an exemplar from a novel category (e.g., a fish), presented side by side. Infants in the word condition revealed a reliable preference for the member of the novel category, indicating that they successfully formed the object category. Infants in the tone condition failed to reveal reliable preferences, suggesting that they had not formed an object category. Thus, by 6 months of age, words facilitate object categorization in a way that well-matched tone sequences do not.

It is important to point out that the claim is not that object categorization depends entirely on the presentation of words. Clearly, there are many circumstances in which humans, and even nonhuman animals, categorize successfully even in the absence of a novel word (e.g., Hespos & Spelke, 2004; Mareschal & Quinn, 2001; Plunkett, Hu, & Cohen, 2008; Quinn, 2002; Santos, Sulkowski, Spaepen, & Hauser, 2002). The claim is more measured and more precise: Even before infants produce words on their own, naming a set of objects with a consistently applied word promotes the formation of object categories, highlighting commonalities among objects in a way that other well-matched auditory stimuli (e.g., tone sequences) do not (Brown, 1957; Waxman & Markow, 1995). Interpreted in this light, the claim is that words support the ubiquitous process of categorization and are especially effective in highlighting commonalities among objects that may otherwise have gone undetected (Fulkerson & Waxman, 2007; Gelman & Kalish, 2006; Plunkett et al., 2008; Waxman & Markow, 1995).

In the current study, we sought to examine the precursors to this phenomenon in infants at 3 and 4 months of age. We focused our efforts here because although 3- and 4-month-old infants share with older infants an interest in human speech, it is not until roughly 6 months of age that they begin to parse individual words (especially their own names) from the stream of fluent speech (Bortfeld, Morgan, Golinkoff, & Rathbun, 2005; Jusczyk & Aslin, 1995). Apparently, then, infants' treatment of words may differ importantly from 3 to 6 months. Although infants prefer human speech to many types of nonlinguistic auditory stimuli even at birth (Ramus, Hauser, Miller, Morris, & Mehler, 2000; Vouloumanos & Werker, 2007), whether this early preference has any consequences on categorization behaviors in infants younger than 6 months remains very much an open question.

Our goal was to examine object categorization under two different auditory conditions, one involving human speech (the word condition) and the other serving as a nonlanguage control (the tone condition). This design permitted us to discover whether words and tones exert the same influence on infants' categorization, or whether words enjoy a privileged status vis-à-vis categorization as early as 3 or 4 months of age.

Method

Participants

Participants included 46 healthy, full-term infants divided into two age groups. There were twenty-four 4-month-olds (9 males, 15 females) with an average age of 4 months 5 days (range = 3 months 23 days to 4 months 21 days) and twenty-two 3-month-olds (13 males, 9 females) with an average age of 3 months 7 days (range = 2 months 19 days to 3 months 21 days). Half of the infants within each age group were randomly assigned to the word condition and the others to the tone condition. All infants in the language condition were from families where English was the predominant language spoken in the home. An additional 13 infants were tested but excluded due to parental or sibling interference (2), fussiness (10), or falling asleep during the study (1). An additional 17 infants, who looked at the stage for less than half of the familiarization period, were included in separate analyses (5 were 3-month-old infants and 12 were 4-month-old infants). Other studies have shown that the amount of exposure infants receive during the familiarization period can affect whether infants will show a novelty or a familiarity preference during test trials (e.g., Theissen, Hill, & Saffron, 2005). We suspected that the low exposure to the familiarization stimuli may have impacted their ability to form a category and separate post hoc analyses were conducted to examine that possibility.

Participant families were recruited from a commercial mailing list from the surrounding area and contacted by mail and telephone. They were given a t-shirt or a book as a gift but were not otherwise compensated for their participation. The participants were predominantly from White, middle-class families. The ethnicity of the sample was 80% non-Hispanic. The racial make-up was 75% White, 5% Asian, 3% Black/African American, 9% multiracial, and 8% chose not to answer.

Stimuli

The stimuli were identical to the stimuli used in Fulkerson and Waxman (2007).

Visual stimuli. Twenty slides of line-drawn dinosaurs and fish were produced to form two familiarization sets of eight stimuli each and two sets of two test stimuli each (see Figure 1). Stimuli were outlined in black and filled in with a solid color. Within each familiarization set, stimuli varied in color; within each test set, stimuli were matched in color.

Auditory stimuli. Two sets of naming phrases (“Look at the *toma/modi.* Do you see the *toma/modi?*”) were spoken by a female in the infant-directed speech register and recorded for presentation. Two sequences of pure tones (400 and 800 Hz), matched to the naming phrases in duration (2.2 s), pause length, and volume (82 dB) were created.

Apparatus

Infants sat on a parent’s lap in a small room in front of a wooden puppet stage measuring 243.5 cm high, 128 cm wide, and 61 cm deep. The infants faced an opening in the front of the stage (93 cm above the floor, 61 cm high, and 106 cm wide). Visual stimuli were projected onto a white screen via a slide projector from behind the stage. A white projection screen was on the stage behind a sheet of black foam core. There were two 18 × 18 cm windows cut into the cardboard. There was 11 cm of separation between the two windows, which were centered approximately 75 cm from the infants’ eye level. Auditory stimuli were presented through a central speaker hidden 56 cm below of the screen. Infants were videotaped through a 3-cm hole in the stage located 12 cm below the projection screens.

Procedure

The novelty-preference task included a familiarization phase and a test phase (see Figure 1). All infants saw the same visual stimuli materials (either dinosaurs or fish). What differed was the accompanying audio: Infants were randomly assigned to either the word or the tone condition. Parents were instructed not to influence their infant’s attention in any way and to close their eyes during test trials.

Familiarization phase. Infants were presented with a sequence of eight different exemplars from a single category (either dinosaurs or fish). The category used was counterbalanced across both word and tone conditions. In the word condition, infants heard a naming phrase as they viewed the stimuli; in the tone condition, infants heard a sequence of pure tones. In both conditions, the auditory stimulus was introduced once at the onset of the visual stimulus and again 10 s after the onset of the visual stimulus. The trials were a fixed duration of 20 s, and the order of presentation was randomized across participants. The position of the image alternated sides from trial to trial. The following factors were counterbalanced across participants: left/right position of the first image, use of toma/modi or 400/800 Hz, and familiarization to a picture of a dinosaur or a fish.

Test phase. All infants saw the same two test stimuli: a new exemplar from the familiar category and an exemplar from a novel category. These were presented side by side in silence. The test phase began with the infants’ first visual fixation to one of the stimuli and lasted until the infant had accumulated 10 s of looking to the test stimuli. The left–right positioning of the test stimuli was counterbalanced across infants.

Coding. Trained observers, blind to the condition assignment, coded infants’ visual fixations online. Later, off-line frame-by-frame coding to determine left and right looks was conducted using ELAN (2007). Thirty-three percent of infants in each age and condition were recoded by an

Test

Figure 1. A representation of the procedure and stimuli for both the word and tone conditions.
Note. In familiarization trials, infants saw eight different line drawings of dinosaurs (or fish). Each dinosaur was accompanied by either a voice saying "Look at the *toma*! Do you see the *toma*?" (word condition) or a series of pure tones (tone condition). During test trials, infants saw a dinosaur and a fish and coders measured how long each infant looked at each image.

independent observer. Reliability between observers was 91% during familiarization and 90% during test.

To measure categorization, a preference score was calculated for each infant by dividing their looking time to the novel-category exemplar at test by their total looking time (10 s). Chance performance was .50. Six 3-month-olds (three in each condition) looked exclusively to one test stimulus. Because we were uncertain whether these infants noticed the other test stimulus, we presented a second test trial and used their performance on this trial to calculate a preference score. We obtain the same results (see below) whether we include these preference scores for these infants or exclude their data entirely.

Preliminary analyses revealed no significant effect of sex, the specific word or tone used during visual stimuli, or left or right position of the test stimuli; the data were therefore collapsed across these variables in subsequent analyses.

Results

The results, depicted in Figure 2, reveal that words and tones have distinct effects on object categorization. Importantly, infants hearing words and tones accumulated comparable looking durations during familiarization, yet only those hearing words revealed evidence of categorization at test.

An analysis of performance during familiarization revealed no differences in infants' looking times in the word condition (*M* = 114.51, *SD* = 20.85) and tone condition (*M* = 118.28, *SD* = 22.28). A univariate analysis of variance (ANOVA) with total looking time during familiarization as a dependent variable and age (3 or 4 months) and conditions (word or tone) as between-subject variables confirmed that there were no significant main effects, $Fs(1, 42) < 1$, or interaction, $F(1, 42) = 2.94$, $p = .09$. This suggests that the words and tone sequences presented in this experiment were equally engaging to our young participants. Importantly however, differences between these conditions did emerge at test.

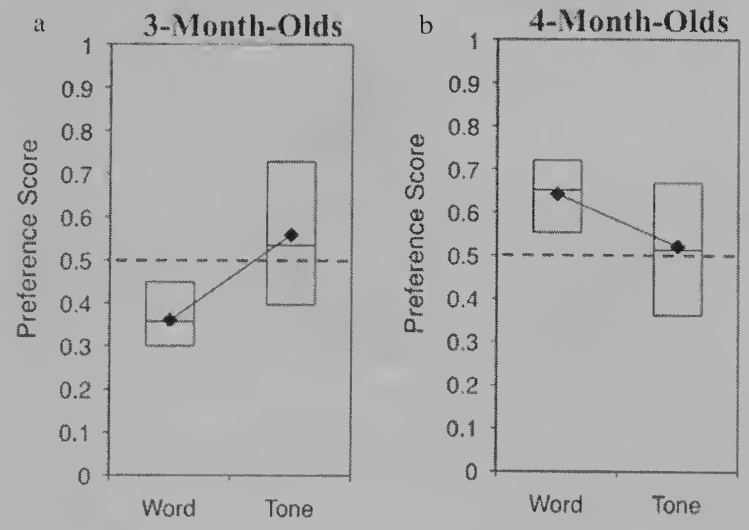

Figure 2. Box plots for mean looking times during test trials for each condition. (a) Preference score for 3-month-olds in the word and tone conditions. (b) Preference score for the 4-month-olds in the word and tone conditions.

Note. Preference score is the looking time to the novel-category exemplar divided by the total looking time. The diamonds represent the mean, the central line in the box is the median, and the upper and lower portions of the box represent the first and third quartiles on either side of the mean. The dotted line represents a chance score.

An Age (3 or 4 months) × Condition (word or tone) ANOVA using infants' preference scores at test as a dependent variable revealed no main effects, but it did reveal a significant Age × Condition interaction, $F(1, 42) = 6.08$, $p = .018$, $\eta^2 = .126$. Further analyses revealed that 3- and 4-month-old infants performed comparably in the tone condition, $F(1, 22) = 0.08$, $p = .78$; at neither age did performance with tones differ from the chance level: 3-month-olds ($M = 0.56$, $SD = 0.24$), $t(11) = .84$, $p = .42$, and 4-month-olds ($M = 0.53$, $SD = 0.22$), $t(11) = .50$, $p = .63$. In contrast, infants' performance in the word condition varied reliably as a function of age, $F(1, 20) = 12.40$, $p = .002$, $\eta^2 = .38$: Three-month-olds showed a reliable preference for the familiar test object ($M = 0.36$, $SD = 0.14$), $t(9) = -3.14$, $p = .01$, and 4-month-olds showed a reliable preference for the novel ($M = 0.64$, $SD = 0.22$), $t(11) = 2.27$, $p = .04$.

An examination of individual infants' performance echoed this pattern of results. We tabulated the number of infants at each age and in each condition demonstrating either a novelty or a familiarity preference and compared these to the number expected by the binomial distribution. In the word condition, nine of the ten 3-month-old infants showed a familiarity preference, and ten of the twelve 4-month-old infants showed a novelty preference (both *p* values < .05). In the tone condition, five of the twelve 3-month-old infants showed a familiarity preference, and seven of the twelve 4-month-old infants (both *p* values > .7) showed a novelty preference.

These results reveal that by 3–4 months of age, presenting infants with words influences object categorization in a way that presenting them with tones does not. Moreover, this influence is expressed as a familiarity preference at 3 months but as a novelty preference at 4 months. To better understand this shift from familiarity to novelty preferences, we examined the correlation between performance in this task and age (in days). For infants in the word condition, there was a strong positive correlation between age and performance, $r(22) = .61$, $p = .003$ (see Figure 3). For those in the tone condition, there was no corresponding correlation, $r(24) = -.18$, $p = .41$.

This developmental shift from familiarity to novelty preference, although unanticipated in the context of the current experiment, is not unprecedented in the infant categorization literature. Both novelty and familiarity preferences are indices of categorization. Roder, Bushnell, and Sasseville

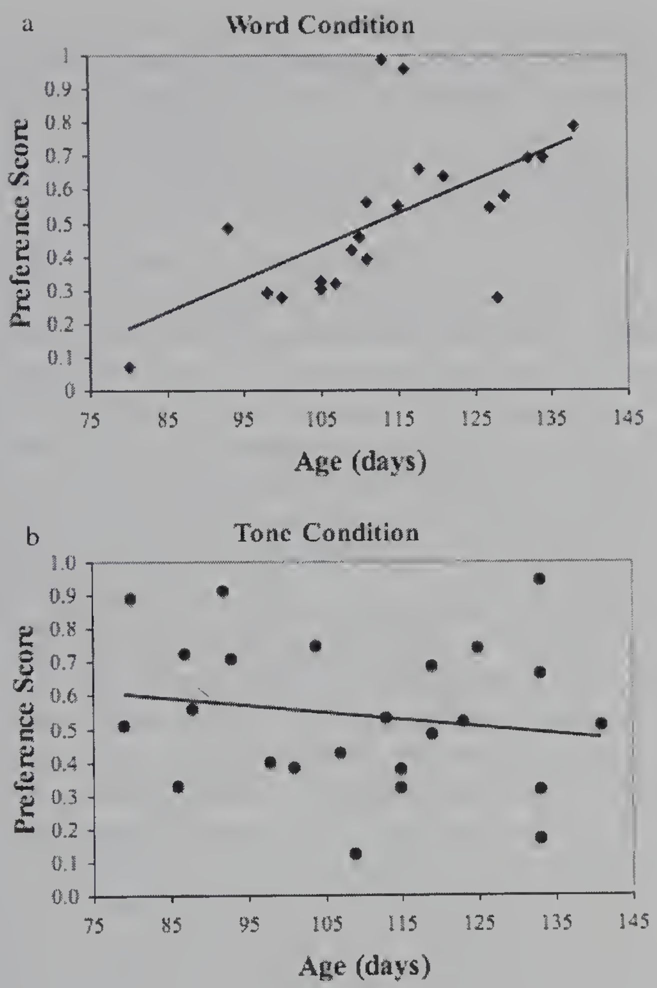

Figure 3. Scatter plot depicting the correlation between each infant's age (in days) and their preference scores. (a) Word condition. (b) Tone condition.
Note. The lines represent the best fit of the correlation between age and preference score within each condition.

(2000) found that this shift in preference was due to the amount of exposure infants had accumulated; infants first demonstrated a reliable familiarity preference prior to expressing a novelty preference. Interpreted in this light, the current results suggest that for 3-month-olds in the word condition, the process of categorization is indeed underway (after all, their performance differed significantly from chance) but that they may require more exposure before they shift from a familiarity to a novelty preference (Roder et al., 2000; Rose, Gottfried, Melloy-Carminar, & Bridger, 1982; Wagner & Sakovits, 1986). If this interpretation is correct, then perhaps 4-month-olds in the word condition who happen to accrue little looking time during familiarization materials should reveal a familiarity preference as well.

To test this possibility, we conducted a post hoc analysis on the twelve 4-month-old infants (five in the word condition, seven in the tone condition) who had been eliminated from the previous analyses because they accrued too little exposure to the familiarization images (recall that for the previous analyses, we excluded infants who looked for less than 50% of the familiarization trials). Performance in the tone condition was unaffected by exposure. These tone condition infants, like those in the main analyses, did not differ significantly from chance, (M = 0.42, SD = 0.22), $t(6) = -.99$, $p = .36$. In contrast, 4-month-olds in the word condition showed a significant familiarity preference (M = 0.35, SD = 0.07), $t(4) = -3.72$, $p = .008$. This is consistent with our interpretation of the shift from a familiarity to a novelty preference at 3 and 4 months, respectively: For the stimuli presented here, infants' expression of a familiarity versus novelty preference at test is related to their exposure during familiarization.

Discussion

The results demonstrate that words influence object categorization at 3 and 4 months, and do so in a way that is distinct from the influence of carefully matched tones. This study makes two primary contributions. First, it offers the earliest evidence to date for a link between words and object categories. While previous studies have demonstrated this link in infants as young as 6 months (Fulkerson & Waxman, 2007), the current findings offer insight into the origins of this ability in 3- and 4-month-old infants. Second, these results indicate that even at this early developmental moment, words exert an influence on object categorization that is distinct from that of tones (Balaban & Waxman, 1997; Fulkerson & Haaf, 2003; Fulkerson & Waxman, 2007; Waxman & Booth, 2003; Waxman & Braun, 2005; Waxman & Markow, 1995; Woodward & Hoyne, 1999; Xu, 1999, 2002).

This finding, intriguing in and of itself, also calls into question the claim that the facilitative effect of words can be accounted for entirely by appealing to matters of paired associations. In the current experiment, the tones as well as the words were correlated perfectly with the visually presented objects. If the categorization effect could be attributed to nothing more than an association between auditory and visual stimuli (e.g., Robinson & Sloutsky, 2007), then infants should have performed comparably, whether they heard words or tones. The fact that they did not serves as evidence that words exert an influence that cannot be accounted for entirely by association, even in infants as young as 3 months of age.

The current results also make important contact with evidence of infants' categorization behaviors.

The classic behavioral index of category formation in infants rests on their treatment of novel versus familiar test stimuli. Previous evidence concerning the link between words and object categorization in infants at 6, 9, and 12 months of age has consistently revealed a preference for the novel test stimuli (Balaban & Waxman, 1997; Fulkerson & Waxman, 2007). In the experiment reported here, 4-month-olds display this novelty preference, but 3-month-olds reveal a familiarity preference. As we have pointed out, familiarity and novelty preferences are both indices of object categorization (Aslin, 2007; Roder et al., 2000). For example, Roder et al. (2000) demonstrated that infants tend to exhibit a familiarity preference early in processing followed by a novelty preference in subsequent trials. The mechanism underlying the expression of novelty versus familiarity preferences is not well understood, but several hypotheses have been advanced. For example, some have argued that familiarity preferences are the result of incomplete encoding (Hunter & Ames, 1988; Roder et al., 2000; Rose et al., 1982; Wagner & Sakovits, 1986) or that subcomponents of fully encoded stimuli can trigger recognition responses for familiarity that are stronger than attention response to novelty (Kaplan & Werner, 1987). Others have suggested that factors including maturity, processing speed, and encoding efficiency are involved (Colombo, 2002; Johnson, Slemmer, & Amso, 2004). The absence of an independent assessment for these confounded cognitive processes makes it impossible to predict familiarity or novelty effects, although the consensus among infancy researchers is that both effects are behavioral indices of category formation. Future studies may pursue this issue by systematically varying exposure to the words, the visual stimuli, or to both over the course of familiarization.

The current findings also raise questions about the range of auditory stimuli that promote categorization at 3 and 4 months of age. We have documented that novel words (presented as nouns) promote categorization in a way that tones do not. In future work, it will be important to identify which auditory features, present in the word condition but absent in the tone condition, might underlie this effect. It will also be important to ascertain which other complex sounds (e.g., backward speech, filtered speech) also promote categorization in young infants and whether this facilitative effect is specific to human vocalizations.

It will also be important to understand better the mechanism underlying the facilitative effect of words on categorization at 3 and 4 months. As we have pointed out, it is unlikely that infants in the current experiment parsed the novel words from the labeling phrases in which they were embedded; it is also unlikely that they somehow understood the meaning of the words and phrases we presented. Why, then, did words promote categorization over and above the effect of tone sequences? We speculate that in the context of hearing human speech, very young infants become engaged in attentional and behavioral processes that they might otherwise not engage in. An analogy may illustrate this point. Recent research has documented a dramatic influence of vocalizations on the behavior of Nile crocodile hatchlings and mothers. Under naturalistic conditions, the vocalizations made by hatchlings just before they hatch can be heard by mothers and by hatchlings in neighboring eggs in the nest. In an ingenious experiment, Vergne and Mathevon (2008) presented hatchlings and mothers with recordings of the vocalizations emitted by other hatchlings just before they had hatched. These recordings had very specific behavioral effects; they motivated hatchlings to tap on their shells and mothers to open their nests. Obviously, it is unlikely that these vocalizations exerted their effects because of the "meaning" they conveyed to mothers and other hatchlings. Instead, exposure to these vocalizations appears to have engendered a series of behaviors that happen to promote hatching and nesting. How does this analogy bear on infants' performance in the current experiment? We suspect that human speech, and perhaps especially infant-directed speech, engenders in young infants a kind of attention to the surrounding objects that promotes categorization. We proposed that over time, this general attentional effect will become more refined, as infants begin to cull individual words from fluent speech, to distinguish among individual words and kinds of words, and to map those words to meaning. A goal for future research will be to identify the processes underlying this developmental trajectory.

The Complex Relation Between Bullying, Victimization, Acceptance, and Rejection: Giving Special Attention to Status, Affection, and Sex Differences

René Veenstra, Siegwart Lindenberg, Anke Munniksma, and Jan Kornelis Dijkstra
University of Groningen

To understand the complex nature of bullies' acceptance and rejection, this article considered goal-framing effects of status and affection as they relate to the gender of the bully (male vs. female bullies), the target (male vs. female victims), and the evaluator (acceptance and rejection from male vs. female classmates). The hypotheses were tested with data from a social network questionnaire conducted in 26 elementary school classes (N = 481 children; M_{age} = 10.5 years). The findings revealed that bullies were only rejected by those for whom they were a potential threat and that bullies generally chose their victims so as to minimize loss of affection by choosing victims who were not likely to be defended by significant others.

Bullying is a common phenomenon in school classes. In this study, we try to clarify the complex relations of bullying with acceptance and rejection. Because peer processes, especially in childhood and early adolescence, often show gender segmentation, we are interested in whether bullying toward same-gender classmates has the same effect on peer acceptance and rejection as bullying toward other-gender classmates. We argue that besides taking the gender of the bully (male vs. female bullies) into account, we should also take the gender of the target (male vs. female victims) and the evaluator (acceptance and rejection by male vs. female classmates) into account to explain the relation between bullying, victimization, and peer status. The following questions will be examined: How are bullying and victimization related to peer status among same-gender and other-gender classmates? Is bullying toward same-gender classmates differently related to status than bullying toward other-gender classmates? And how is this for victimization by same-gender or other-gender classmates?

Theoretical Elaboration

In the goal-framing approach, focal goals are hypothesized to influence what people attend to, what knowledge is being activated, how people evaluate things, and how they process information (Lindenberg, 2006). People are aware of aspects in the situation that potentially help or hinder their goal pursuit, and they positively evaluate (like) the former and negatively evaluate (dislike) the latter. Liking and disliking are thus the result of different goal-related processes. This goal-framing approach has recently been applied to questions of acceptance and rejection (Dijkstra, Lindenberg, & Veenstra, 2007), to questions concerning who bullies whom (Veenstra et al., 2007), and to the role of popular adolescents in bullying (Dijkstra, Lindenberg, & Veenstra, 2008).

When studying interactions among children, what goals should be considered? Status and affection goals have frequently been identified as important for all human beings (Barkow, 1989; Baumeister & Leary, 1995; Huberman, Loch, & Önçüler, 2004; Ormel, Lindenberg, Steverink, & Vonkorff, 1997). Although we do not measure these goals directly, we have good evidence for their importance. Pendell (2002) has reviewed much literature that shows affection to be a universal need. The evolutionary and developmental importance of affection has also been shown (MacDonald, 1992). Status has also been established as a universal goal (Barkow, 1989; Huberman et al., 2004), and the importance of this goal for bullying has recently been directly assessed (see Sijtsema, Veenstra, Lindenberg, & Salmivalli, 2009). Both goals are prominent in childhood and preadolescence as well

(Buhrmester, 1990; Hawley, 2003; Jarvinen & Nicholls, 1996; Oldehinkel, Rosmalen, Veenstra, Dijkstra, & Ormel, 2007). Thus, it seems to be a safe assumption that bullies, like other human beings, want to realize status *and* affection.

Given these goals, the crucial aspect of the pursuit of status is that it is conditioned by the pursuit of affection. People want both status and affection and are not eager to forego one for the sake of the other (Lindenberg, 2001). For bullying this means that children who want to dominate will be keenly aware of opportunities to do so without risking loss of affection from significant others (O'Connell, Pepler, & Craig, 1999). Thus, bullies (i.e., instrumental and not reactive bullies) can be expected to strategically choose victims who are already rejected (disliked) by significant others in the class. Bullies are likely to divide the classroom into potential sources of affection (significant others) and potential sources of domination (victims for whom the significant others do not care). For children, the significant others are likely to be same-gender classmates (Dijkstra et al., 2007; Maccoby, 1998; Martin & Halverson, 1981). Thus, bullies can also be expected to desire to be accepted by the significant same-gender classmates and not to care much about rejection by the rest (Olthof & Goossens, 2008).

Bullies thwart the goal pursuit of victims and, on the basis of goal-framing theory, can be predicted to be rejected by their victims and by others for whose goal pursuit they are a potential threat. From this follows our first set of hypotheses (on selective threat and rejection). We expect that the rejection of bullies will only come from the gender to which the victim belongs: (1a) Bullying same-gender classmates is related to being rejected by same-gender classmates only. (1b) Bullying other-gender classmates is related to being rejected by other-gender classmates only.

With regard to affection, goal-framing theory predicts that male bullies are likely to strategically choose victims who pose a minimal risk for a loss of affection: those boys who have low acceptance among boys (i.e., they are not important for affection) and are rejected by boys. Considering that children rarely have best friends in the other-gender group, we argue that for boys it is slightly different to bully girls: Male bullies are likely to choose those girls as victims who are rejected by boys (liking is not an issue here). For female bullies, we expect the converse: Female bullies are likely to choose those boys as victims who are rejected by girls. There is no a priori reason to assume that for them the two goals work differently, although there will be fewer girls for whom domination is a prominent goal (Espelage, Mebane, & Adams, 2004; Hanish & Guerra, 2004).

From the foregoing, we can deduce our second set of hypotheses (on bullying and the avoidance of loss of affection). We expect that bullies will avoid loss of affection by choosing victims that are not cared for by significant others: (2a) If children bully same-gender classmates, they will focus on those potential victims who are rejected by and have low acceptance from the bullies' same-gender classmates. (2b) If children bully other-gender classmates, they will focus on those potential victims who are rejected by the bullies' same-gender classmates. (2c) There will be no negative relation between being a bully and the level of acceptance from boys and girls (bullies do not lose affection). If all these hypotheses are supported by the data, it will be likely that it is indeed avoidance of loss of affection that drives the results.

Note that the hypotheses contain different sources of acceptance and rejection. In theory, victims have low acceptance and are already rejected *before* being bullied. Choosing these victims is part of the bully's strategy to avoid loss of affection, in particular from same-gender classmates. Bullies are rejected if they pose a threat. Given the gender segmentation of children, they are expected to be rejected by members of the gender of the victim and ignored by the rest.

Method

Sample

Network questions on bullying and victimization were collected in middle and late elementary education (Grades 5–8 in the Netherlands). The sample yielded 481 children from 26 classrooms (23 for regular and 3 for special education): 218 girls (45.3%) and 263 boys (54.7%), with a mean age of 10.5 years ($SD = 1.5$). The mean class size was 19.4 children ($SD = 4.4$). Schools were situated in both rural and (sub)urban areas. The percentage of children with parents with a low educational level, at maximum a certificate of secondary vocational education, was 16.9%. The percentage of children from ethnic minorities (of whom at least one parent was born outside the Netherlands) was 18.7%.

Procedure

Data were collected from October 2005 to March 2007. After parental consent was obtained, children filled out the questionnaires in the school class, under the supervision of a well-trained research assistant. Ninety-seven percent of all children participated in the study. The dyadic peer-nomination assessment took place at school. The number of nominations the children could make was unlimited (they were not required to nominate anyone), and same-gender as well as other-gender nominations were allowed.

Measures

Peer acceptance and rejection. The numbers of nominations children received individually from their same- and other-gender classmates with regard to "best friends" and "dislike" were used to create measures of same- and other-gender peer acceptance and peer rejection. After the numbers of received nominations had been summed, proportions were calculated to take differences in the number of respondents per class into account, yielding scores from 0 to 1 (see Veenstra et al., 2007, for more information on this dyadic peer nomination procedure).

Bullying and victimization. The term *bullying* was defined to the students in the way formulated in the Olweus's (1996) Bully/Victim Questionnaire, which emphasizes the repetitive and intentional nature of bullying and the power imbalance between the bully and the victim. Several examples covering different forms of bullying were given. In addition, examples of behaviors that should not be considered as bullying (teasing in a friendly and playful way, fighting between children of equal strength) were also provided.

The numbers of nominations children received individually from their same- and other-gender classmates with regard to different forms of bullying and victimization were used to create measures of same- and other-gender bullying and victimization. We asked "who do you bully by . . . ?" and "by whom are you bullied by . . . ?" using five forms of bullying and victimization: (a) excluding or ignoring; (b) calling names or laughing; (c) hitting, kicking, or pinching; (d) taking things; (e) throwing things. There were no clear differences in the association of the different forms of bullying and victimization with peer status. For that reason, we combined the different forms in highly reliable scales for bullying and victimization (Cronbach's alphas = .89 and .87, respectively).

Table 1
Means and Standard Deviations of Peer Status, Bullying, and Victimization for Boys (N = 263) and Girls (N = 218)

	Boys	Girls
Acceptance by boys	.393 (.203)	.110 (.121)
Acceptance by girls	.110 (.142)	.474 (.250)
Rejection by boys	.119 (.160)	.163 (.183)
Rejection by girls	.267 (.250)	.091 (.142)
Bullying toward boys	.065 (.083)	.034 (.051)
Bullying toward girls	.064 (.092)	.035 (.053)
Victimization by boys	.041 (.070)	.032 (.057)
Victimization by girls	.023 (.045)	.022 (.053)

Analyses

We tested our hypotheses with multivariate analyses using cross-sectional data. Because both acceptance and rejection deviated from normality, we conducted regression analyses with the Tobit model, which accounts for violations of normality of the dependent variables (Long, 1997; Smith & Brame, 2003; Tobin, 1953). The regression analyses included main effects of gender, bullying toward boys and toward girls, victimization from boys and from girls, and (the significant) interaction effects between gender and either bullying or victimization. The effects for girls are equal to the main effects in Tables 2 and 3, but the effects for boys are the sum of the main and interaction effects (Aiken & West, 1991). All continuous variables were standardized for the whole sample ($M = 0$, $SD = 1$). Finally, we examined whether the effects differed by age.

Results

Table 1 shows that same-gender classmates were more accepted and less rejected than other-gender classmates by both boys and girls. Furthermore,

Table 2
Multiple Regression Analyses on Peer Rejection and Its Relation to Bullying and Victimization (N = 481)

	Peer rejection by boys	Peer rejection by girls
Gender (1 = boys)	−.77 (.18)**	.94 (.19)**
Bullying toward boys	.74 (.15)**	.36 (.15)*
Bullying toward girls	−.03 (.11)	.37 (.09)**
Victimization by boys	.35 (.06)**	.15 (.11)
Victimization by girls	.16 (.09)†	.18 (.06)**
Gender × Bullying Toward Boys	−.38 (.14)**	−.33 (.19)†
Pseudo R^2	13.8%	15.9%

$^{*}p < .05$. $^{**}p < .01$.

boys were more rejected than girls. Table 1 also shows that boys were more often nominated than girls as perpetrators of bullying toward both boys and girls.

Testing the Selective Threat Hypotheses

The multivariate analyses are depicted in Tables 2 and 3. Let us first turn to the selective threat hypotheses about the rejection of bullies. As hypothesized, boys bullying boys are only rejected by boys, $b = .36$, $t(480) = 2.78$, $p < .01$, and not by girls, $b = .03$, $t(480) = 0.30$, $p = .76$. If boys bully girls, they are only rejected by girls, $b = .37$, $t(480) = 4.10$, $p < .01$, and not by boys, $b = -.03$, $t(480) = -0.33$, $p = .75$.

For girls, the selective threat hypotheses are similarly supported by the data: Girls who bully girls are rejected by girls, $b = .37$, $t(480) = 4.10$, $p < .01$, and girls who bully boys are rejected by boys, $b = .74$, $t(480) = 5.10$, $p < .01$.

Testing the Avoidance of Loss of Affection Hypotheses

With regard to avoidance of loss of affection for boys, we see from Table 2 that victims of male bullies are indeed rejected by boys only, $b = .35$, $t(480) = 6.05$, $p < .01$, and victims of female bullies are rejected by girls, $b = .18$, $t(480) = 2.92$, $p < .01$.

From Table 3, we see that male victims have a low level of acceptance among boys, $b = -.31$, $t(480) = -3.91$, $p < .01$. Among girls, female as well as male victims have a low level of acceptance, $b = -.17$, $t(480) = -2.02$, $p = .04$.

On the whole, there is, as predicted, no negative relation between bullying and acceptance. Girls even seem to welcome boys who bully boys: acceptance, $b = .22$, $t(480) = 1.93$, $p = .05$. There is one exception, though: Girls who bully boys have a low level of acceptance by both genders (see Table 3), acceptance by boys, $b = -.46$, $t(480) = -2.50$, $p = .01$, and by girls, $b = -.28$, $t(480) = -1.99$, $p = .05$.

Differences Between Middle Childhood and Preadolescence

Given the age range, we controlled for age and examined whether the results differed for middle childhood and preadolescence (median split at 10.45 years). Age had no main effect on acceptance and rejection. Only the results for peer acceptance by boys showed age differences. Girls bullying boys was more strongly related to low levels of male acceptance in middle childhood, $b = -.67$, $t(480) = -3.49$, $p < .01$, than in preadolescence, $b = -.35$, $t(480) = -1.96$, $p = .05$. Bullying girls was positively related to male acceptance in middle childhood, $b = .29$, $t(480) = 3.58$, $p < .01$, but negatively in preadolescence, $b = -.17$, $t(480) = -2.19$, $p = .03$. Victims of female bullies had low levels of male acceptance in middle childhood, $b = -.23$, $t(480) = -2.62$, $p < .01$, but not in preadolescence.

Discussion

Bullies and victims are not equally disliked. To understand the complex nature of bullies and victims' acceptance and rejection for children in middle and late elementary education, we considered goal-framing effects of status and affection as they relate to the gender of the bully (male vs. female bullies), the target (male vs. female victims), and the evaluator (acceptance and rejection from male vs. female classmates).

Our first set of hypotheses dealt with bullying as a selective threat to goal pursuit. We hypothesized that bullies would only be rejected by those for whom they were a potential threat, and this bore out. Bullies, whether male of female, were indeed rejected by the gender to whom the bullying was directed but not by the gender to whom it was not directed.

Our second set of hypotheses dealt with the bullies' avoidance of loss of affection by choosing victims that were not cared for by significant others. We predicted that bullies focus strategically on those potential same-gender victims who were rejected by and had low acceptance from same-gender classmates. For potential other-gender victims we hypothesized that children would focus on those who were rejected by the bullies' same-gender classmates. We found that victims of male bullies were indeed rejected by boys only and that male bullies were never low on acceptance. Thus, as expected, boys seem to choose their victims so as to minimize loss of affection.

Girls victimized by girls were rejected and unaccepted by girls, as goal-framing theory had predicted. However, girls who bullied boys lost acceptance and were more rejected by both genders. We have no way of saying whether this latter finding is specific to the data we used or whether it can be replicated in other studies. Girls do not frequently bully boys, but if they do they might do so because they have lost strategic control through habituation of aggression and the ensuing desensitization to its consequences (Guerra, Huesmann, & Spindler, 2003). The important point of this article is that for the vast majority of bullies, the pursuit of status *and* affection seems to foster strategic control of bullying behavior: realize one without losing the other.

There were age differences in the relation of bullying and victimization with peer acceptance by boys. Bullying toward girls was positively related to male acceptance in middle childhood, but negatively in preadolescence. Furthermore, victims of female bullies had low levels of male acceptance in middle childhood, but not in preadolescence. It might be that boys perceive cross-gender bully–victim relationships less negatively when they enter preadolescence because they become more interested in girls and may see this interaction with girls as attention (Adler & Adler, 1998; Maccoby, 1998; Pellegrini & Bartini, 2001).

There was one circumstance in which bullying was significantly positively associated with acceptance (cf. Luthar & McMahon, 1996; Salmivalli, Kaukiainen, & Lagerspetz, 2000): Male bullying of same-gender classmates was positively related to female acceptance. Again, at least for some girls, boys might have already become romantically important, with bullying fitting into a prototypical mold of being male. It should be noted, however, that the female acceptance of male–male bullying did not vary by age. Thus, older girls were not more likely to welcome male–male bullying. Yet, with regard to rejection, the selective threat effect could be observed here as well: Male bullying of girls was positively related to female rejection. By distinguishing the targets' gender, we could make clear that the evaluation of bullying depends on whether the bullying is perceived as a threat. Our findings also show that avoidance of loss of affection depends on the gender of the bully and the target.

In line with Dijkstra et al. (2007), we found that acceptance and rejection are not tied to the same process. For example, male bullying was positively related to peer rejection by the gender to which the victim belonged, but not negatively to peer acceptance. We also found that the explained variance for acceptance (about 20%) was higher than the explained variance for rejection (about 15%). It is likely that this difference is due to the fact that in preadolescence gender plays a larger role in the realization of interaction goals (and thus peer acceptance) than in disturbance or threat of disturbance of goal pursuit (and thus peer rejection). As can be seen from the multivariate analyses, gender is the factor that explains acceptance and rejection the most, but acceptance to a larger extent than rejection. The goal-framing approach also throws light on the question when behavior of the other gender will be met by positive or negative evaluation and when it will be ignored (Dijkstra et al., 2007). It depends on the contribution that a particular reaction from the other gender will make for the realization of affection and status goals.

Strengths and Limitations

Our study had a number of strengths and limitations. One strength is the elaboration of the complex nature of acceptance and rejection related to bullying. Another strength is the inclusion of boys' and girls' nominations for peer status, bullying, and victimization, each with dyadic same-gender and other-gender nominations. A strong point is also the relatively large sample. We used a sample of almost 500 children, including a proportional number of boys and girls. In view of this sample size and the use of network questions, the findings can be considered rather robust.

However, it should be taken into account that a cross-sectional correlational design was used. Even though the hypotheses derived from the goal-framing approach were supported by the results, these associations are not determinant. Ultimately, the relation between same-gender and other-gender bullying, victimization, and peer status should be tested with longitudinal data. Bidirectional influences between bullying and peer relations (Cillessen & Mayeux, 2004) would fit well into the approach taken here. Classmates who are not accepted might be even less accepted when they are bullied because victimization is likely to lower their status. Being associated with them might lower one's own status and, for this very reason, may make one more vulnerable for becoming a victim oneself (Hodges, Boivin, Vitaro, & Bukowski, 1999).

In sum, the complex nature of acceptance and rejection can be traced quite well by hypotheses derived from goal-framing theory and the assumed simultaneous pursuit of status and affection. We found that bullies are not rejected in general, but only by those for whom they are a potential threat. Bullies seem to choose their victims so as to minimize loss of affection. To this end, they are likely to bully victims that are rejected by their same-gender classmates. To understand these processes it is necessary to distinguish the gender of the bully (male vs. female bullies), the gender of the target (male vs. female victims), and the gender of the evaluator (male vs. female classmates who accept and reject bullies and victims).

This study examined the associations of 11 discipline techniques with children's aggressive and anxious behaviors in an international sample of mothers and children from 6 countries and determined whether any significant associations were moderated by mothers' and children's perceived normativeness of the techniques. Participants included 292 mothers and their 8- to 12-year-old children living in China, India, Italy, Kenya, Philippines, and Thailand. Parallel multilevel and fixed effects models revealed that mothers' use of corporal punishment, expressing disappointment, and yelling were significantly related to more child aggression symptoms, whereas giving a time-out, using corporal punishment, expressing disappointment, and shaming were significantly related to greater child anxiety symptoms. Some moderation of these associations was found for children's perceptions of normativeness.

The study of parents' disciplinary practices has been central to developmental psychology for at least the last half century, tracing back to Sears, Maccoby, and Levin's (1957) landmark book, *Patterns of Child Rearing*. Their study of several hundred White working- and middle-class parents in and around Boston in the 1950s provided the first detailed data on what discipline techniques parents use, why they use them, and how discipline is linked with children's behaviors. Theirs was one of the first studies to document that, contrary to predictions that controlling parents would have better behaved children, in fact the opposite was true. In the ensuing 50 years, researchers have taken these same themes and tested relations among them in increasingly sophisticated models. What the field has not done consistently is to expand the populations of interest beyond families in the United States, or, in many cases, beyond White, middle-class parents.

The overreliance on children and parents from North America in research on parenting has led to the criticism that the theories and recommendations developed from North American samples are not universal (as they are often assumed to be) and may not apply to parents and children in other

countries and cultures (Dasen & Mishra, 2000; Rogoff, 2003). Cultures differ in the value they place on different child qualities and behaviors and in their beliefs about which parenting practices will promote these qualities and behaviors (Bornstein, 1995; Mistry, Chaudhuri, & Diez, 2003; Ripoll-Nuñez & Rohner, 2006; Super & Harkness, 1986). Cultures also differ in their evaluations of what parenting practices are considered to be either physically or emotionally abusive (Korbin, 2003).

Links between cultural values and parents' preferred childrearing practices have indeed been documented. A study of mothers in China and India found that differences in the two groups' use of authoritative and authoritarian parenting practices were related to relative differences in their valuing of goals of social emotional development and honor of the family (Rao, McHale, & Pearson, 2003). An analysis of ethnographies from 186 preindustrial societies found corporal punishment to be most likely among societies high in social stratification, political integration, long-term use of an alien currency, undemocratic political decision making, and a culture of violence (Ember & Ember, 2005). Parents in countries with more collectivist orientations, such as China, tend to emphasize the importance of behavioral inhibition and subjugation of individual wants for the good of the family, whereas parents in Western individualist cultures typically value assertiveness and independence in their children (Rothbaum, Morelli, Pott, & Liu-Constant, 2000).

Much of the research on discipline to date, both domestically and internationally, has focused on parents' use of corporal punishment, most likely because corporal punishment is a controversial form of discipline (Gershoff, 2002). However, corporal punishment is but one of many disciplinary techniques parents use in trying to control their children's negative behavior and promote their positive behavior. Although there is great variation in usage, with some parents using it everyday and some never using it, American parents tend to report using corporal punishment relatively rarely, peaking at one and a half times per month when children are 2 years old and decreasing to less than once per month by the time children are 12 years old (Straus & Stewart, 1999). In a recent longitudinal study of parents' use of 10 different disciplinary tactics, corporal punishment was one of the three least common techniques used by parents of preschoolers (Socolar, Savage, & Evans, 2007). Most common were monitoring child behavior, talking with children, distracting, and modeling.

In order to understand parental discipline we must expand our focus to the full range of parents' disciplinary techniques, particularly those they use more frequently than corporal punishment. There is very little research on the broad array of parental discipline techniques that are used in non-U.S. countries. The theories behind whether various discipline techniques should or should not be effective in promoting appropriate child behavior have largely been developed by researchers in North America (e.g., Bornstein, 1995; Dodge & Pettit, 2003; Grusec & Goodnow, 1994; Hoffman, 1983; Lepper, 1983). Whether parents in other countries differ in their preferences for disciplinary techniques and whether these techniques have similar associations with child behavior across countries remain open questions.

One reason discipline techniques may not have similar effects on children across countries is that the effects may depend on the extent to which the techniques are normative within a culture (Deater-Deckard & Dodge, 1997). When children perceive a discipline technique to be normative within their culture or community, they may be less likely to evaluate their parents' use of it as aberrant or objectionable. Discipline is most likely to be effective when children perceive it to be fair and reasonable (Grusec & Goodnow, 1994); if children believe the discipline they received to be out of the range of what their peers receive, they will reject and thus fail to internalize the parents' intended disciplinary message. Discipline that is perceived by children to be nonnormative is likely to be ineffective in promoting appropriate child behavior and may inadvertently lead to increases in problematic child behavior.

Parents' perceptions regarding the normativeness of the techniques they use may also moderate the effects of the techniques on children. When parents perceive a technique to be normative, they may feel more confident and justified in using it and thus may be more likely to use it in a planful and controlled, rather than impulsive and unregulated, manner. The planful, instrumental use of a disciplinary technique is thought to be less likely to cause fear or anxiety in children or to evoke reactive aggression from children (Holden, Miller, & Harris, 1999; Straus & Mouradian, 1998).

The Present Study

In order to advance our understanding of discipline in countries beyond the United States, we collaborated with colleagues in six understudied countries, namely, China, India, Italy, Kenya, the Philippines, and Thailand. This sample of countries was diverse on several demographic dimensions, including predominant race/ethnicity and predominant religion. They also varied on several key social and economic indicators, including: gross national income (from highest to lowest: Italy, Thailand, China, Philippines, India, and Kenya, with Italy's income 49 times as large as that of Kenya; World Bank, 2008), individualist versus collectivist social orientation (from most to least individualistic: Italy, India, Philippines, Kenya, China, and Thailand; Hofstede, 2001), and overall child well-being, indexed as the mortality rate for children < 5 years old, the underweight rate for children < 5 years old, and the percent of primary-school-aged children not enrolled in school (ranked from best to worst: Italy, China, Thailand, Philippines, Kenya, and India; Save the Children, 2008). Although Italy is first in all three of these rankings, the order of the remaining five countries is not the same for all three indicators, indicating that these countries vary from one another on multiple dimensions. By studying families from each of these countries, we created a diverse international sample with which to examine parent discipline and child behavior.

In a previous study with these data (Lansford et al., 2005), we examined the extent to which the normativeness of harsh corporal punishment (which included spanking, slapping, grabbing, shaking, and beating up) in each of the country subsamples moderated the association between frequency of harsh corporal punishment and children's aggression and anxiety symptoms. More frequent use of harsh corporal punishment was associated with more child aggression and anxiety across all six countries, but the strength of these associations was strongest in country subsamples in which harsh corporal punishment was least normative (Lansford et al., 2005).

Whether children's and mothers' perceptions of cultural normativeness play similar moderational roles for other disciplinary techniques remains unknown. Thus, for this study, we used the same international sample to address two new research questions, namely: (a) When multiple discipline techniques are considered simultaneously, which forms of discipline emerge as having the strongest associations with children's aggressive and anxious behaviors? and (b) Are any significant associations between discipline practices and child behaviors moderated by the extent to which mothers and children perceive these practices to be normative within their communities? We hypothesized that high normativeness will only moderate techniques that are most likely to be experienced as negative events by the child, namely, corporal punishment and yelling. We expected that more benign techniques, such as reasoning, will not be affected by normativeness, although we left open the possibility that less aversive forms of discipline may actually have a stronger impact on children if they are less normative and thus experienced by children as salient positive events.

Method

Participants

The sample of 292 families for this study was drawn from a complete project sample of 336 children and their mothers from seven metropolitan areas in six countries: China (Beijing), India (Delhi), Italy (Rome and Naples), Kenya (Rachuonyo District of Nyanza province), Philippines (Manila), and Thailand (Chiang Mai). Within each country, samples were recruited through public schools in neighborhoods that were identified by local contacts as primarily middle class. After permission was obtained from appropriate local authorities (e.g., principals, teachers), children and their parents were invited to participate in a study of how parents discipline children and how parents' behavior affects how children learn and grow. For a family to be eligible for inclusion in the study, both the mother and the child had to be willing to complete the interview.

Although the target age group for the study was mothers and children aged 8–12 years old, the range of ages of children who actually participated was 6–17 ($M = 10.57$, $SD = 1.86$). Because discipline techniques are used differently with children in early childhood, middle childhood, and adolescence and may have different effects depending on the developmental stage in which they are used (Collins, Madsen, & Susman-Stillman, 2002; Giles-Sims, Straus, & Sugarman, 1995), we restricted our sample for these analyses to the target age group of middle childhood (range = 8–12; $M = 10.22$, $SD = 1.30$). This restriction resulted in our sample of 292 children and their mothers (87% of the original sample) for the analyses reported here. The number of participants and percent of the children who were female in each country-level sample were: China: $n = 49$, 47% girls; India: $n = 36$, 58% girls; Italy: $n = 73$, 43% girls; Kenya: $n = 17$, 53% girls; Philippines: $n = 50$, 38% girls; and Thailand: $n = 58$, 57% girls.

Mothers ranged in age from 20 to 59 years (M = 38.66, SD = 5.87). Although there are ethnic minorities in these countries, the participants did not identify themselves as being members of any ethnic minority groups. In 95% of the cases, the biological mother was interviewed; in the remaining cases, a female adoptive parent or relative who was the child's primary caregiver was interviewed. Henceforth, we will refer to the parent respondents as "mothers." Within each country, the samples were considered primarily middle class and had similar standings in terms of within-country socioeconomic status. Mothers reported their families' annual income in local currency using ranges that reflected income distributions within a particular country. The median annual income range (converted to U.S. dollars) in each country subsample was as follows: (a) Chinese subsample median = \$2,172–\$5,796 (which may be an underestimate because it does not include bonuses that many Chinese employees earnin addition to their base salary), (b) Indian subsample median = \$13,728–\$16,464, (c) Italian subsample median = \$32,585–\$37,799, (d) Kenyan subsample median = \$1,560–\$2,352, (e) Philippines subsample median = \$3,306–\$4,404, and (f) Thai subsample median = \$3,036–\$15,180. The differences in the width of these income ranges are reflective of the, sometimes widely varying, range of incomes in the communities from which our sub-samples were drawn. Differences in relative income between countries were accounted for by our use of fixed effects models.

Procedure

All interviews were conducted in the homes of the participants by trained interviewers who were natives of the country. Most of the interviewers were graduate students in psychology and all conducted pilot trials before the actual interview. Before the formal interview began, both the mother and the child gave consent to participate in the interview. During each interview, which lasted about 1 hr, the interviewer read aloud each question individually from the printed questionnaire. Because not all participants were literate, all questions were asked orally. After each question was read, the participant verbalized or pointed to the answer on the printed questionnaire or on a separate pictorial response card and responses were recorded by the interviewer. When any participant expressed confusion about a given question, the interviewer provided only brief explanations or elaborations on it, typically consisting of paraphrasing the question only. The mother and the child were interviewed separately in different rooms or at different times so that they could not hear each other's responses. To minimize social desirability, during the course of the interviews participants were reminded that their answers would be kept confidential, that there were no right or wrong answers to the questions, and that it was important for them to answer as honestly as possible. Country-level differences in social desirability were accounted for, along with all other unmeasured differences between countries, by our use of fixed effects models in the analyses described below.

Measures

A procedure of translation and back-translation was used to ensure the linguistic and conceptual equivalence of measures across languages. The translators were fluent in English and the target language. Translators were asked to note places in the research instruments that did not translate well, were inappropriate for the age groups in the study, or were culturally insensitive. Any problems noted were resolved through discussions among the translators and investigators. Additionally, the appropriateness of the terms used to assess each form of discipline (e.g., *spank*, *slap*, or *hit*) was evaluated through qualitative interviews with a separate pilot sample of mothers in each country. English versions of the measures were administered in India and the Philippines, countries where English is an official language. Measures in the other countries were administered in Mandarin Chinese, Italian, Dholuo (Kenya), and Thai.

Maternal discipline techniques. The frequency with which mothers reported using each of 11 different types of discipline was assessed through a measure that was developed for the present study, adapted from other instruments that assess parents' discipline strategies (Deater-Deckard, Dodge, & Sorbring, 2005; Straus, 1979). The discipline questionnaires were introduced by saying, "All children misbehave sometimes. One of the things we need to learn about is what parents do to deal with their children's misbehavior. Think about when your child has misbehaved in the last year." Mothers were then asked a series of questions specific to each discipline technique, such as "How frequently do you teach your child about good and bad behavior? Like, it's not nice to hit, or it's polite to say 'thank you'." Mothers reported how frequently they used each discipline technique on a 5-point scale (1 = *never*, 2 = *less than once a month*, 3 = *about once a month*, 4 = *about once a week*, 5 = *almost every day*). The 11 discipline techniques as they were described in the interviews, listed in the order they were presented to the mothers and followed by the abbreviations we will use hereafter, were: (1) "teach your child about good and bad behavior" (*teach about good and bad behavior*); (2) "get your child to apologize or make amends" (*get child to apologize*); (3) give child a time-out or send him/-her to his/her room" (*give a time-out*); (4) "take away privileges" (*take away privileges*); (5) "spank, slap, or hit your child" (*use corporal punishment*); (6) "say you are disappointed with your child, or say that his/her misbehavior hurt your feelings" (*express disappointment*); (7) "tell your child s/he should be ashamed of her/himself" (*shame*); (8) "raise your voice, yell, or scold your child" (*yell or scold*); (9) "tell your child you won't love him/her if he/she acts that way again" (*withdraw love for misbehavior*); (10) "threaten your child with some punishment" (*threaten punishment*); and (11) "promise a treat or privilege to your child for good behavior" (*promise a treat or privilege*). Pooled sample means and country means are reported in Table 1.

Perceived normativeness of discipline techniques. Both mothers and their children were asked a question about how normative they perceived each discipline technique to be in their community. For each of the 11 techniques listed above, mothers were asked a question beginning with the stem, "How frequently do other parents in your community . . . " Similarly, children were asked a question beginning with the stem, "When kids do something wrong how often do their parents . . . " for each discipline technique. Both parents and children reported how often they thought other parents in their community used each technique according to the same scale mothers used to report the frequency with which they used each discipline technique, namely: 1 = *never*, 2 = *less than once a month*, 3 = *about once a month*, 4 = *about once a week*, 5 = *almost every day*. Mothers' and children's ratings of normativeness were significantly correlated across 10 of the 11 discipline techniques, with the significant correlations ranging from $r(273) = .13$, $p < .05$, for *teach about good and bad behavior*, to $r(274) = .46$, $p < .001$, for *give a time-out*. Mothers' and children's ratings of the extent to which other parents *get children to apologize* were the only ratings not significantly correlated, $r(275) = .02$, $p = .71$. Pooled sample means and country means for mother and child ratings of the normativeness of each discipline technique are reported in Table 1.

Child behaviors. Children's aggression and anxiety behaviors were obtained from mothers' reports using the aggression subscale (20 items) and the Anxiety/Depression subscale (14 items) of the Child Behavior Checklist (CBCL; Achenbach, 1991a). Self-reported symptoms were obtained through youth responses to the Aggression subscale (19 items) and the Anxiety/Depression subscale (16 items) of the Youth Self-Report (YSR; Achenbach, 1991b). The CBCL and YSR have been translated into at least 69 languages, and over 5,000 published studies have used these measures with at least 60 cultural groups (Achenbach, 2004; Crijnen, Achenbach, & Verhulst, 1997). The Achenbach measures have been used previously in all of the countries involved in the present study: China (e.g., Dong, Wang, & Ollendick, 2002; Guo et al., 2000), India (Gill & Kang, 1995; Shenoy, Kapur, & Kaliaperumal, 1998), Italy (Artigas, 1999), Kenya (Weisz, Sigman, Weiss, & Mosk, 1993), the Philippines (Florencio, 1988), and Thailand (Weisz, Suwanlert, et al., 1993). In the current study, both subscales had strong internal reliability for the entire sample, for mother and child reports, respectively: aggression $\alpha s = .80$, $.80$; anxiety $\alpha s = .74$, $.75$. Within-country internal consistencies for mother and child reports of aggression were: China, $\alpha s = .79$, $.80$; India, $\alpha s = .58$, $.54$; Italy, $\alpha s = .67$; Kenya, $\alpha s = .73$, $.81$; the Philippines, $\alpha s = .84$, $.79$; Thailand, $\alpha s = .80$, $.83$. For the anxiety subscales, internal consistencies for the mother- and child-reports were: China, $\alpha s = .88$, $.76$; India, $\alpha s = .50$, $.71$; Italy, $\alpha s = .71$; Kenya, $\alpha s = .64$, $.81$; the Philippines, $\alpha s = .81$, $.82$; Thailand, $\alpha s = .69$, $.71$. Because the YSR was only added to the study after the Italian families had participated, we do not have youth self-ratings of aggression and anxiety for the Italian subsample.

Analyses

We utilized two complementary analytic approaches in order to account for between-country differences. For each dependent variable, we first estimated a multilevel model, which is suitable for estimating the association of a set of independent variables with a dependent variable of interest. Multilevel models are commonly employed in situations where data are clustered, as in this case where data are clustered by country (Hox, 2002; Raudenbush & Bryk, 2002). In the multilevel models used in this analysis, the clustering of data is accounted for by allowing the intercept term of the

Table 1
Within-Country Means of Reported Use of and Perceived Normativeness of 11 Discipline Techniques

		Pooled sample mean	Country					
			China	India	Italy	Kenya	Philippines	Thailand
Teach about good and bad behavior	Frequency of use	4.42 (0.88)	4.29 (0.96)	4.60 (0.54)	4.36 (0.89)	3.53 (1.18)	4.76 (0.62)	4.43 (0.90)

	Normativeness (C)	3.28 (1.42)	1.92 (1.15)	3.49 (0.85)	3.60 (1.46)	1.71 (1.36)	3.94 (1.00)	3.78 (1.17)

Note. Scale values are: 1 = *never,* 2 = *less than once a month,* 3 = *about once a month,* 4 = *about once a week,* 5 = *almost every day.* M = mother report; C = child report. Means are presented with standard deviations in parentheses.

model to randomly vary across countries (Raudenbush & Bryk, 2002; Stata Corporation, 2005). Multilevel models estimate both within country and between country differences (Raudenbush & Bryk, 2002). In other words, there may be differences in parenting and child behavior between two families in the same country, but there may also be differences in parenting and child behavior across countries. Both sources of variation are incorporated into the parameters of the multilevel models.

However, one drawback of using multilevel models for this project is that with a relatively small number of Level 2 units (six countries), the distributional assumptions necessary for estimation of a random intercept may not be satisfied (Maas & Hox, 2004). Therefore, for each dependent variable we also estimated a fixed effects model. As the name of these models suggests, country-specific intercepts are estimated as fixed, rather than random, and thus the models are not subject to the same distributional concerns as multilevel models. In addition, fixed effect models are able to control for both observed and unobserved country subsample-level differences (Allison, 2005). One potential limitation of fixed effects models is that all between-country differences are subsumed into the country-specific terms, and the parameter estimates of the model only reflect differences between individuals in the same countries. In the present article, we conducted parallel multilevel and fixed effects analyses in order to identify and understand potential moderation by country of residence in the most robust manner.

Because the country subsamples were small and were not chosen to be representative of their respective countries, we cannot extrapolate any subsample differences up to country-level differences. Our emphasis in these analyses is on whether country of residence explains any significant portion of the associations of 11 discipline techniques with child mental health and behavior. We cannot make conclusions about any given country included in our study, but rather treat ours as an international sample with which to determine whether the associations of parental discipline with child mental health and behavior are culture- (i.e., country-) specific or potentially universal.

Results

Discipline Techniques in Relation to Children's Aggression and Anxiety Across Countries

Table 2 summarizes the results for the models in which mother- and child-reported aggression were regressed on the 11 discipline techniques considered simultaneously; all models control for children's gender and age. The significant intercepts for country variance in both multilevel models (intercepts = 0.48 and 0.46, both *p*s < .01) indicate that there are country-level differences in average levels of child aggression across the countries,

Note. Standardized coefficients and their standard errors are presented. The models for mother-rated outcomes included 275 families in the six countries. Because the Youth Self-Report was not asked of children in the Italian sample, the models for child-rated outcomes include 206 families and five countries.

[a] 0 = boys, 1 = girls.

**p* < .05. ***p* < .01. ****p* < .001.

while the significant R^2s from the fixed effects models (R^2s = 0.47 and 0.28, both ps < .001) indicate that parent discipline techniques do a good job explaining the variance in child aggression, with 47% of the variance in mother-reported aggression explained and 28% of child-reported aggression explained. Mothers rated their boys as more aggressive than did mothers of girls; however, there were no gender differences in child-reported symptoms of aggression.

The results from the multilevel and fixed effects models were consistent—in all but one case (child-reported aggression as a function of mothers' *use corporal punishment* in the multilevel model), all coefficients significant in the multilevel model were also significant in the fixed effects model. Across both the multilevel and fixed effects models, the more often mothers *use corporal punishment*, the more aggressive they reported their children were (βs = .17 and .18, $p < .01$, for the multilevel and fixed effects models, respectively). The frequency with which mothers yell or scold was significantly associated with mothers' ratings of children's aggression (βs = .14 and .13, $p < .01$, in the multilevel and fixed effects models). Both *use corporal punishment* and *yell or scold* similarly were associated with children's self-reported aggression, although corporal punishment was not significant in the multilevel model (β = .15, *ns*, and β = .16, $p < .05$, for *use corporal punishment* in the multilevel and fixed effects models; βs = .21 and .20, $p < .01$, for *yell or scold*). The extent to which mothers reported that they *express disappointment* was associated with more mother-reported aggression (β = .13, $p < .01$, in both models), but not with more child-reported aggression (βs = .09 and .10, *ns*). The remaining eight discipline techniques were not significantly associated with child aggression in any of the models.

Results from the multilevel and fixed effects models for the dependent variables of mother- and child-reported anxiety symptoms while controlling for child gender and age are presented in Table 3. As with the models for child aggression symptoms, the results from the multilevel and fixed effects models for child anxiety symptoms were generally the same. The one difference was again for *use corporal punishment*, which was significantly associated with child-reported anxiety symptoms in the fixed effects model (β = .17, $p < .05$) but not in the multilevel model (β = .15, *ns*). The 11 discipline techniques did a fair job accounting for child anxiety symptoms, explaining 34% of the variance in mother-reported symptoms and 19% of the variance in child-reported symptoms. Different discipline techniques were significant in relation to mother- versus child-reported anxiety symptoms. In the mother-reported models, the frequency with which mothers *give a time-out* was significantly correlated with child anxiety symptoms (βs = .13 and .14, $p < .05$, respectively, for the multilevel and fixed effects models) as was the frequency with which mothers *shame* their children (β = .12, $p < .05$, in both models). In the models with children's own reports of their anxiety symptoms as the dependent variable, the frequency with which mothers report they *use corporal punishment* was significant in the fixed effects model only (β = .17, $p < .05$) while *express disappointment* was significantly associated with children's anxious behaviors in both models (β = .15, $p < .05$, in both models). Seven discipline techniques were not associated with child anxiety symptoms in any of the four models tested.

For all forms of discipline in the multilevel models statistically significant at $p < .05$, models were re-estimated with random slope parameters in order to see whether there was variation in the significant slopes by country. In only two cases did a likelihood ratio test indicate that there was statistically significant variation by country in the slope parameter for a specific discipline type. There was statistically significant variation in the slope for the association of *use corporal punishment* with child-rated aggression and in the slope for the association of *express disappointment* with mother-rated aggression. Both of these models were then re-estimated with country differences treated as fixed in order to examine country-specific slopes.

A fixed effects model examining country-specific slopes for the association of *use corporal punishment* with child-rated aggression did not find any statistically significant country-level variation in the slope. This finding indicates that the variation in slope found in the multilevel model might have been due to the distributional assumptions required by multilevel models or to unobserved differences between countries. In contrast, results from these fixed effects models suggested that *express disappointment* was more strongly associated with increased levels of mother-rated aggression among families in the Chinese, Italian, Philippine, and Thai subsample than among families in the Kenyan subsample. *Express disappointment* was more strongly associated with mother-rated aggression for families in the Chinese subsample than for families in the Indian subsample. However, across all country subsamples, more frequent use of

Perceived Normativeness as a Moderator of Associations Among Discipline Techniques and Children's Aggression and Anxiety

To examine whether mothers' and children's perceptions of the normativeness of discipline techniques moderated their associations with child behavior, we focused on the discipline techniques that were significant main effects in either the multilevel or the fixed effects models for the child aggression and anxiety dependent variables in Tables 2 and 3. We thus examined the potential for perceived normativeness to moderate the statistically significant relations between 5 of the 11 discipline techniques and one or both of the child behaviors. Specifically, we focused on the associations of *give a time-out* with mother-rated anxiety, *use corporal punishment* with mother- and child-reported aggression and child-reported anxiety, *express disappointment* with mother-reported aggression and child-reported anxiety, *shame* with mother-rated anxiety, and *yell or scold* with mother- and child-reported aggression. For each of these nine discipline–outcome combinations, we ran the models separately for moderation by mother-perceived normativeness and by child-perceived normativeness. Employing a similar approach to that used above, each model was run as a multilevel model and then again as a fixed effects model; in all cases, the results were nearly identical for each approach. For ease of interpretation, we present and discuss only the results from the multilevel models.

Table 4 displays the results from the tests of moderation by mother-reported normativeness. Each of these models controlled for child age and child gender. In only one of the models was the main effect for mother-reported normativeness significant as well as the interaction term. The more normative mothers thought *express disappointment* was in their community, the more anxiety symptoms their children self-reported. The significant negative interaction term between the frequency with which mothers *express disappointment* and how normative they perceived it to be, β = −.12, *p* < .001, is graphed in Figure 1. The slope of the regression line between frequency with which mothers *express disappointment* and the number of anxiety symptoms reported by their children is steeper under conditions of low normativeness than under high normativeness. The intercept was higher for the high normativeness condition.

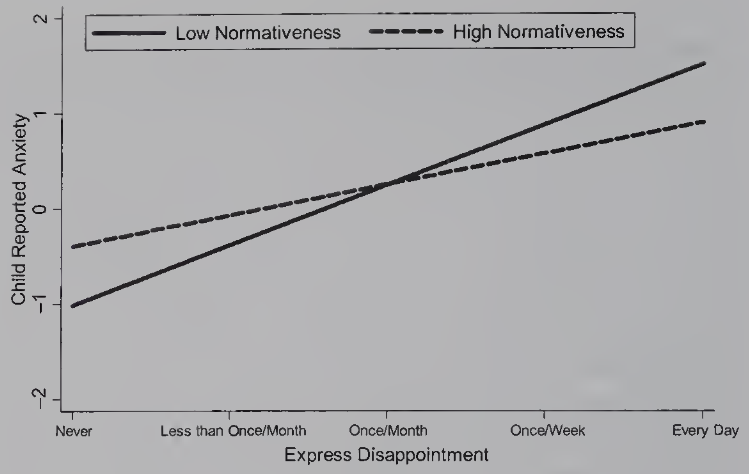

Figure 1. Plot of the link between frequency of mothers' expressions of disappointment and children's anxiety symptoms as moderated by mothers' perceptions of the normativeness of expressing disappointment.
Note. "Low normativeness" and "high normativeness" reflect the frequency with which mothers express disappointment at −1 and +1 *SD*, respectively, from the mean of mothers' reports of normativeness across the sample.

Children's perceived normativeness of various discipline techniques was a stronger moderator of the associations between discipline and child behavior; it was significant in five of the nine models tested (see Table 5). Children's perceptions of the normativeness of corporal punishment significantly moderated the associations of mothers' use of corporal punishment with children's aggression and anxiety, βs = −.07, −.14, and −.10. $^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

of these significant interactions are presented in Figure 2. The slope of the regression line under the condition of low normativeness was steeper than that for high normativeness in each case. These findings suggest that although more frequent corporal punishment is associated with more child- and mother-rated aggression and child-rated anxiety in both conditions, mothers' use of corporal punishment is less strongly associated with child behaviors when children believe it to be normative in their communities.

Similar results were found for moderation of *express disappointment* and *yell or scold*. In both cases, the interaction of child-perceived normativeness with the frequency with which mothers used each technique was negative ($\beta = -.19$, $p < .001$, and $\beta = -.06$, $p < .01$), indicating a decreased slope. The graphs of these interactions are displayed in the right half of Figure 2. As with the other interaction terms, the slopes of the regression lines under high-normativeness conditions are less steep than the slopes of the lines under the low-normativeness condition. Also of interest is that, similar to the other graphs, the intercept is higher under the high-normativeness condition.

Discussion

This study examined the disciplinary practices of mothers in six countries as well as the associations of these discipline techniques with child aggression and anxiety. In parallel analyses with country of residence treated as a random intercept (in multilevel models) and as a fixed parameter (in fixed effects models), we tested the extent to which the associations of maternal discipline techniques with children's aggressive and anxious symptoms are culture (country) specific or universal across countries. We also examined the extent to which perceived normativeness of a given discipline technique might moderate these links. Our goal in this manuscript was to examine links between a range of discipline techniques and child aggression and anxiety in a unique, international sample, with country differences treated by our choice of analytic techniques. In other words, our intention was not to treat this as an opportunity to make generalizations about parents in particular countries.

Our first research question was, once you take into account that parents differ by country in their preferred discipline techniques, is each form of

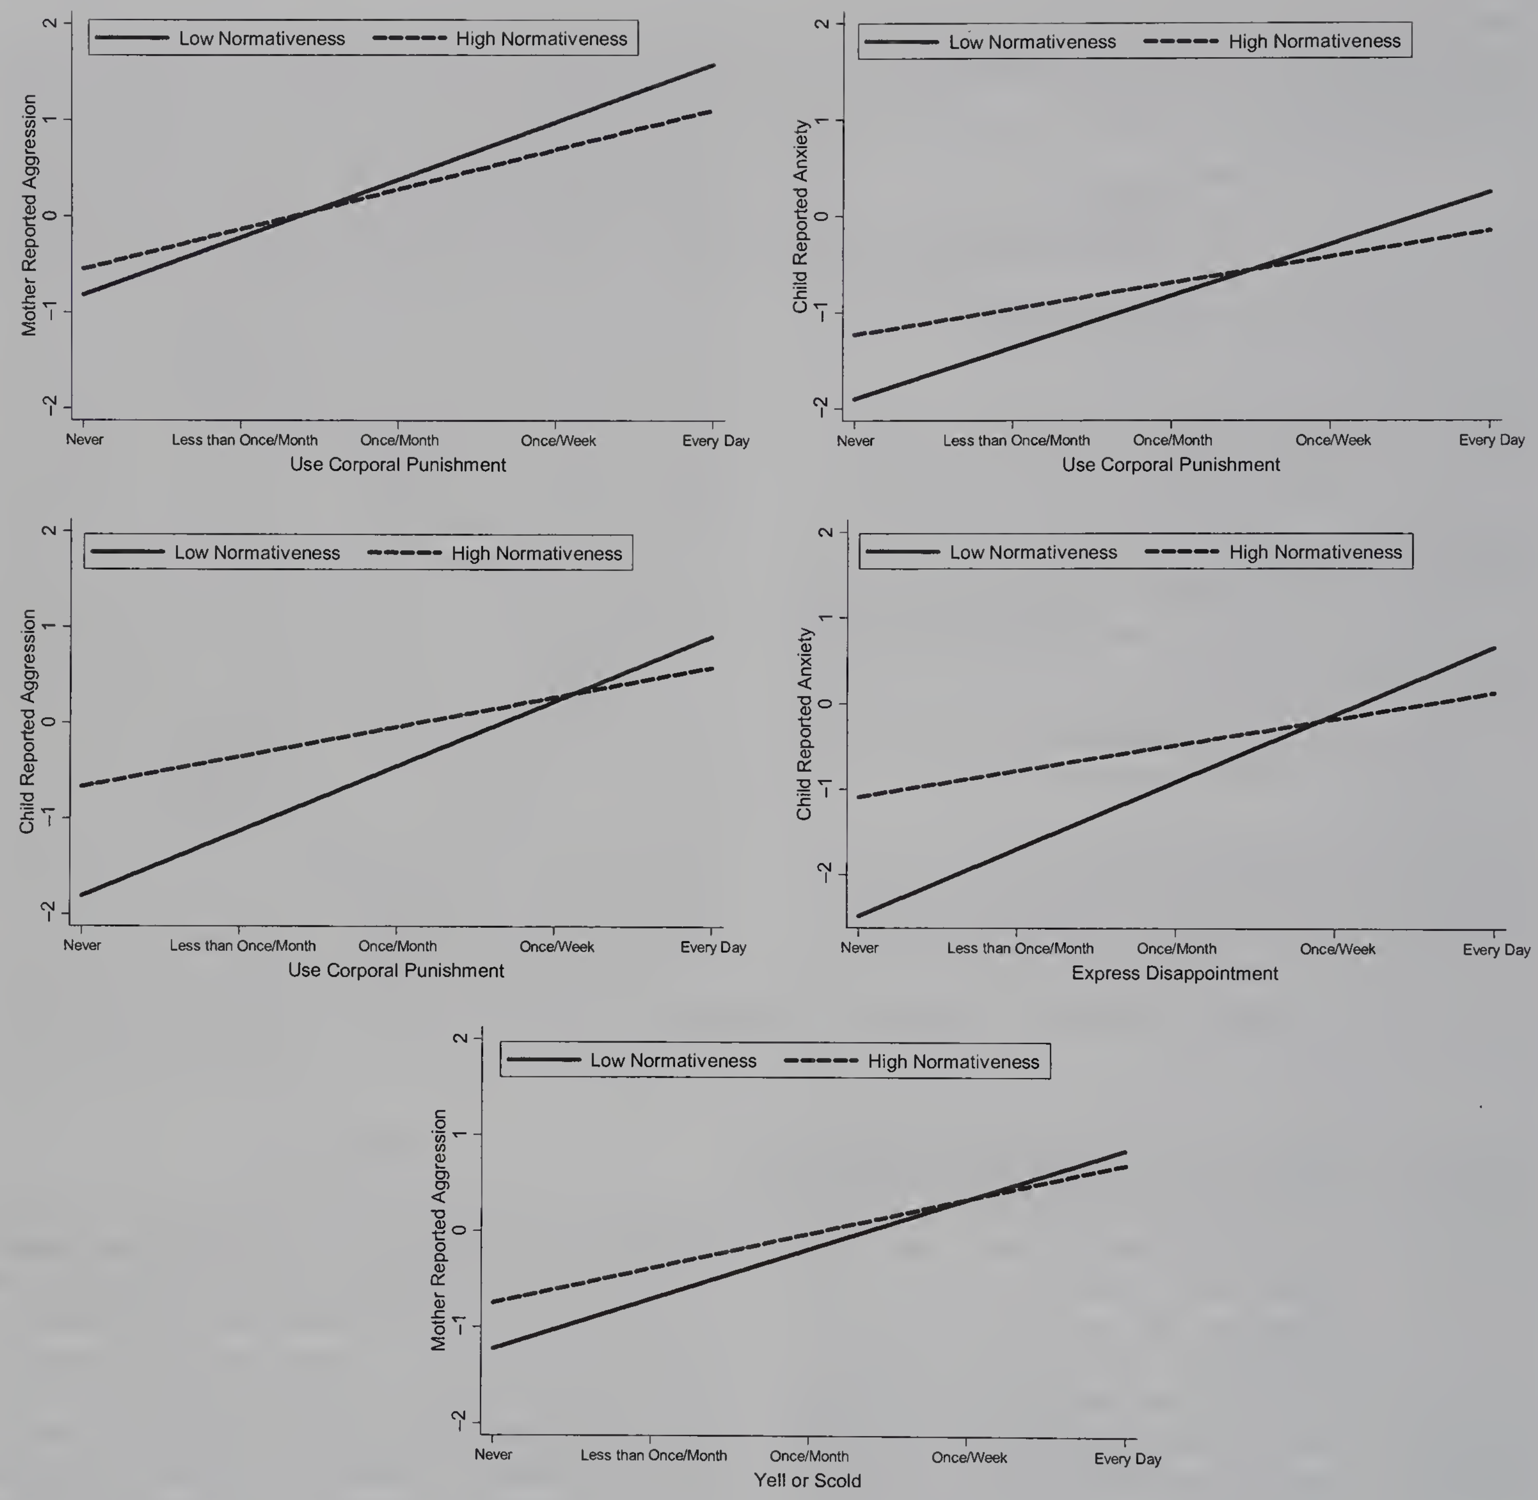

Figure 2. Plots of the links between the frequencies with which mothers use corporal punishment, express disappointment, and yell or scold with children's aggression or anxiety symptoms as moderated by children's perceptions of the normativeness of each discipline technique.

Note. "Low normativeness" and "high normativeness" reflect the frequency with which mothers report using each discipline technique at −1 and +1 *SD*, respectively, from the mean of children's reports of normativeness across the sample.

discipline associated with children's aggressive and anxious behaviors across an international sample made up of families in six countries? The first conclusion to be drawn from our parallel multilevel and fixed effects models that considered all 11 discipline techniques simultaneously is that only three techniques were significantly associated with levels of child aggression and only four techniques were significantly related to levels of child anxiety. In other words, the frequencies with which mothers in this international sample reported using most of the disciplinary techniques were not associated with their children's aggressive or anxious behaviors. The second conclusion is that none of the discipline techniques was associated with less child aggression or less child anxiety. Using corporal punishment, expressing disappointment, and yelling or scolding were each associated with more child aggression, while giving a time-out, using corporal punishment, expressing disappointment, and shaming were associated with more child anxiety.

For the techniques found to be significantly associated with child aggression or anxiety when country was controlled, we added random intercepts to the multilevel models to determine whether there were in fact significant between-country differences in the extent to which that discipline technique was related to child behavior. Of the nine models examined in this way, significant country differences were found only for the association of *express disappointment* with mother-rated aggression; the association was stronger among families in China, Italy, the Philippines, and Thailand than among families in Kenya. However, normativeness does not explain theses differences; normativeness did not moderate the association of *express disappointment* with mother-rated aggression in the final set of analyses. Why this particular discipline technique is more strongly associated with mothers' ratings of child aggression in some countries than in others remains a question for future research.

The cross-sectional nature of the data raises the question of direction of effect. Specifically, does parents' use of these discipline techniques predict more aggression in children, or do aggressive children elicit more discipline? The question of whether such associations are evidence of a parent effect or a child effect has been raised most often with regard to parents' use of corporal punishment (Baumrind, Larzelere, & Cowan, 2002; Larzelere, Kuhn, & Johnson, 2004). It is undoubtedly true in some cases that aggressive children elicit more parental discipline; difficult children have indeed been found to elicit harsh behavior even from nonfamiliar adults (Anderson, Lytton, & Romney, 1986). It is a logical extension of this argument that difficult children should elicit more of *all* forms of discipline from their parents, not just corporal punishment (Larzelere et al., 2004).

Although these data do not permit a rigorous test of this important question (at minimum, longitudinal data would be needed), some patterns of the correlational effects are suggestive of the presence of parent effects on child behavior. First, we did not find that parents use more of all forms of discipline with aggressive children; rather, only 4 of the 11 forms of discipline were significantly associated with child aggression. If aggressive children were eliciting more parent discipline overall, we would have expected them to elicit more of the most frequently reported forms of discipline. However, although mothers reported they *teach about good and bad behavior* and *get child to apologize* most often, they were not using these techniques any more frequently for children they rated as high in aggression. These findings are not consistent with a "child effect" explanation.

Second, although it is not hard to imagine an aggressive child eliciting more discipline from a parent, it is less clear whether a child's symptoms of anxiety would elicit discipline, particularly potentially harsh techniques such as corporal punishment and yelling. Rather, longitudinal research has found that parents typically use less, not more, harsh discipline with anxious and fearful children (Kochanska, Aksan, & Joy, 2007). They do so with good reason: Discipline techniques high in power assertion, including punishment, have been found to substantially undermine moral internalization among children high in fearfulness or anxiety (Kochanska et al., 2007). Children's levels of depression and anxiety have also been found to predict less corporal punishment in particular (Grogan-Kaylor & Otis, 2007). Clearly these analyses will need to be replicated with quasi-experimental or longitudinal data to definitively identify direction of effect, but our findings for both child aggression and child anxiety are more consistent with a parent effect rather than a child effect explanation.

Our decision to use both multilevel and fixed effects analyses exploited the benefits and reduced the costs of using either method alone. The overwhelming consistency of the results across the two sets of models added to our confidence in the robustness of our findings. We encourage future researchers to similarly employ parallel methods when analyzing complex and nested datasets.

Although the associations of discipline with child behavior were almost entirely consistent across cultures when indexed as countries, we did find some evidence that more proximal measures of culture, namely, children's beliefs about the normativeness of discipline within their local communities, did dampen the associations of three forms of discipline with child behavior. In all cases, however, the slopes were positive, such that more frequent use of a particular discipline was associated with greater child behavior problems; even when moderation was present, the association between a discipline technique and a child outcome never reversed direction. This association is also evident in the higher intercepts for the high normativeness group in all of the graphs of the significant moderations. If children's beliefs about normativeness are largely driven by what they see their own parents doing, then it makes sense that the effects of perceived normativeness would be similar in direction and magnitude to the effects of their own parents' use of discipline. It of course may also be that children with higher symptomatology perceive adults in their communities as more punitive. We need to know more about how children form beliefs about normativeness to truly understand these findings.

Mothers' perceptions of normativeness moderated only one of the discipline–child behavior associations. This finding suggests that mothers' perceptions of normativeness and children's perceptions of normativeness may have different functions. Further exploration into how parents develop beliefs about discipline normativeness and into how such beliefs may moderate their own behavior is an exciting avenue for future research.

We had hypothesized that normativeness would moderate the associations of techniques most likely to be perceived as negative events by the child, namely, corporal punishment and yelling, with child behaviors. This was indeed found to be the case. The associations of corporal punishment frequency with child aggression and child anxiety, and of yelling and scolding with child aggression, were less strong when children perceived these techniques to be normative, although again the slope was always positive (more frequent use of the technique associated with a greater number of problem behaviors). We also found the association between expressing disappointment and child-reported anxiety to be moderated by both mothers' and children's perceptions of the normativeness of the technique. In our data, normativeness only played a role for the most negative of the discipline techniques, namely corporal punishment and yelling. Given that the findings for *express disappointment* were similar to these more objectively negative forms of discipline, it appears that when parents express disappointment in their children, children experience that as a distressing event that is linked with more behavior problems the less common it is in the children's community. All other forms of discipline were not affected by normativeness, which suggests to us that the effects of some forms of discipline are robust to community norms. However, given the limited number of significant associations between discipline and child behavior, there is typically no effect of discipline for normativeness to moderate.

Although we worked to ensure the linguistic and cultural equivalence of each discipline technique across the six countries through qualitative interviews and translation and back-translation procedures, it is still possible that there remained some cultural differences in the interpretation of the types of discipline techniques or in the extent to which responses are affected by social desirability bias. An important extension of this work would be to determine whether discipline measures created as indigenous to each country would generate other discipline techniques that are used often in some countries while used rarely or not at all in others (i.e., taking a truly ''emic'' approach; Berry, 1999; Dasen & Mishra, 2000; Harkness & Super, 2002). Additionally, the measure with which we asked parents about their disciplinary techniques focused on individual strategies and not on how parents might combine them; more detailed information, such as diary records (e.g., Chapman & Zahn-Waxler, 1982; Larzelere, Schneider, Larson, & Pike, 1996), could help identify patterns of disciplinary combinations. We also note that the CBCL and YSR subscales used in this article were only modestly internally consistent for the mothers and children in the Indian sample. This was unexpected given that the CBCL has been used successfully with families from the Indian subcontinent (Shenoy et al., 1998).

This study advances our very limited knowledge about parents' use of a wide range of discipline techniques around the world and about links between use of these techniques and children's aggressive and anxious behaviors. We found little evidence that the associations of these discipline techniques with children's behaviors vary by the country in which families live. However, our findings that children's perceptions of the normativeness of discipline were related directly to their behavior and that they moderated the associations between parent discipline and child behavior confirm a potentially important role for children's perceptions of normativeness in understanding how parent discipline impacts child behavior. We encourage more researchers to consider the role of perceived normativeness in their studies of parental discipline and to assess the opinions of those most affected by discipline, the children themselves.

Coercive and Prosocial Fathering, Antisocial Personality, and Growth in Children's Postdivorce Noncompliance

David Scott DeGarmo
Oregon Social Learning Center

To better understand quantity and quality of divorced father contact, a weighted county sample of 230 divorced fathers with a child aged 4–11 years was employed to test whether fathers' antisocial personality (ASP) moderated effects of monthly contact with children in predicting children's observed noncompliance. Eighteen-month latent growth models obtained significant individual differences in levels of noncompliance and growth rates. ASP significantly moderated beneficial impact of fathers' monthly contact. Fathers' observed parenting practices significantly predicted noncompliance levels but not growth. Parenting did not account for the effect of Contact × ASP, suggesting both environmental and potentially genetic influences on child adjustment. Findings were robust across boys and girls and age levels. Implications for preventive intervention are discussed.

Recent representative findings are showing that fathers' involvement is beneficial for children following divorce; however, this influence is not beneficial if father contact is influenced or moderated by fathers' antisocial behaviors or antisocial personality (ASP; Coley & Medeiros, 2007; Jaffee, Moffitt, Caspi, & Taylor, 2003; King & Sobolewski, 2006). The existing research testing these effects has focused mainly on adolescents and little research has been carried out focusing on father's actual parenting behaviors in addition to fathers' amount of contact. The present study tests whether fathers' monthly contact following divorce is moderated by antisociality for younger children and whether parenting practices account for this relationship. Multiple methods were used including direct observation of fathering behaviors and child noncompliance to better address our understanding of the quantity and quality of divorced father contact.

Father Involvement and Child Adjustment Following Divorce

A generative fathering perspective focuses on a positive growth-promoting model seeking to transcend the deficit model of men in families (Brotherson, Dollahite, & Hawkins, 2005; Hawkins & Dollahite, 1997). This perspective is particularly relevant for divorced fathers (Pasley & Minton, 1997) given that for some, the role of father may increase in importance and fathers may become more involved with their children, while for others, factors such as increased role strains, ambiguities over parenting, conflict with the former spouse, and lack of institutional and personal supports can contribute to decreases in father contact and postdivorce parenting (Braver et al., 1993; Stephens, 1996).

Contributing to the pervasive dichotomy of the good father or bad father is research on fathers' influence on children following divorce or separation. Studies on resident and nonresident fathers (divorced and never married) have produced mixed findings showing that fathers' involvement can contribute both positively and negatively to child development. A generative perspective is supported from studies showing that quality father involvement of nonresident fathers has beneficial impacts children's adjustment (Simons, Whitbeck, Beaman, & Conger, 1994). For example, in a meta-analysis of younger and older children, Amato and Gilbreth (1999) found that nonresidential father involvement and authoritative parenting (e.g., instructive, noncoercive parenting) were associated with higher levels of children's academic success and lower levels of internalizing and externalizing. More recently, King and Sobolewski (2006) found

that father involvement and father–child relationship quality in the National Survey of Households and Families predicted lower levels of internalizing problems for adolescents with high father involvement compared to adolescents with low-involved fathers. Similarly, data from the Three-City Representative Study of Low-Income Fathers also found that greater nonresident father involvement predicted subsequent decreases in adolescent delinquency, particularly for high-delinquent adolescents (Coley & Medeiros, 2007). Similar results were found for father involvement in the United Kingdom for families at risk for children's conduct problems (Dunn, Cheng, O'Connor, & Bridges, 2004).

In contrast, father involvement can have a detrimental impact on children's well-being. Key findings from an epidemiological twin study found that the negative impact of fathers' contact and parenting on children's problem behaviors was conditioned by fathers' own antisocial behaviors. Jaffee et al. (2003) found that the more time children lived with fathers, the fewer conduct problems children had; however, this finding was moderated by antisocial behaviors of fathers measured from interview data of lifetime prevalence of antisocial behaviors (e.g., stealing, fighting, antisocial beliefs). Jaffee et al. reported a "double whammy" of genes and environments for antisocial fathers influencing child behaviors. They found that antisocial behaviors are highly heritable; at the same time, however, effects of father ASP on children's behavior problems remained significant controlling for (a) any genetic influence of the father, (b) influence of resident nonbiological father figures, and (c) influence of maternal antisocial characteristics, thus suggesting the importance of parenting. Also supporting an environmental effect, Simons et al. (1994) found main effects showing that nonresident divorced fathers' positive reinforcement and noncoercive discipline were associated with lower levels of adolescent conduct problems. Fathering effects were also independent of the mothers' parenting and cocustody conflict in the sample of coparenting couples. These findings showing the impact of antisocial fathers and coercive discipline are consistent with the coercion model of family process (Patterson, 1982).

Together these studies suggest that the impact of nonresident father involvement is beneficial on children's problem behaviors in the absence of fathers' antisocial behaviors or in the absence of coercive parenting practices. With the exception of the Simons et al. (1994) study, very little research has been carried out on divorced fathers' actual fathering behaviors or parenting practices. Until recent federal fatherhood initiatives, the majority of prior studies have relied on single sources of data or mother reports of father involvement (Parke et al., 2004), chiefly, the frequency or amount of contact and child support (Dunn et al., 2004; Pasley & Braver, 2004). Furthermore, studies on divorced fathers' parenting are still relatively small in number compared to studies of fathers in general. Research has also focused mainly on the period of adolescence. The present study attempts to add to our understanding of fathering impacts on child development by operationalizing father contact as a continuum and father's effective parenting as a continuum to test generative and coercion model perspectives in a sample of recently divorced fathers and their young pre- and elementary-school-aged children, a group shown to be more vulnerable to the effects of divorce (Hetherington & Clingempeel, 1992).

Theoretical Model of Fathers' Parenting and Growth in Children's Problem Behaviors

Several studies have shown how the marked and significant changes in parenting routines, residence, and social roles during marital separation, divorce, and repartnering directly interfere with effective parenting and subsequent child adjustment (Capaldi & Patterson, 1991; Hetherington & Clingempeel, 1992; Ronald L. Simons and Associates, 1996; Simons, Beaman, Conger, & Chao, 1993). The present study employs Patterson's (1982) coercion model specifying how parents' antisocial characteristics are linked to coercive parenting behaviors that are the mechanism reinforcing the development of and growth in children' antisocial behaviors. The theoretical model is also more broadly known as the social interactional–social learning model of child development (Patterson, 1982, 2005; Reid, Patterson, & Snyder, 2002) because it focuses on the influence of the family social environment in shaping overlearned patterns of behavior that can generalize across social settings for the child. Parenting practices are seen as the key agent of child socialization. Parent–child interaction patterns (i.e., *a social interactional perspective* of parenting) are the behavioral mechanism reinforcing the child's likelihood of engaging in future prosocial or antisocial behaviors (i.e., *the social learning perspective* of child development). A child's interpersonal style and behavioral repertoire learned within the family is presumed to carry over to his or her interactions with peers and adults in other settings.

More specifically, a coercion model focuses on how harsh punitive and ineffective discipline is associated with growth in children's problem behaviors. There are several ways in which a child's problem behaviors can be reinforced. A classic example is a child requesting candy in the grocery store. When a parent says ''no'' to the child's request, a child may throw a tantrum that is aversive to the parent. An unskilled parent may reward the child with candy to terminate the aversive tantrum, thus reinforcing the likelihood of future tantrums and a child learning to be rewarded. Similarly, an unskilled parent may use hitting, yelling, and harsh punishment to discipline a child to extinguish an aversive child behavior when a child misbehaves. Coercive discipline works in the short run; however, a child can learn that coercion among family members can be used to terminate aversive behaviors of other family members. A child may then learn to apply coercion in relationships with peers and other adults. In the absence of skilled parenting, a child may progress from trivial displays of aversive behaviors to growth in aggression and future delinquency (Patterson & Yoerger, 1999).

The coercion model is relevant for understanding fathering. Studies have shown that antisocial behaviors of fathers and coercive parenting are associated with increased child and adolescent behavior problems over time (Dishion, Owen, & Bullock, 2004; Jaffee et al., 2003). Relative to mothers, one study reported that fathers' inept discipline can explain twice the variance in children's problem behaviors (Patterson & Dishion, 1988). Dishion et al. (2004) employed the Oregon Youth Study (OYS) to test competing models of a direct effect of parenting (a family management model) or a direct effect of father's deviance (a cultural deviance model) on the early adolescent deviant peer association. They found a direct link between father antisocial behaviors and the selection of deviant peers, suggesting that fathers have an important leadership and modeling role in the socialization of sons with respect to norms, values, and deviance, with antisocial fathers potentially encouraging it. Dishion et al. also found significant associations from father antisocial characteristics to less effective parenting and boys' antisocial behaviors in early childhood as shown previously in the OYS.

The broader social interactional–social learning model also specifies a methodological paradigm using multiple-method assessments including observation to more reliably measure parent–child interaction patterns. Most recently, this model has also focused on evaluation of parenting training outcomes in randomized intervention trials (Patterson, 2005). For fathering, an experimental evaluation of parent training for a sample of 110 recently married stepfather families produced medium effect sizes, demonstrating improvements in observational-based measures of stepfathers' prosocial parenting and coercive parenting at 6 and 12 months postintervention follow-ups (DeGarmo & Forgatch, 2007). These improvements in stepfathering predicted reductions in children's reported internalizing and reductions in observed noncompliance, independent of mothers' parenting. In another report of the same study, the intervention produced significant improvements in mother–father coparenting behaviors, which were associated with reductions in mother-, stepfather-, and teacher-reported problem behaviors at the 2-year follow-up (Forgatch, DeGarmo, & Beldavs, 2005).

The present study based on the social interactional–social learning model of child development is not an experimental trial but is the first effort to test the hypothesized coercion model with a sample of recently divorced fathers. Like the stepfather intervention study discussed earlier, the focus here is on children's noncompliance, a primary marker in young children for the development of later conduct disorder (Martinez & Forgatch, 2001; Vuchinich, Hetherington, Vuchinich, & Clingempeel, 1991). The present study was designed to examine fathering effects across a range of custodial responsibility and father–child contact. In the first report of this data set, the amount of contact and time spent with children varied according to custody as expected: Full-custody fathers reported more time with children than shared-custody fathers, and each respectively more time than no-custody fathers. However, no differences were obtained by custody on coercive parenting practices (DeGarmo, Patras, & Eap, 2008). That is, the amount of time varied by custody but not the level of coercive fathering. Because no-custody fathers can have regular contact with children, and therefore potential impact, the social interactional parenting model is tested using father contact as a continuum rather than court-defined custody status.

Present Study Hypotheses

The following hypotheses were developed based on the literature above:

1. Divorced fathers' monthly contact is expected to have a beneficial impact preventing

growth in children's noncompliance over time but is hypothesized to be moderated by level of fathers' ASP, such that contact by fathers with high ASP is expected to be detrimental and contact by fathers with low ASP is expected to be beneficial.

2. Fathers' coercive parenting practices are expected to predict children's noncompliance over time and will account for effects of fathers' ASP and levels of contact.

Method

Participants

A total of 230 fathers were recruited to participate in a study focusing on father and child adjustment to divorce, the Oregon Divorced Father Study (ODFS). A unique aspect of the study was to evaluate adjustment for divorced fathers, including a range of father–child contact including custodial and noncustodial fathers. Therefore, all divorced fathers with children in the focal age range were eligible for selection within the county sampling frame. Fathers were recruited through public court records. Eligible fathers had a focal child between the ages of 4 and 11 (boy or girl) and had obtained a divorce decree within the prior 24 months. Court records were screened for children within the targeted age range. We randomly selected the focal child if there was more than one eligible child. If the father could not enroll that child, we randomly selected the next eligible child for potential participation until we either enrolled a child or exhausted all eligible children.

After selecting eligible records, fathers were invited to participate with their child through a recruitment letter explaining the study and how they were selected. Among the 230 enrolled fathers, 180 (78%) chose and were able to enroll the focal child. For comparison of nonparticipants, custody status was defined as legal custody reported in the court records. We found that 92% of full-custody and 95% of shared-custody fathers enrolled the targeted focal child, whereas 41% of no-custody fathers enrolled their focal child. Therefore, not all full- and shared-custody fathers had their children participate in the center assessments. However, all fathers, including no custody, filled out questionnaires and interview data on their children's behavior and their own parenting practices. The large majority of fathers (96%) reported contact with the focal child with in-person visitation, e-mail, telephone, or written correspondence.

Fathers' age ranged from 22.9 to 63.4 ($M = 37.8$, $SD = 7.7$), education from 1 (< *8th grade*) to 13 (*advanced doctorate*; $M = 7.2$, $SD = 2.9$), and income from 1 (< *$5K*) to 10 (> *$100K*; $M = 5.4$, $SD = 2.2$). Twenty-three percent of the fathers were below federal guidelines for poverty thresholds. Children's age ranged from 4.0 to 12.0 ($M = 7.6$, $SD = 2.0$). Forty-seven percent of the enrolled children were girls. Thirteen percent of the fathers identified themselves as a racial minority (5% Hispanic, 1% African American, 1% Asian American, 1% Native American, and 5% multiracial) and 17% of their children (1% Hispanic, > 1% African American, > 1% Asian American, 1% Native American, and 14% multiracial), reflective of county demographics. The county sampling frame consisted of 37% no-, 54% shared-, and 10% full-custody fathers. The ODFS comprised 32% no-, 53% shared-, and 14% full-custody fathers with an overall participation rate of 40% (35% no-, 41% shared-, and 55% full-custody fathers).

Neighborhood demographics were collected for eligible participants and nonparticipants. There were no differences between participants and nonparticipants when comparing neighborhood characteristics from census tract and geo-coded police call response data near the father's address (e.g., unemployment rates, proportion homeownership, poverty rates, racial makeup, and police call frequency and severity ratings). To generalize beyond the community level to a county level, sample weights were obtained as correction factors for selection bias based on county proportions of custody. In short, the sampling weights adjust for differential participation, eligibility, and location rates by custody and potential selection bias. Details are provided in DeGarmo et al. (2008).

Data Collection and Assessment Procedures

Data were collected during a father–child visit at each wave. Each center visit took approximately 2.5 hr. All participants were provided child care, transportation, and a meal if requested (delivered local take out). Father and child were each paid approximately $25 an hour for their time. Data were from paper-and-pencil questionnaires, face-to-face interviews, self-administered and computer questionnaires, and observational coding of father–child interaction. Observational data were obtained from a total of 24 min of videotaped interaction scored across four structured interaction tasks during the father–child visit. The tasks were a refreshment task lasting 5 min, a problem-solving discussion focusing on a parenting issue lasting 7 min, a play task with the father lasting 7 min, and an academically challenging teaching task lasting 5 min. The refreshment task was a "warm up" in which father and child were asked to take a break from interviews and filling out questionnaires. Each of the problem-solving discussions focused on current father-selected topics from a checklist of common parent–child issues. They were asked to resolve issues rated as "hottest." In the teaching task, fathers were asked to work with the child on a typical homework problem. Children were provided a homework problem that was one grade level beyond the child's current grade.

Trained observers scored father–child interaction with the Family and Peer Process Code (FPP; Stubbs, Crosby, Forgatch, & Capaldi, 1998) obtaining data on discrete positive, negative, and neutral behaviors in real-time coding along with data on the initiator, recipient, sequence, and affect. Fifteen percent of videotapes were randomly selected for blind reliability checks. For all content and affect codes, two coefficients of intercoder reliability were assessed: percent agreement and Cohen's Kappa, an indicator of agreement above chance. Reliabilities are reported next (FPP manual available at http://www.oslc.org/resources/codingsystems.html).

Father ASP

Fathers' antisocial characteristics were measured using two self-report instruments. The first indicator was the 20-item Acting Out subscale of the Minnesota Multiphasic Personality Inventory–Test–Retest Index (MMPI–TRI; Swanson, Templer, Streiner, Reynolds, & Miller, 1995). The MMPI–TRI is a shortened version of the MMPI and MMPI–2 self-report personality inventories. The MMPI–TRI has demonstrated construct validity with the full MMPI and has been normed with inmate and psychiatric populations (Swanson et al., 1995). Twenty acting-out items evidencing content validity and the highest point-biserial item-total correlations were retained for the shortened MMPI. Statements were rated true or false and then summed. Items included: was suspended from school one or more times, when people do me wrong I feel I should pay them back, when I was young I stole things, at times I feel like picking a fist fight with someone, I can easily make people afraid of me and sometimes do it for fun, and so on. Cronbach's alpha for the ODFS was .82.

The second indicator was the Agreeableness subscale (NEO–A) from the NEO–Five Factor Inventory (NEO–FFI; Costa & McCrae, 1995). The NEO is a standard personality inventory with alpha coefficients of internal consistency ranging from .89 to .92 for extroversion, openness, and agreeableness in validation studies of men and women (Costa & McCrae, 1995). The NEO–A was chosen because it has been validated with the DSM–IV manual as a marker of ASP for men scoring low on the NEO–A (Costa & McCrae, 1992). Agreeableness was a 12-item subscale rated from 5 (*disagree*) to 1 (*strongly agree*). Items included: I often get into arguments with my family and coworkers, if I don't like people I let them know it, if necessary I am willing to manipulate people to get what I want, I try to be courteous of everyone I meet, most people I know like me, and so on. Items were rescaled 0–4 and summed to obtain norming scores. Data from the norming sample of 500 adult men produced a mean of 31.93 ($SD = 5.03$) for the NEO–A (Costa & McCrae, 1992). ODFS fathers revealed no significant difference in mean or variance ($M = 31.74$, $SD = 5.31$, $t = 0.43$). Cronbach's alpha for the ODFS was .82 for the NEO–A.

Father–Child Monthly Contact

The central focus of the present analyses is fathers' monthly contact with child indexed by day and night visits. Contact was measured from a computerized interview with the father adapted from Braver et al. (1993) and was computed as the mean total number of weekday and weekend days per month of contacts with the child and the number of overnight stays and visits during the typical school year. Time-use measures were not collected; therefore, each visit may have varied from father to father, and monthly contact was therefore a discrete time index of involvement. Monthly contact is confounded with custody status, to illustrate variation within custody, Figure 1 plots the histogram distributions of monthly contact by custody and provides the boxplot distribution of variation for the total sample.

Children's Observed Noncompliance

Noncompliance was the rate per minute (rpm) of a noncomply scored across all father–child interaction tasks. FPP coders first coded any directive or command provided by the father. A toggle code then records whether the child was compliant or cooperative or not. Compliance is defined as the act of clearly obeying a father's request or command and noncompliance the act of clearly disobeying a father's request or command. Only one compliance behavior (either comply or noncomply) may be entered in response to each directive. Hypothetical,

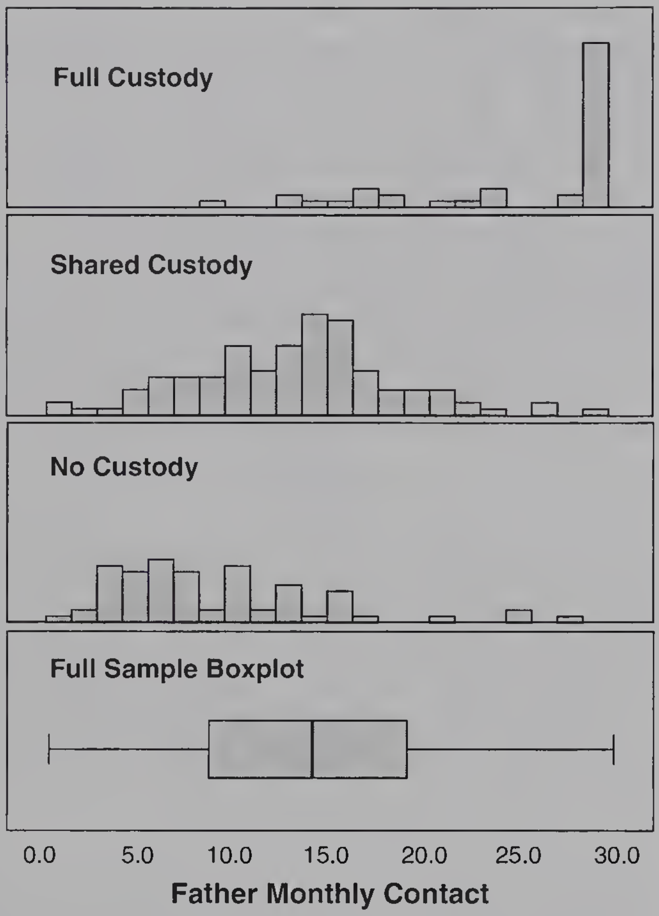

Figure 1. Histogram distribution of index for fathers' monthly contact with child by custody status and boxplot of monthly contact for full sample.

ambiguous, or unclear responses to a directive are not coded. For father command or directives, the percent agreement ranged from .84 to .86 from baseline to the 18-month follow-up. Kappas ranged from .85 to .86. For noncompliance, percent agreements ranged from .66 to .77 over time with Kappas of .75–.77.

Fathers' Parenting Practices

Fathers' parenting was assessed using previously validated indicators assessing "coercive" and "prosocial" fathering using multiple sources of data (DeGarmo & Forgatch, 2007; DeGarmo et al., 2008) including self-report, discrete or microsocial behavior codes from the FPP coding system, and coder Likert-type ratings of parenting. These measures of the latent variable were operationalized with four indicators: ratings of coercive harsh discipline during the structured interaction tasks, coded rpm of verbal and physical aggression of the father directed to the child, self-reported harsh discipline, and ratings of prosocial parenting during the interaction tasks.

Harsh discipline ratings were a five-item scale of the coder's impression of discipline after scoring FPP discrete behaviors. Rated from 1 (*very untrue*) to 5 (*very true*), items included overly strict, authoritarian, expressed hostility during discipline, used nagging, hovered too closely, and used inappropriate discipline. Cronbach's α was .86.

Father total aversives from the FPP coding system included cluster scores of father-initiated behaviors directed to the child that included physical and verbal aggression codes (e.g., physical aggression, verbal aggression, negative tease, negative interpersonal, physical attack, verbal attack; coding system history and details are available for download on the Internet). The FPP percent agreement for reliability checks for content codes were .87, .87, and .89 for content behavior codes, and .95, .96, and .96 for affect codes. Cohen's Kappas were .78, .79, and .81 for content codes over time, and .80, .78, and .76, respectively, for affect codes.

Self-report harsh discipline was a self-administered questionnaire including a five-item summative index rated from 1 (*never or almost never*) to 5 (*always or almost always*) in which fathers responded to the question "When [focal child] misbehaves, how often do you . . . ?" Rated items were: raise your voice/scold, yell, spank on bottom, slap, hit. Cronbach's alpha was .85.

Prosocial parenting was the mean of two scales from coder ratings of positive involvement and skill encouragement. *Positive involvement* was obtained from 14 items rated after each father–child interaction task. Items included ratings on how much the parent treated the child with warmth, empathy, affection, and respect, maintained good eye contact and interactive posture, and so on. Cronbach's alpha was .94.

Skill encouragement was based on ratings of fathers' ability to promote children's skill development through contingent encouragement and scaffolding strategies observed during the teaching and construction play tasks. In both tasks, the child is given challenging problems and the father is asked to assist. The scale includes 11 items such as: breaks task into manageable steps, reinforces success, prompts, corrects appropriately. Cronbach's alpha was .92. Both prosocial scale scores were rescaled from 0 to 1 and averaged to form a composite prosocial parenting indicator.

Control Variables

Age of the child in years computed from date of assessment and date of birth. Sex of child coded as 0 for girls and 1 for boys.

Analytic Strategy

The main study hypotheses were tested with structural equation modeling (SEM) specified as latent variable growth models in the MPlus5 program (Muthén & Muthén, 2007). MPlus provides the ability to apply sample weights using the MLR option, or maximum likelihood estimation with robust standard errors. MLR standard errors and chi-square model test are robust to non-normality. Latent growth models (LGM) provide advantages for modeling developmental changes over time and are a special case of multilevel modeling in the SEM framework in which repeated measure outcomes at Level 1 are nested within individuals at Level 2.

Also known as random intercepts models, LGM estimates the individual differences or variation in the levels of noncompliance (random intercepts) as well as the increases or decreases in child outcomes (random slopes) for each individual at Level 1. The individual intercepts and slopes are then summarized as latent variable factor components at Level 2 representing the sample means and slopes. The present LGM analyses were modeled as two factors, the average level intercepts over time and as linear growth slopes (Biesanz, Deeb-Sossa, Papadakis, Bollen, & Curran, 2004). This is obtained by fixing the three random intercept factor loadings at 1, respectively, for baseline, 9, and 18 months, and by specifying chronometric time weights for the slope factor at −1, 0, and 1. Data were modeled using full-information maximum likelihood (FIML), which uses all available information from the observed data in handling missing data. FIML estimates are computed by maximizing the likelihood of a missing value based on observed values in the data. For any individual who has baseline data only and no follow-up data, such individuals contribute nothing to the likelihood of estimates and are effectively excluded from change analyses (Brown et al., 2008). Compared to mean-imputation, listwise, or pairwise models, FIML provides more statistically reliable standard errors (Wothke, 2000).

To test whether father ASP moderated father contact, variables were entered as centered first-order terms and centered cross products of ASP and monthly contact using regression approaches for testing interactions (Cohen, Cohen, West, & Aiken, 2003). In addition, to test latent variable interactions of ASP, two specific approaches were used. First, ASP factors scores were saved and used to compute a centered cross product of Monthly Contact × ASP. The second method used latent variable interaction modeling in MPlus using maximum likelihood and a numerical integration algorithm (Muthén & Muthén, 2007). Standardized solutions and explained variance are not available for the latent variable interaction approach; therefore, model fit and standardized solutions were reported next using centered cross products, but findings were tested using both methods of assessing interaction effects.

Results

Eighty-four percent of the families were retained at 9 months and 82% at 18 months. Attrition analyses revealed no significant differences between children in families remaining in the study compared with those lost to follow-up by 18 months when comparing the baseline rpm of child noncompliance. Child noncompliance scores were log transformed for the multivariate analyses, although the MLR estimates are robust to non-normality. Descriptives of study variables are provided in Table 1.

The first step in the LGM analysis was to estimate the linear growth in child noncompliance. Known as the unconditional model, the LGM analyses describe the pattern of change for the developmental outcomes. The average level intercept factor represents the continuum of low noncompliance levels to chronically high levels averaged over time. Average rpm levels of noncompliance were different from zero ($M = 0.08$, $p < .001$) for the sample and the variance component was different from zero ($\sigma^2 = 0.005$, $p < .001$), indicating significant individual differences among children's levels of noncompliance.

The linear growth slope or change factor obtained significant variance, meaning there were individual differences in the increases and decrease trajectories of noncompliance ($\sigma^2 = 0.004$, $p < .001$); however, the sample mean was not different from zero. This meant that the sample was characterized by a range of children increasing in noncompliance and children decreasing in noncompliance. The chi-square minimization fit indicated a linear growth model provided good fit to the repeated measures noncompliance data, weighted MLR growth model fit, $\chi^2(1) = 2.26$, $p = .14$; comparative fit index = .95, standardized root mean square residual = .02. Results of the unconditional noncompliance LGM model are provided in Table 2.

The next step of analyses tested Hypotheses 1 and 2. The first model specified father ASP, father contact, and the centered cross-product term as

Table 1

Sample Descriptives for Observed Variables in Latent Growth Analyses

	Min.	Max.	*M*	*SD*
Child noncompliance				
Observed rpm T1	0.00	0.89	0.09	0.13
Observed rpm T2	0.00	0.97	0.10	0.16
Observed rpm T3	0.00	0.58	0.08	0.12
Natural log rpm T1	0.00	0.64	0.08	0.11
Natural log rpm T2	0.00	0.68	0.09	0.12

predictors of levels and growth in child noncompliance. Findings are displayed in Figure 2 in the form of standardized paths. For clarity, only significant paths from the control variables are displayed, and significant paths from the hypothesized constructs are shown in bold. Results supported Hypothesis 1, indicating that father ASP moderated the effect of monthly contact in predicting both the average levels over time ($\beta = .31$, $p < .001$) and linear growth rates ($\beta = .30$, $p < .05$). The main effect of fathers' monthly contact was marginally associated with decreases in noncompliance over time at the $p = .06$ level ($\beta = -.19$, $p < .062$), which is interpreted as the effect of contact at average levels of ASP in the presence of a significant interaction (Cohen et al., 2003). Therefore, ASP conditioned the impact of fathers' contact on children's noncompliance. Older children displayed lower levels of noncompliance relative to younger children ($\beta = -.28$, $p < .001$), and sex of the child was not associated with noncompliance factors. The overall model predicted 39% of the variance in average levels and 11% of the variance in growth rates.

The next model specified linkages from father ASP to noncompliance through fathers' coercive parenting practices. It was expected that higher levels of coercive parenting would be associated with higher levels of child noncompliance and growth in noncompliance. Furthermore, it was predicted that coercive parenting practices would account for the interaction effect of Contact × ASP. Results are displayed in Figure 3. Hypothesis 2 was partially supported. Father ASP predicted higher levels of coercive parenting practices ($\beta = .42$, $p < .01$), and fathers' coercive parenting in turn predicted higher levels of noncompliance ($\beta = .43$, $p < .01$). Parenting practices explained an additional 14% of the variance noncompliance levels. Contrary to expectations, coercive parenting did not predict growth rates. In addition, parenting did not account for the Contact × ASP interaction effect on noncompliance. Therefore, ASP was a significant moderator of fathers' monthly contact in predicting noncompliance following divorce and ASP was a contributor indirectly through coercive parenting practices.

Exploratory Models of Gender and Age

Three related approaches were used to explore potential gender and age variation in the main findings. These included (a) multiple group SEMs for boys versus girls and youngers (younger than 8) and olders (older than 8), (b) computed interaction terms, and (c) latent variable interaction models. No moderating effects were obtained comparing boys versus girls as multiple group SEMS. For age, a multiple group split of youngers ($n = 133$) and olders ($n = 97$) would not converge for the older group due to reduced n and variance in the LGM factors. For a computed interaction model, Contact × ASP × Age did not predict growth in noncompliance over and above the significant effect of Contact × ASP. However, the effect for Contact × ASP × Age on the average level intercept factor obtained a significant standardized beta ($\beta = -.159$, $t = -2.09$, $p < .04$). This suggested that the impact of antisocial fathers' contact was lessened for older children relative to younger children in predicting individual differences in average levels of noncompliance. This is consistent with the notion that younger children are both more noncompliant and more vulnerable to the effects of divorce. However, inspection of the explained variance showed that this three-way interaction contributed an additional 1% explained variance to the model predicting average levels. Using latent variable interaction terms, the two-way interaction effect of Contact × ASP was replicated in predicting the intercept ($t = 2.065$) and the growth factor ($t = 2.694$). However, the effect of Contact × ASP × Age on the intercepts term was marginal using the latent variable interaction approach ($t = -1.78$, $p < .08$).

In summary, the findings showed that the effect of fathers' ASP moderating his monthly contact was robust in predicting intercepts and growth rates in noncompliance for boys and girls and across child age. Results for the average levels of noncompliance were somewhat stronger for younger children relative to older, but this effect was not very meaningful in that one test produced an additional 1% of explained variance and the latent variable interaction test was marginal. To illustrate the main finding, the Contact × ASP effect was plotted using the estimated growth slopes from Figure 3 for 1 *SD* above the mean of ASP and 1 *SD* below the mean (Figure 4).

Discussion

This study investigated the impact of father involvement indexed as a continuum of monthly contact with his child following divorce and attempted to add to the previous literature by focusing on fathers of young children who are more vulnerable to behavioral effects of divorce. By comparison, a majority of prior research has focused less on fathers' actual parenting behaviors and more so on father contact only. The present study employed multiple-method assessment

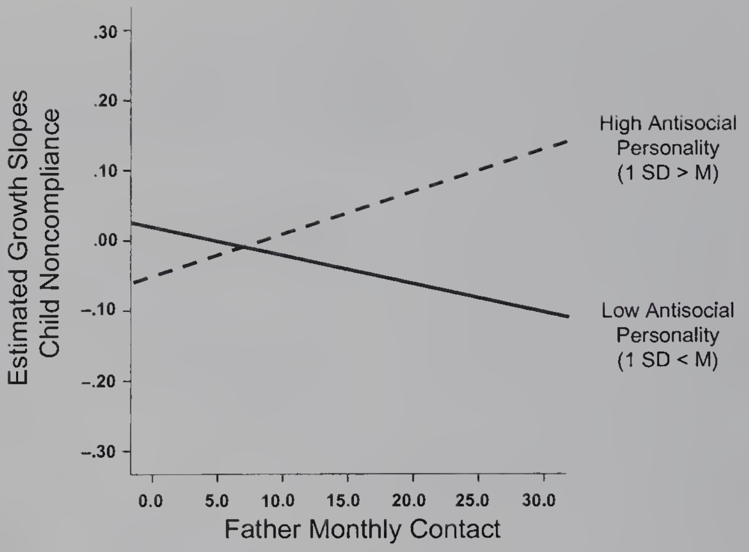

Figure 4. Plot of estimated linear growth slopes for effect of father antisocial personality as a moderator of monthly contact. *Note.* Slopes are plotted for 1 *SD* above the mean of antisocial personality and 1 *SD* below the mean.

including direct observation of fathering and child noncompliance. Furthermore, extant research has focused mainly on the period of adolescence.

The theoretical model employed the coercion model of child development and the generative theories of father involvement. Fathers that have regular contact with their children can have a positive developmental impact. However, fathers' ASP was expected to moderate monthly contact, and ASP was expected to be associated with higher coercive parenting.

The unconditional growth models showed significant individual differences in children's noncompliance and individual variation in trajectories of increases and decreases. Supporting the hypotheses, latent growth prediction models showed that monthly contact was negatively associated with children's growth in noncompliance at average levels of antisociality (ASP); however, father ASP significantly moderated the effect of monthly contact. As shown in Figure 4, increased contact of low-antisocial fathers was associated with decreases in noncompliance over 18 months and contact with high-antisocial fathers was associated with increases. Exploratory models showed that this effect was robust for younger and older children and for boys and girls.

Partially supporting the hypotheses, fathers' ASP predicted higher levels of coercive parenting practices, and coercive parenting predicted average levels of noncompliance but not growth rates. Conversely, it should be noted that latent variable models also imply that effective prosocial parenting practices were associated with lower levels of noncompliance, underscoring the importance of prosocial parenting skills. From a clinical perspective, it is important to note that the coercion model is complementary and not antithetical to a generative fathering approach. Preventive intervention approaches based on the coercion model emphasize positive parenting as the cornerstone to reducing coercive parenting, including positive reinforcement, skill encouragement, and emotion regulation (Patterson, 2005).

Contrary to expectations, parenting practices did not account for the interaction effect of Fathers' Contact × ASP. Although this study was not a genetically informed design, the pattern of findings replicated what Jaffee et al. (2003) described as the ''double whammy'' of environmental and genetic influence of antisocial fathers. Given that parenting did not account for the ASP interaction, this suggested a potential genetic influence on children's problem behaviors. At the same time, controlling for ASP, parenting practices explained an additional 14% of the variance in levels of noncompliance, underscoring the importance of fathers' parenting practices. Parenting did not predict variance in growth trajectories.

Limitations

A key limitation existed regarding the prediction of parenting on change in noncompliance. Predivorce levels of parenting and noncompliance were not collected. It is likely parenting effects on growth in noncompliance were more influential during earlier socialization prior to divorce. The fact that fathers' contact conditioned by ASP was predictive of increases in noncompliance also suggested that other potential mechanisms in addition to genetic influence may account for the effects of father's monthly contact effect, such as the child's experience of socioemotional closeness with fathers or conversely subjective distress associated with divorce-related stressors between parents (Wolchik, Tein, Sandler, & Doyle, 2002).

It is important to note that the present study was based on public court records with a divorce decree from a county sampling frame including rural and urban areas. There are known limitations to court records based studies involving participation of families who separate and do not file for divorce and inferences based on families in which the marital dissolution and disruptions to social interactional may have occurred long before filing. As noted earlier, the present study was limited because it was not a prospective study of divorce and did not have measures of children's predivorce functioning, parenting, or mothers' parenting, all of which are probably influencing the average levels of children's problem behaviors and growth. For shared- and no-custody fathers, mothers' parenting is likely a key predictor children's noncompliance. Furthermore, although recent studies have shown independent effects of nonresidential fathers net of mothers, it is likely that effects of fathers' antisociality may share variance with mother's antisociality influences due to assertive mating.

Another limitation was the measure of monthly contact. A more refined measure of father contact would be time-use diary approaches for measuring father involvement (e.g., Hofferth, Stueve, Pleck, Bianchi, & Sayer, 2002). Recently, however, Wical and Doherty (2005) have shown that fathers are reliable reporters of their contact. Nonetheless, given the limitations, the present findings replicated associations reported for adolescence and included direct observation of fathers' parenting and child adjustment. The findings underscored the impact of residential and nonresidential fathers on children's behaviors following divorce and potential mechanisms of preventive intervention.

Implications

Prevention programs may be designed to be universal, selective, or indicated programs to address child adjustment problems in the hopes of delaying or preventing onset of problem behaviors. As opposed to universal programs for an entire population, selective prevention programs target subsets of the population that are at risk by a common membership, for example, children of divorced parents. As opposed to treatment, selective prevention targets individuals in a group (divorced fathers) regardless of individual risk or without prior screening. Indicated prevention focuses on individuals from a risk group that are showing early signs of problems (e.g., deficient parenting or onset of conduct disorder in children). Currently, many individual and community-based programs for promoting effective fathering and preventing child adjustment problems exist due largely in response to the Department of Health and Human Services Fatherhood Initiative (National Center on Fathers and Families, 2006). The majority of fatherhood programs, however, have limited theoretical or evidence-based foundations (McBride & Lutz, 2004).

Exceptions are programs focusing on father involvement and the reduction of coparenting conflict, the Dads for Life (DFL) program (Braver, Griffin, & Cookston, 2005) and the Strengthening Father Involvement (SFI) program (Cowan, Cowan, Pruett, & Pruett, 2007). Like the DFL, the SFI has demonstrated reductions in coparenting conflict over time and more recently has shown benefits to children's problem behaviors (Cowan, Cowan, Pruett, Pruett, & Wong, 2009). From a parent training perspective, the Oregon Model of Parent Training (PMTO) is another exception (Patterson, 2005). To date, the Forgatch et al. (2005) intervention was only one of two theory- and evidence-based parent training programs involving stepfathers. One critical finding was that the intervention produced the largest effect size on improved parenting behaviors for stepfathers when compared to effects for mothers (DeGarmo & Forgatch, 2007). It is likely that a selective preventive intervention program for divorced fathers would benefit children's behavioral adjustment over time.

In addition to direct work with fathers or couples, approaches involving direct work with children incorporating father involvement may benefit divorced families. For example, parent–child interaction therapy effectively reduces children's problem behaviors. Recent efforts have shown benefits for maintenance of effects involving components of father involvement (Bagner & Eyberg, 2003).

Generative fathering perspectives may be helpful in delivering prevention programs to antisocial fathers. Dishion et al. (2004) argued that it is likely that deviant fathers are underrepresented in prevention research, and currently little research exists on how antisocial fathers respond to parenting interventions and may, therefore, show larger effects. Examples from clinical treatment work with maltreating and abusive fathers have shown that fathers are more responsive to interventions pointing out the welfare and needs of the children as a focal point for addressing harmful interactions with spouses and children (Rosenberg & Wilcox, 2006; Scott & Crooks, 2004). A coupling of the social interactional–social learning intervention model with generative fathering perspectives might show great promise. Although the coercion model focuses on a deficit of skilled parenting, the model is not antithetical to generative fathering perspectives in its theoretical approach. For example, PMTO (Patterson, 2005) focuses on positive reinforcement, encouragement, and positive involvement as cornerstones for reductions in coercive parenting and child noncompliance. Because of fathers' desire to stay involved with their children, effective programs may benefit from father-oriented components increasing men's awareness of child-centered needs and parenting (Brotherson et al., 2005; Parke & Brott, 1999).

Finally, given the main effect of parenting practices, it is argued the present findings do not imply that only antisocial fathers would benefit from parenting intervention or that all divorced fathers are in need of parent training. The present findings suggest that both promoting more effective parenting skills would benefit a sample of divorced fathers and a focus on antisociality would be important. Prevention programs are designed to address populations with a range of parenting skills as opposed to screening and targeting fathers with parenting deficiencies. Evidence-based programs have benefited single mothers and their children using community and court-mandated samples and selected and indicated samples, all of which comprised mothers ranging in parenting skill and antisociality. Programmatic intervention with divorced fathers should also prove independently beneficial for divorced families members.

The Tuning of Human Neonates' Preference for Speech

Athena Vouloumanos

Janet F. Werker
University of British Columbia

Alia Martin
New York University

Human neonates prefer listening to speech compared to many nonspeech sounds, suggesting that humans are born with a bias for speech. However, neonates' preference may derive from properties of speech that are not unique but instead are shared with the vocalizations of other species. To test this, thirty neonates and sixteen 3-month-olds were presented with nonsense speech and rhesus monkey vocalizations. Neonates showed no preference for speech over rhesus vocalizations but showed a preference for both these sounds over synthetic sounds. In contrast, 3-month-olds preferred speech to rhesus vocalizations. Neonates' initial biases minimally include speech and monkey vocalizations. These listening preferences are sharpened over 3 months, yielding a species-specific preference for speech, paralleling findings on infant face perception.

How do initial perceptual biases and learning from specific experience interact to prepare infants to adapt optimally to their world? Across perceptual domains, infants use early biases to organize the world. For example, young infants are able to discriminate non-native speech sounds that are unfamiliar to them (Kuhl, Williams, Lacerda, Stevens, & Lindblom, 1992; Werker & Tees, 1984) and identify individual faces of species they have never encountered before (Pascalis, de Haan, & Nelson, 2002). By the end of the 1st year of life, these biases become attuned to sounds and visual information in the infant's environment, such that infants no longer readily discriminate non-native speech sounds (Kuhl et al., 1992; Werker & Tees, 1984) nor do they identify unfamiliar species' faces (Pascalis et al., 2002). Initial biases, and rapid attunement, may constitute conserved and fundamental principles that underwrite the development of perceptual systems across the animal kingdom. In this article, we explore the ontogeny of the specificity of the neonatal preference for human speech.

Many species are endowed with an innate preference to attend to the visual and auditory cues of their conspecifics (Gottlieb, 1997; Johnson, Bolhuis, & Horn, 1985; Marler & Peters, 1977). For example, precocial birds preferentially approach the calls of conspecifics, whereas the young fledglings of song learning birds will selectively acquire their species-specific song if they are exposed to it during a sensitive period (Gottlieb, 1997; Marler & Peters, 1977). A common perspective in studies of language acquisition is that humans are similarly endowed with a preference for conspecific vocalizations and, more specifically, that speech is special for humans (Liberman & Whalen, 2000; Pinker & Jackendoff, 2005), perceived in unique ways from the earliest stages of development (Vouloumanos & Werker, 2007). Support for this hypothesis comes from studies showing that neonates exhibit a preference for speech over filtered (Spence & DeCasper, 1987) and reversed speech (Peña et al., 2003), as well as synthesized signals such as complex synthetic sounds (Vouloumanos & Werker, 2007) and white noise

(Butterfield & Siperstein, 1970). Such a preference for speech suggests that infants are prepared to attend to auditory stimuli in their environment that are relevant for language, thus facilitating language acquisition (Kuhl, Coffey-Corina, Padden, & Dawson, 2005).

Although previous studies support the hypothesis that speech is a privileged sound for infants, they leave open the possibility that neonates' listening preference is based on properties of speech that are not unique to speech but instead are shared with the vocalizations of related species. Speech and nonhuman primate vocalizations share some acoustic properties and are coded similarly in the human auditory system (Altmann, Doehrmann, & Kaiser, 2007; Smith & Lewicki, 2006). We selected rhesus monkey calls for comparison because, although acoustically distinct from human speech, they are similarly spectrally rich. In particular, rhesus have a broad vocal repertoire spanning a wide range of activities, including calls produced during the discovery of food sources (e.g., coos, warbles) and affiliative social behavior (e.g., girneys; Hauser, 2000). Like human speech, some rhesus monkey calls are produced by oscillations of the larynx (phonation) and filtered by the supralaryngeal vocal tract, which dampens or amplifies different frequencies (Fitch & Hauser, 1995; Hauser, Evans, & Marler, 1993; Rendall, Owren, & Rodman, 1998; see Figure 1). This filtering of frequencies generated by the laryngeal oscillations produces discrete formants, or concentrations of energy, whose distribution and fluctuations across time generate a wide range of speech sounds. As a result of constraints on the movements of rhesus articulators, however, the "phonetic" repertoire of rhesus monkeys is limited by comparison with that of humans (Belin, 2006; Fitch, 2000) and the frequency spectrum of calls is broader and higher so that, perceptually, rhesus calls present a broader distribution of spectral energy and a higher pitch than human speech (Fitch, 1997; Owren & Rendall, 2003). Although some rhesus calls have an acoustic resemblance to human affective vocalizations, adult human listeners do not perceive rhesus calls as being generated by humans (see ratings in the Method section that follows), nor do they explicitly distinguish these calls based on their affective valence (Belin et al., 2008). Testing a preference for speech against the vocalizations of a closely related primate provides a strong test for an early specialization for speech in humans.

Using a contingency procedure in which infant participants could control the presentation of different sounds, we tested neonates on their preference for speech compared to the vocalizations of another primate—the rhesus macaque (*Macaca mulatta*). There are three possible outcomes. First, if neonates prefer speech to rhesus calls, then this supports earlier reports that speech is privileged for human neonates, distinct from the vocalizations of another related species. The neonatal preference for speech would then be based on properties that are not shared with rhesus calls. Second, if neonates prefer rhesus calls to speech, then the task is most likely picking up on a novelty preference. Although this would be a surprising outcome as previous studies showed a neonatal preference for speech over many other novel sounds, previous studies never evaluated the preference for human speech against the calls of a related species. Finally, if neonates show equal interest in speech and rhesus calls, with no preference for one sound over the other, then this suggests that the initial bias for speech may derive from properties shared by speech and nonhuman primate vocalizations. In this case, to ensure that the lack of preference was not simply the result of a methodological failure, it would be important to show—as in earlier work on the neonatal speech preference—that neonates also prefer rhesus vocalizations to other acoustic signals. Finally, we

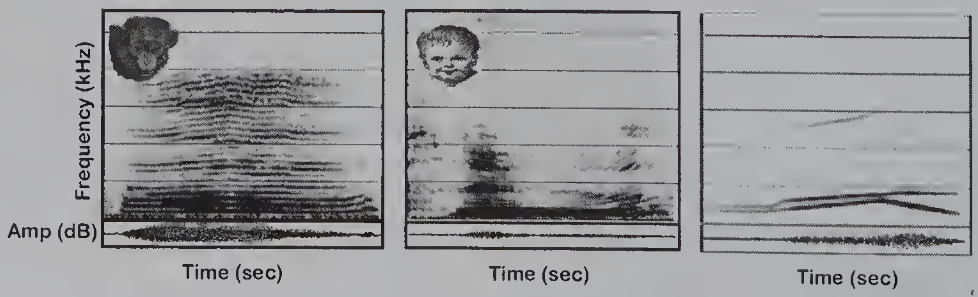

Figure 1. Spectrogram (top) and waveform (bottom) of a rhesus monkey vocalization (coo; on the left), a human speech token ("ploo"; in the middle), and a synthetic nonspeech sound (on the right).
Note. Horizontal lines denote frequency increments of 2000 Hz.

examine the listening preferences of 3-month-old infants.

Experiment 1

We tested human neonates on their preference for speech compared to rhesus calls using an infant-controlled high-amplitude (HA) sucking method (e.g., Butterfield & Siperstein, 1970; DeCasper & Fifer, 1980; Moon, Cooper, & Fifer, 1993; Vouloumanos & Werker, 2007). In this procedure, neonates sucked on a sterilized non-nutritive pacifier to control the presentation of sounds. We presented nonsense speech using English-like speech syllables and rhesus monkey calls in alternating trials, and measured the number of neonates' HA sucks for each of the two types of vocalizations.

Method

Participants

Thirty full-term (minimum of 37.5 weeks gestational age) human neonates (M = 47 hr, range = 18–120 hr; 12 females and 18 males) completed the study. An additional 44 neonates were excluded for noncompliant behavior, such as fussing or falling asleep (24), parental interference (1), or failing to meet established experimental criteria (Floccia, Nazzi, & Bertoncini, 2000; Vouloumanos & Werker, 2007) of a minimum of 10 HA sucks in the first 4 min and at least 1 suck in every subsequent experimental minute (19). Neonates were tested at a birthing Hospital in Vancouver, British Columbia. Reflecting the diversity of the local community, the languages spoken in neonates' home environment varied, with the percentage of English spoken between 0% and 100%. We did not collect additional demographic information about family ethnicity. Parents gave informed consent on behalf of their infants. All procedures were approved by the university's Research Ethics Board.

Stimuli

In selecting specific monkey and human stimuli, it was important to control for factors that in and of themselves might bias infants toward one or the other group of sounds. As neonates listen less to angry and sad voices than they do to happy or neutral voices (Aldridge, 1994, as cited in Walker-Andrews, 1997), we excluded rhesus calls produced during aggressive behaviors (e.g., screams, barks, and copulatory screams). Instead, we selected calls produced during positive social contexts such as affiliative interactions (girneys, coos) and the discovery of food (coos, warbles; Hauser, 2000) considered to be of positive affect in previous studies (Belin et al., 2008; Nicastro & Owren, 2003).

Speech. Ten nonsense speech sounds were produced in infant-directed speech by three native English female speakers (Speaker 1: ''ploo,'' ''keev,'' ''yut,'' ''boola,'' ''nahod,'' ''kraw''; Speaker 2: ''trom,'' ''fi''; Speaker 3: ''dup,'' ''makalak'') with average pitch of 283 Hz, and average duration of 468 ms.

Monkey calls. Ten rhesus monkey calls were recorded on Cayo Santiago, Puerto Rico, from three female rhesus monkeys (Caller 1: 3 coos [social or food related], 3 girneys [affiliative]; Caller 2: 1 coo, 1 warble [food related]; Caller 3: 1 coo, 1 girney) with average pitch of 346 Hz and average duration of 531 ms. Calls were recorded with a highly directional shotgun microphone at a distance of 1–3 m. The calls were selected such that there was a high signal-to-noise ratio, only one concurrent vocalization, and no interference from other biotic sounds. Stimulus duration did not differ, $t(18) < 1$, *ns*, but rhesus calls naturally exhibit a slightly higher pitch, $t(17) = 2.3$, $p < .05$. (For description of acoustic morphology and context, see Hauser, 1992, 1996; Hauser & Fowler, 1992; Hauser & Marler, 1993.)

Adult ratings of vocalizations. Thirty undergraduates rated the 20 primate vocalizations described on a 5-point scale for how likely they were to have been produced by a human. The 10 monkey calls were rated as significantly less human-like than the 10 human nonsense speech ($M = 2.97$, $SE = 0.924$ for monkey vocalizations; $M = 4.63$, $SE = 0.122$ for human nonsense speech), $t(18) = 5.61$, $p < .001$.

Apparatus and Procedure

Neonatal listening preferences were quantified by means of a HA sucking procedure (Eimas, Siqueland, Jusczyk, & Vigorito, 1971) in which the presentation of different sounds was contingent on the newborn delivering an HA suck (Vouloumanos & Werker, 2007). Approximately 2 hr after feeding, neonates were brought to a sound-attenuated room and placed supine in a bassinette. During the experiment, a parent was seated behind and out of reach of the bassinette. An experimenter wearing headphones playing music presented neonates with a sterilized pacifier coupled to a Gould P23 pressure transducer, which was connected to an IBM-PC-compatible computer. After presenting the pacifier to the neonate, the experimenter only interacted with the newborn to reinsert the pacifier if it had been released. If the pacifier could not be reinserted immediately, the neonate's data were discarded from the sample. The computer registered air pressure changes caused by infant sucks.

Each individual infant's sucking amplitude range was measured during a silent baseline minute. The mean baseline HA sucking rate was 33.7 HA sucks/min (*SE* = 2.93). Following the calculation of their baseline sucking amplitude, neonates were presented with a sound stimulus whenever they applied suction in the upper 80% of their sucking amplitude range. The stimulus onset asynchrony (from the start of one stimulus to that of the next) was set at 1500 ms to accommodate the longest sound duration. The presentation rate was thus one stimulus per 1.5 s. All sounds were presented at 70 dB (±4 dB). The presentation of speech and rhesus calls was alternated every minute, with order counterbalanced across participants, and the 8 min postbaseline submitted to analysis. The HA sucking software implements the minute-by-minute change independently of the baby's sucking behavior as in many HA sucking experiments (Bertoncini, Bijeljac-Babic, Blumstein, & Mehler, 1987; Bertoncini, Bijeljac-Babic, Jusczyk, Kennedy, & Mehler, 1988; Floccia et al., 2000; Mehler et al., 1988; Nazzi, Floccia, & Bertoncini, 1998). To ensure that newborns heard sounds during every minute, we excluded newborns that produced fewer than 10 sucks in the first four experimental minutes or 0 sucks during any of the 8 min. Within each minute, tokens were presented randomly with replacement allowing repetitions of a given token. Earlier applications of this procedure have been successful in showing that newborns prefer speech over complex synthetic sounds (Vouloumanos & Werker, 2007).

Results and Discussion

As there were no significant effects of infant sex or sound order on listening preferences ($F < 1$, *ns*), we collapsed across these factors for all analyses. As sampling over blocks can yield more stable measurements and has successfully revealed neonatal preferences in previous studies (Vouloumanos & Werker, 2007), we analyzed HA sucks in two observation blocks (first 4-min block vs. second 4-min block) in a repeated measures analysis of variance (ANOVA). Results indicated no main effects and no interactions (all *ns*). Neonates sucked equivalently for speech ($M = 33.3$ HA sucks, $SE = 2.4$) and for rhesus calls ($M = 33.8$ HA sucks, $SE = 2.7$), $F(1, 29) < 1$, *ns*. An additional ANOVA analyzing preference for speech and monkey calls for each experimental minute also revealed no main effects and no interactions (all *ns*). Next, we examined whether neonates' HA sucking changed over the two observation blocks for speech or for rhesus calls and found no statistically significant effect (using Bonferroni corrections for multiple comparisons) for either speech, $t(29) = 2.12$, *ns*, or rhesus calls $t(29) = 1.02$, *ns* (see Table 1). Thirteen of 30 neonates exhibited a preference for speech (see Figure 2). To examine whether the amount of English exposure in the neonates' home environment had an effect on neonates' listening preferences, we ran an ANOVA with sound type (speech, rhesus) and percentage of English exposure (as estimated by parental report at the time of consent) as a covariate and found no main effect of English exposure, $F(1, 28) < 1$, *ns*, and no modulatory effect of English exposure on neonates' listening preference for speech and rhesus calls, $F(1,28) = 1.19$, *ns*.

Table 1

High-Amplitude (HA) Sucking Across the Three Studies: (a) Speech Versus Rhesus Monkey Calls, (b) Rhesus Monkey Calls Versus Synthetic Sounds, and (c) Speech Versus Synthetic Sounds (Reported in Vouloumanos & Werker, 2007)

Sound comparison	*n*	Sound	HA Sucking Block 1	HA Sucking Block 2	Relative change in HA sucking
Speech versus monkey calls	30	Speech	71.20	61.73	−4.4
		Monkey calls	69.90	64.83	
Monkey calls versus synthetic sounds	16	Monkey calls	68.75	60.50	12.3*
		Synthetic sounds	74.50	54.00*	
Speech versus synthetic sounds[a]	22	Speech	71.91	73.00	14.5*
		Synthetic sounds	76.91	63.45*	

[a] Previously reported in Vouloumanos and Werker (2007).

Note. Neonates' HA sucking decreases significantly across blocks for the synthetic sounds; no significant decrease across blocks is observed for either speech or rhesus monkey calls. The relative change in HA sucking in the speech versus rhesus call comparison is significantly different both from the monkey call versus synthetic sound comparison, and from the speech versus synthetic sound comparison. The relative change in HA sucking for monkey over synthetic sounds is equal to that for speech over synthetic sounds. See the Results section for more details.

$^{*}p < .05$.

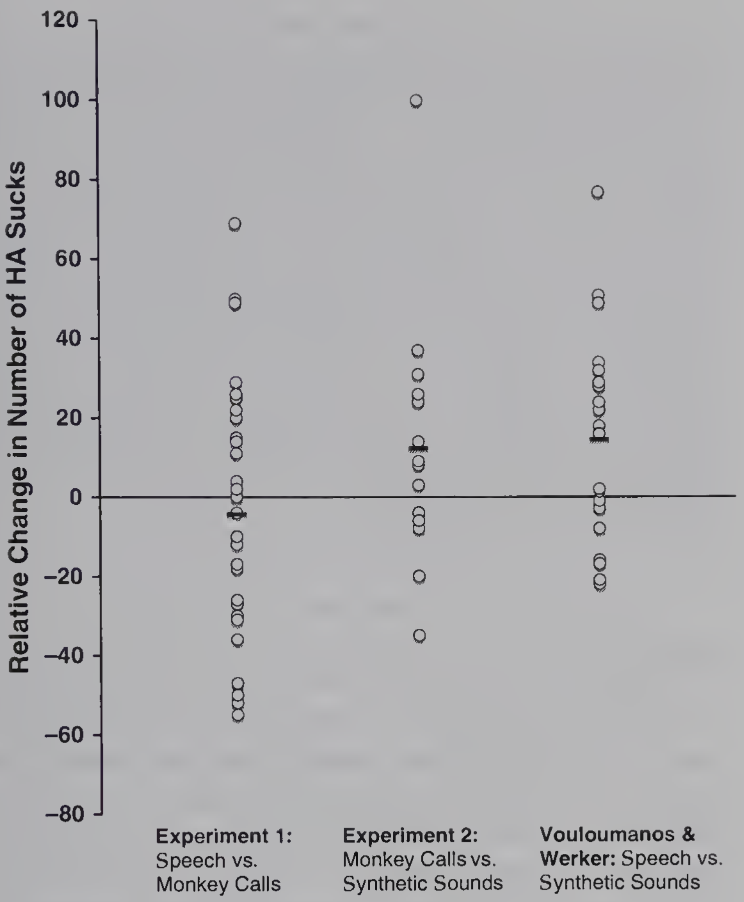

Figure 2. Scatterplot of individual neonates' relative change in the number of high-amplitude sucks for sound types across the three experiments.

Note. For Experiment 1, we plot as positive the relative change for speech over monkey calls; for Experiment 2, we plot as positive the relative change for monkey calls over synthetic sounds; and for Vouloumanos and Werker (2007), we plot as positive the relative change for speech over synthetic sounds.

Although earlier work showed that neonates preferred speech to artificial sounds and manipulated speech sounds (Butterfield & Siperstein, 1970; Peña et al., 2003; Spence & DeCasper, 1987; Vouloumanos & Werker, 2007), this study demonstrates that neonates have no preference for speech over rhesus calls, responding equivalently to both.

Experiment 2

To ensure that the equivalent interest in speech and rhesus calls reflects a legitimate preference for listening to these two types of vocalizations, as opposed to a null result, we ran an additional condition. In a previous study, neonates preferred speech to complex synthetic sounds (Vouloumanos & Werker, 2007). These complex synthetic sounds were composed of four sinusoidal waves that emulated the frequency changes of speech and thus contained a similar pitch contour and some of its spectral features (Vouloumanos & Werker, 2004, 2007); in some contexts, adult listeners can even perceive these types of complex synthetic sounds as speech-like (Remez, Rubin, Pisoni, & Carrell, 1981). In this previous study, neonates manifested a preference for speech by adjusting their sucking rate over the course of the experiment so as to listen to speech more than to the complex synthetic sounds. Over the two observation blocks, neonates in this previous study maintained their HA sucking rate for speech, $t(21) = 0.315$, *ns*, but significantly decreased their sucking for the complex synthetic sounds, $t(21) = 2.92$, $p < .02$ (Vouloumanos & Werker, 2007). To test whether human neonates show a similar sustained interest in listening to rhesus monkey calls, we presented rhesus monkey calls and complex synthetic sounds to 16 neonates. If both speech and rhesus calls are preferred vocalizations for human neonates, then neonates' HA sucking in this experiment should show differential arousal to rhesus monkey calls over complex synthetic sounds.

Method

Participants

Sixteen full-term (minimum of 37.5 weeks gestational age) human neonates (M = 46 h, range = 20–97 hr; 7 females and 9 males) completed the study. An additional 21 neonates were excluded for fussing or falling asleep (10), parental interference (1), or not meeting the established experimental criteria (10). Neonates were tested at a birthing hospital in Vancouver, British Columbia. As in Experiment 1, the percentage of English spoken in neonates' home environment varied between 0% and 100%, and additional ethnographic information was not collected. Parents gave informed consent on behalf of their infants. All procedures were approved by the university's Research Ethics Board.

Stimuli

Monkey calls. These were identical to those used in Experiment 1. As there were four different complex synthetic tokens in total, we randomly selected a different subset of 4 monkey tokens from the full set of 10 tokens for presentation for each neonate.

Synthetic sounds. Synthetic sounds consisted of time-varying sinusoidal waves tracking the main regions of significant energy, namely, the fundamental frequency and the first three formants of a nonsense speech token. By tracking changes across time for the peak frequencies of their speech counterparts, these synthetic sounds follow very closely the spectral and timing changes of speech. The average pitch of the synthetic sounds was 227 Hz, and the average duration was 589 ms. Stimulus pitch did not differ between sound types, $t(8) = 2.2$, *ns*, but synthetic sounds were significantly longer than rhesus monkey calls, $t(8) = 4.1$, $p < .01$ (for a complete description of the stimuli, please see Vouloumanos & Werker, 2004). Consistent with previous studies with similar synthetic sounds (Remez & Rubin, 1993), adults in pilot studies did not report perceiving these synthetic sounds as speech.

Apparatus and Procedure

These were identical to Experiment 1. The presentation of rhesus calls and synthetic tokens was alternated every minute, with order counterbalanced across participants, and the 8 min postbaseline submitted to analysis. Within each minute, tokens were presented randomly with replacement.

Results and Discussion

Neonates preferentially listened to rhesus monkey calls, maintaining their HA sucking for rhesus calls, $t(15) = 2.01$, *ns*, while decreasing their HA sucking for complex synthetic sounds, $t(15) = 2.64$, $p = .038$, over the two observation blocks. Eleven of the 16 neonates exhibited a preference for rhesus monkey calls (see Figure 2). As a final direct test of listening preferences, we compared the relative change in HA sucking across the three studies: Speech versus rhesus calls (Experiment 1), speech versus complex synthetic sounds (Vouloumanos & Werker, 2007), and rhesus calls versus complex synthetic sounds (Experiment 2). In planned comparisons, we found that the HA sucking pattern of neonates' privileging rhesus calls over complex synthetic calls was similar to that of neonates privileging speech over complex synthetic calls (one-tailed, *ns*), and different from neonates that listened to speech and monkey calls equivalently (one-tailed, $p < .05$; see Table 1).

Neonates responded preferentially to speech and to rhesus calls over complex synthetic sounds but showed no preference for speech over rhesus calls. Together, these studies suggest that neonates privilege both speech and calls of rhesus monkeys. The auditory biases of human neonates appear more broadly tuned to properties that are shared by the vocalizations of nonhuman primates.

Experiment 3

To examine whether infants' listening preferences change during early development, we tested 3-month-olds on their preference for speech over rhesus calls. Three-month-old infants were presented with nonsense speech sounds and rhesus monkey calls in alternating trials using an infant-controlled sequential looking preference procedure (Cooper & Aslin, 1990; Vouloumanos & Werker, 2004) in which infants could use their looking behavior to control the presentation of sounds. We measured infants' average looking times for the two types of vocalizations.

Method

Participants

Sixteen 3-month-old infants ($M = 100$ days, age range = 87–111 days) completed the study. An additional 20 infants were excluded as a result of fussing or crying (6), inattention to the screen (5), difficulty seeing infants' eyes (2), failure to look away from the screen to end the trial before the maximum trial length of 60 s had been reached for three or more of the test trials (2), or experimenter error (5). Parents gave informed consent on behalf of their infants. All procedures had been approved by the university's Research Ethics Board.

Stimuli

The auditory stimuli were the same 10 human nonsense speech tokens and 10 rhesus monkey calls that were used in Experiment 1.

Materials and Procedure

Infants were tested using an infant-controlled sequential looking preference procedure (Cooper & Aslin, 1990; Vouloumanos & Werker, 2004) in which infants controlled trial onset and offset by looking at or away from a monitor displaying a fixation checkerboard. Testing was conducted in a sound-attenuated room where infants were seated on a parent's lap in front of a computer monitor. Parents wore headphones playing music to mask the presentation of the experimental sounds. Sounds were played with an average amplitude of 60 dB (±5 dB) from speakers placed below the monitor. Following a musical pretest, infants heard speech and rhesus calls in alternating trials, with order counterbalanced across participants, for a total of eight trials, four trials per sound type.

Infants' attention was drawn to the screen by a red flashing light at the beginning of the experiment and between every trial. Once the infant fixated on the screen, a black and white checkerboard was presented in tandem with one of the sets of sounds. Presentation ceased when the infant looked away from the monitor for a consecutive 2-s period or the maximum trial length of 60 s had been reached. Once the infant looked back at the screen, presentation of the checkerboard recommenced with a new set of sounds. Within each trial, tokens were presented in semirandom order, such that no tokens were ever repeated consecutively. All infants heard a Bach violin concerto in a pretest before the experimental trials began to familiarize them with the procedure. Infants' average looking times for human speech and rhesus monkey calls were calculated based on frame-by-frame offline coding (30 frames/s) of infant looks toward the monitor during each test trial by a coder blind to the experimental condition being tested. Reliability coding performed on 25% of the trials was extremely high (Pearson's $R = .999$, $p < .01$). Three infants were missing values for one trial within a set of four human or four monkey vocalizations; these values were replaced by taking an average of the remaining 15 infants' looking times for that particular sound trial.

Results and Discussion

As there were no significant main or interactive effects of infant sex or order on looking time ($F < 1$, *ns*), we collapsed across these between-subject factors and performed a repeated measures ANOVA on infant looking time with sound type (speech, monkey calls) and trials (1, 2, 3, 4) as within-subject factors. Results revealed a significant main effect of sound type, with 3-month-olds looking longer for speech ($M = 14.6$ s, $SE = 2.01$) compared with rhesus calls ($M = 11.5$ s, $SE = 1.67$), $F(1, 15) = 8.49$, $p = .01$, as well as a main effect of trial, $F(3, 45) = 5.13$, $p < .01$, with overall looking times decreasing in later trials. Twelve of the sixteen 3-month-olds looked longer for speech, as compared to 13 of 30 neonates, Pearson's chi-square $\chi^2(1, N = 46) = 4.22$, $p < .05$ (see Figure 3), confirming a developmental difference in infants' preference for speech relative to rhesus monkey calls.

By at least the age of 3 months, human infants prefer listening to speech compared to rhesus calls. Rapidly in early human development, the relatively broad tuning of neonatal listening preferences is sharpened, becoming selective for speech.

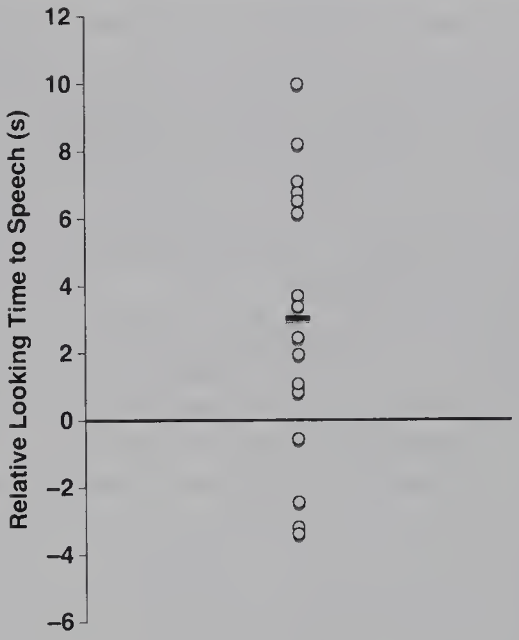

Figure 3. Scatterplot of individual 3-month-olds' relative looking time for speech compared to rhesus monkey vocalizations.
Note. We plot as positive the relative change for speech over monkey calls.

General Discussion

In contrast to previous studies suggesting that humans are born with a listening preference for speech (Vouloumanos & Werker, 2007), these results demonstrate that neonates' listening biases privilege human speech and the calls of another primate, the rhesus macaque. Infants' initial, relatively broad, tuning sharpens rapidly over the course of the first 3 months, resulting in a preference for speech over rhesus calls.

The lack of preference for speech over rhesus monkey calls in neonates is striking, especially when considered in light of previous studies on auditory preferences in human neonates. Neonates typically show preferences for specific speech sounds heard prenatally: They prefer listening to their mother's voice compared to the voice of other females (DeCasper & Fifer, 1980), privilege the rhythmic pattern of their native language over that of unfamiliar languages (Mehler et al., 1988; Moon et al., 1993), and show postnatal recognition of specific songs and stories that had been read to them prenatally (DeCasper & Spence, 1986). These prior findings indicate that the human womb is permeable to sound and, crucially, that the auditory system of the fetus can perceive, encode, and remember some of the specific features of the sounds that are available in the prenatal environment. Given infants' prenatal exposure to speech and their capacity to hear in the third trimester, as well as our selection of speech sounds with attractive intonation patterns (Cooper, Abraham, Berman, & Staska, 1997; Fernald, 1985), one might have expected neonates to prefer speech to monkey calls. Instead, the comparison between speech and monkey calls—as well as the experimental condition confirming a preference for rhesus monkey calls over complex synthetic sounds—demonstrates that speech and rhesus monkey calls can be similarly engaging to newborns.

Why do neonates fail to show a preference for relatively more familiar speech sounds when these are compared to rhesus monkey calls given that they recognize and prefer familiar native and maternal speech vocalizations when various *speech* sounds are contrasted? Previous speech preference studies with newborns used full sentences composed of connected speech (DeCasper & Fifer, 1980; Mehler et al., 1988; Moon et al., 1993). In contrast, our preference studies used isolated words (as in Vouloumanos & Werker, 2004, 2007). Compared to single nonsense words, the connected speech of sentences is longer and, partly as a function of greater length, conveys more of the acoustic (e.g., syllable length, formant structure) and linguistic (e.g., rhythmic, intonational) properties of speech. Sentences may thus allow neonates to extract more information about the signal, including acoustic cues to maternal voice and native language. A comparison of connected speech and rhesus monkey vocalizations could thus reveal a neonatal preference for speech, but isolated words do not.

Neonates may have a general interest in the acoustic properties of voices, harmonically rich sounds composed of quasiperiodic waves punctuated by spectral and temporal irregularities (e.g., Belin, 2006). If this were the case, any vocalization produced by a range of species may engage newborns. More narrowly, neonatal listening preferences may extend to acoustic properties that are shared by other nonhuman primates or may be restricted to vocalizations that show more humanlike spectral filtering. The vocal repertoire of rhesus monkeys is certainly not unique among nonhuman primates, as many other monkeys and apes demonstrate both spectral and temporal variation, with resulting differences in affective and semantic information (Arnold & Zuberbuhler, 2006; Owren, Seyfarth, & Cheney, 1997; Rendall, Seyfarth, Cheney, & Owren, 1999; Zuberbuhler, Cheney, & Seyfarth, 1999). More importantly for this study, rhesus monkeys and humans show similarities in the production mechanisms of their vocalizations. Like humans, rhesus monkeys may be able to control the laryngeal source of their calls independently of the supralaryngeal filter, suggesting possible similarities between human and rhesus neuromotor organization (Hauser & Schon-Ybarra, 1994; Hauser et al., 1993; Rendall et al., 1998). Although few studies have directly examined how humans perceive rhesus monkey calls (cf. Belin et al., 2008; Lewkowicz & Ghazanfar, 2006; Owren & Rendall, 2003), the superficial similarities between the two species' vocalizations may have been sufficient to engage neonates.

What accounts for the developmental shift in infant listening preferences between birth and 3 months? One possibility is that newborns simply could not discriminate between speech and rhesus monkey calls, whereas 3-month-olds did discriminate and therefore preferred listening to speech. Although this possibility cannot be ruled out, it seems unlikely because newborns robustly discriminate much more subtle acoustic differences, for example, between [ba] and [da] (Bertoncini et al., 1987) and between [taep] and [paet] (Moon, Bever, & Fifer, 1992). Our results are thus most likely explained by neonates' engagement with the sounds rather than a failure to discriminate.

A second possibility is that 3-month-olds' preference for speech is a product of increased experience with specific properties of English. Although the increased experience is undeniable, other studies have shown that infants do not recognize native language sound sequences or stress until 9 months of age (Jusczyk, Cutler, & Redanz, 1993; Jusczyk, Friederici, Wessels, & Svenkerud, 1993) and, crucially, do not become attuned to the specific speech sounds of their native language until 6–10 months (Kuhl et al., 1992; Werker & Tees, 1984). Given this relatively late tuning (6–10 months) to native language sound structure, it seems unlikely that the speech preference observed in these relatively younger 3-month-olds in our studies derived specifically from properties of English. Instead, accrued exposure to speech of any kind, or human vocalizations in general, is more likely to contribute to the sharpening of infant preferences.

Finally, the developmental shift may also reflect a shift in infants' attention to different properties of sounds. By 3 months, infants may start to attend to some characteristic properties of speech, such as the alternations between rapid frequency transitions and steady-state frequencies that characterize consonant–vowel alternations (Ladefoged, 2006). Concurrently or alternatively, infants may attend to the specific frequency range (50–5000 Hz) that is characteristic of the human voice. In this latter case, neutral and positively valenced vocalizations that are recognized by infants as human productions, including yawns and laughter, would trigger infants' attention.

The observed shift from more general to species-specific processing in the vocal domain parallels recent results on infant face processing and cross-modal matching: Infants begin life without a human-specific face bias but by 9 months show better processing of human faces compared to the faces of other species (Lewkowicz & Ghazanfar, 2006; Pascalis et al., 2002). Such tuning mechanisms have been observed not only for faces but for language as well. Infants' initial language-general discrimination abilities become language specific by the end of their 1st year (Kuhl et al., 1992; Werker & Tees, 1984). It seems likely that tuning mechanisms are at work in early infancy, sharpening broad initial biases into more specific ones in many domains, and that this may represent a general principle of early perceptual development (Scott, Pascalis, & Nelson, 2007).

Auditory tuning to conspecifics, observed here by 3 months, appears earlier than visual tuning to conspecifics, apparent only at 9 months (Lewkowicz & Ghazanfar, 2006; Pascalis et al., 2002). This is likely because of a combination of maturational and experiential differences in the two systems. Specifically, whereas the auditory system appears functional and responsive by the 6th month of gestation (Gerhardt & Abrams, 2000; Kisilevsky et al., 2003), the visual system, although functional before birth, can only respond to external visual stimuli such as faces after birth. Humans become tuned to conspecific auditory stimuli, and speech in particular, earlier and on a faster time scale (6 vs. 9 months of relevant experience) than they become tuned to conspecific faces. This may very well be because speech, the communicative signal of human conspecifics, *is* special, and rapid tuning reflects this special status.

Early Gesture Predicts Language Delay in Children With Pre- or Perinatal Brain Lesions

Eve Sauer, Susan C. Levine, and Susan Goldin-Meadow
University of Chicago

Does early gesture use predict later productive and receptive vocabulary in children with pre- or perinatal unilateral brain lesions (PL)? Eleven Children with PL were categorized into 2 groups based on whether their gesture at 18 months was within or below the range of typically developing (TD) children. Children with PL whose gesture was within the TD range developed a productive vocabulary at 22 and 26 months and a receptive vocabulary at 30 months that were all within the TD range. In contrast, children with PL below the TD range did not. Gesture was thus an early marker of which children with early unilateral lesions would eventually experience language delay, suggesting that gesture is a promising diagnostic tool for persistent delay.

Children with pre- or perinatal unilateral brain lesions (PL) exhibit marked plasticity for language functions. Even when their lesions affect classic language areas, children typically do not exhibit the aphasias that adults with similar lesions display (e.g., Bates & Dick, 2002; Feldman, 2005; Levine, Kraus, Alexander, Suriyakham, & Huttenlocher, 2005; Reilly, Levine, Nass, & Stiles, 2008; Stiles, Reilly, Paul, & Moses, 2005; Woods & Teuber, 1978). However, children with PL often exhibit delays in both productive and receptive language (e.g., Bates, Thal, & Janowsky, 1992; Chilosi, Cipriani, Bertuccelli, Pfanner, & Cioni, 2001; Feldman, Holland, Kemp, & Janosky, 1992; Marchman, Miller, & Bates, 1991; Thal et al., 1991). Importantly, these delays are transient for some children with PL but persistent for others (Bates et al., 1997; Feldman et al., 1992; Thal et al., 1991; Vicari et al., 2000). The question we ask here is whether early child gesture can be used to predict subsequent vocabulary development in children with PL, just as it can for typically developing (TD) children (Rowe & Goldin-Meadow, 2009a). If so, gesture may be a potential early diagnostic indicator of which children with PL will exhibit subsequent language delays and which will catch up and thus fall within the normative range.

The relation between early gesture and vocabulary growth has been extensively studied in TD children. Many children begin by communicating through gesture and over time replace gesture with speech (Bates, Benigni, Bretherton, Camaioni, & Volterra, 1979; Bates & Dick, 2002; Iverson, Capirci, & Caselli, 1994). Early gesture use not only precedes subsequent vocabulary development, it also predicts subsequent vocabulary production and comprehension (Goldin-Meadow & Butcher, 2003; Iverson & Goldin-Meadow, 2005; O'Reilly, Painter, & Bornstein, 1997; Rowe & Goldin-Meadow, 2009a, 2009b; Rowe, Özçaliskan, & Goldin-Meadow, 2006, 2008). For example, Iverson and Goldin-Meadow (2005) were able to predict which lexical items entered a child's spoken vocabulary from looking at the child's gestures several months earlier. Specifically, they found that children produced a deictic pointing gesture to refer to an object, person, or location (e.g., point at a ball) approximately 3 months before producing a word for that object, person, or location (e.g., the word *ball*). As a second example, Rowe et al. (2008) found that the number of different meanings children conveyed with their gestures at 14 months was significantly related to the size of their receptive vocabularies at 42 months (see also Rowe & Goldin-Meadow, 2009a, 2009b).

This research was supported by P01HD40605 from NICHD and a grant from the Brain Research Foundation. We thank the participating families for sharing their child's language development with us; K. This relation held even after controlling for the number of different spoken words that the children produced at 14 months.

Previous research has examined gesture use in children with PL but has not directly related it to language delay. For example, Bates et al. (1997) found that children with early right hemisphere lesions show delays in gesture between 10 and 17 months of age, based on parent responses on the MacArthur Communicative Development Inventory (MCDI; see also Marchman et al., 1991). Are the children who exhibit delays in gesture the same children who exhibit delays in vocabulary development? We might expect delays in gesture use to go hand in hand with language delays simply because gesture and language form an integrated system, not only in adults (McNeill, 1992) but also in TD children at the early stages of language learning (Goldin-Meadow, 2003). If the gesture–language system is robust in the face of early unilateral brain injury, children whose language development is proceeding at a typical pace should display typical gesture, and children whose language is delayed should display delays in gesture. Moreover, early gesture should predict subsequent language development as it does in TD children.

It is, of course, possible that gesture and language do *not* form an integrated system in children with PL. Early brain injury could disrupt the relation between language (both receptive and expressive) and gesture, leading to different patterns of gesture–language development than those observed in TD children. In addition, children with PL frequently have motor impairments involving the contralesional hand and arm (Huttenlocher, 2002; Levine, Huttenlocher, Banich, & Duda, 1987; Mercuri et al., 2004; Staudt et al., 2002). Such impairments might limit the use of gesture in early language development and thus disrupt the gesture–language link in children with PL.

The goal of our study is to explore whether early child gesture predicts later vocabulary size in children with PL as it does in TD children. If so, not only will we have evidence that gesture and language form a tightly organized system that can withstand early injury to the brain, but we also will have uncovered an early marker that might be used to identify those children with PL who are at risk for subsequent language delay and who might benefit from early intervention.

Method

Participants

Participants were 11 children with PL (8 girls, 3 boys) studied longitudinally between 18 and 30 months. For 7 of the 11 children, we also have data about language comprehension based on parental responses on the MCDI (Fenson et al., 1993). Lesion characteristics of the individual children are given in Table 1; for 10 of the 11 children, these characteristics were based on magnetic resonance imaging (MRI), and for the remaining child, the characteristics were based on detailed medical notes from previous CT and MRI scans. Two pediatric neurologists reviewed all of the information available and agreed that each of the 11 children has a unilateral lesion. The lesions were either the result of cerebrovascular infarcts of the middle cerebral artery territory (CV lesions), primarily

Table 1
Lesion Characteristics for Individual Children With Pre- or Perinatal Unilateral Brain Lesions

ID	Sex	Hemisphere	Size	Type	Location
1	Female	Left	Large	Cerebrovascular infarct	F, T, P, O, subcortical
2	Female	Right	Large	Cerebrovascular infarct	F, T, P, subcortical
3	Male	Right	Small	Periventricular	Subcortical
4	Female	Left	Large	Cerebrovascular infarct	F, T, P, subcortical
5	Male	Left	Medium	Cerebrovascular infarct	F, T, P, subcortical
6	Male	Left	Small	Periventricular	F, T, subcortical
7	Female	Left	Large	Cerebrovascular infarct	F, T, P, O subcortical
8	Female	Left	Large	Cerebrovascular infarct	F, T, P
9	Female	Right	Large	Cerebrovascular infarct	F, T, P, O, subcortical
10	Female	Left	Small	Periventricular	T, subcortical
11	Female	Left	Small	Periventricular	Details not available

Note. F = frontal, T = temporal, P = parietal, O = occipital, subcortical = involves subcortical areas.

affecting inferior frontal and superior temporal regions, or the result of periventricular lesions (PV lesions), primarily affecting subcortical structures and white matter tracts. Periventricular lesions in very low birthweight, prematurely born children have been the focus of much previous literature (although see Krägeloh-Mann & Horber, 2007, for a review of recent studies of PV lesion in full-term infants). Our sample is more restricted because we excluded children born earlier than 36 weeks gestation. Children were recruited through area health providers and parent support groups, and came from middle- to upper-middle-class Caucasian families. All children were being raised as monolingual English speakers.

Lesions were characterized by type (CV or PV), laterality (left or right), and size (small, medium, or large). Lesion size was determined using the following criteria: Small lesions affected only one lobe or minimally affected subcortical regions, medium lesions affected more than one lobe or extended into more than one subcortical region, and large lesions affected three or four lobes and often affected subcortical regions and the thalamus (large lesions were typically cerebrovascular infarcts). Four children with PL had small lesions, 1 had a medium lesion, and 6 had large lesions; we collapsed children with small and medium lesions into a single group based on previous findings indicating that the language development of these groups tend to pattern together (Brasky, Nikolas, Meanwell, Levine, & Goldin-Meadow, 2005). Four of the children had periventricular lesions (PV) and 7 had cerebrovascular infarcts (CV). Eight children had left hemisphere lesions and 3 had right hemisphere lesions.

To situate the gesture and speech development of children with PL within a normative sample, we also observed 53 TD children (26 girls, 27 boys) between 18 and 26 months whose gesture and speech development have been previously described (Rowe et al., 2006, 2008; Rowe & Goldin-Meadow, 2009a, 2009b). All TD children were being raised as monolingual English speakers and had no known medical conditions. The families of the TD children reflected the demographic diversity of the Chicago area in terms of family income and ethnicity, and thus contained families of low, middle, and high socioeconomic status (SES). In contrast, the families of the children with PL were skewed toward the high end of the SES continuum. Because children from higher SES families tend to have larger vocabularies than children from lower SES families (Hart & Risley, 1995), the SES difference between the two groups would work against our finding language delays in the children with PL. Furthermore, findings from Rowe et al. (2008) suggest that early gesture predicts subsequent vocabulary comprehension in TD children regardless of SES. Thus, the SES difference between the two groups is not likely to affect the pattern of results.

Procedures

All children were observed in their homes for 90 min while interacting naturally with their primary caregivers at 18, 22, and 26 months. Parents were asked to perform their everyday activities and interact with their children as they typically would. The Peabody Picture Vocabulary Test–Third Edition (PPVT–3; Dunn & Dunn, 1997), a normed test of vocabulary comprehension, was given to the children at 30 months.

Coding Speech and Gesture

All child speech produced during each videotaped session was transcribed. Sounds that were reliably used to refer to entities, properties, or events (e.g., ''doggie,'' ''nice,'' ''broken''), along with onomatopoeic sounds (e.g., ''meow,'' ''choo-choo'') and conventionalized evaluative sounds (e.g., ''oopsie,'' ''uh-oh''), were counted as words. We established reliability for our speech transcripts by having a second individual transcribe 20% of the videotapes; reliability was achieved when the second coder agreed with the first on 95% of the transcription decisions.

Any communicative hand movement that did not involve direct manipulation of objects (e.g., twisting a jar open) or a ritualized game (e.g., patty cake) was considered a gesture. Each gesture was classified as deictic, iconic, or conventional: (a) *Deictic gestures* were those that indicated concrete objects, people, or locations. We considered these objects, people, and locations to be the referents of the deictic gestures (e.g., pointing to a dog referred to a *dog*, holding up a bottle referred to a *bottle*). (b) *Iconic gestures* were those that depicted the attributes or actions of an object via hand or body movements (e.g., moving the index finger in circles to convey a ball *rolling*). (c) *Conventional* gestures were those whose forms and meanings are prescribed by the culture (e.g., nodding the head to mean *yes*, extending an open palm next to a desired object to mean *give*). We assessed reliability for gesture on a subset of the videotaped sessions coded by an independent coder. Agreement between coders was 88% (κ = .76; $N = 763$) for identifying gestures and 91% (κ = .86; $N = 375$) for assigning meanings to gestures.

Measures

We calculated the number of unique spoken words (speech types) that each child produced during a single session and used this measure as an index of the child's productive vocabulary in speech at each age. Several decisions were made as to what constituted a word type. Morphologically inflected variants of words (e.g., *run*, *running*) were considered a single type. Words produced in imitation of the mother were included in the corpus of child word types, as were words that the child produced in the context of book reading. We included imitations because children typically only imitate linguistic structures that are within their spontaneous language reach (Slobin & Welsh, 1967). Furthermore, the children with PL produced a very small number of imitations ($M = 1.09$, accounting for only 1.53% of their total speech types), as did the TD children ($M = 1.42$, accounting for 1.9% of their total speech types). Thus, it is likely that including imitations has little effect on the results. The number of word types produced by each child at each session served as our measure of productive vocabulary.

The PPVT–3 (Dunn & Dunn, 1997), administered at 30 months, served as our measure of children's receptive vocabulary. We chose this measure because it is widely used, sensitive to individual differences, standardized, and can be used reliably with children as young as 30 months.

We calculated the number of unique gesture meanings (gesture types) that each child produced at each session. We counted gestures that conveyed different meanings as unique gesture types. The meaning assigned to a deictic gesture was the object, person, or place to which the deictic gesture referred. Note that under this system, each pointing gesture indicating a different entity is considered a unique type. For example, if a child pointed to a ball and a cup, the child would be given credit for two gesture types in his repertoire, *ball* and *cup*. This procedure for attributing meaning to early child gesture has been used in previous studies and, importantly, results in systematic patterns. For example, when this system is used to code early child communications in TD children, we are able to predict the size of a child's later receptive vocabulary (Rowe & Goldin-Meadow, 2009a, 2009b) and the onset and nature of the child's two-word speech (Goldin-Meadow & Butcher, 2003; Iverson & Goldin-Meadow, 2005; Özçaliskan & Goldin-Meadow, 2005; see Goldin-Meadow & Mylander, 1984; Iverson & Goldin-Meadow, 2005, for further justification of the coding system, and details of how meanings were assigned to gestures).

Results

Gesture Use From 18 to 26 Months in Children With PL

We first investigated the spontaneous use of gesture in children with PL at 18, 22, and 26 months. When looking at overall amount of gesturing, we find that most of the gestures that the children with PL produced at all three ages were deictic gestures (average across ages = 72%), as were the gestures produced by the TD children (average across ages = 75%) and there was not a significant difference between children with PL and TD children on this measure ($F = 1.05$, $p = .31$). Also, children with PL did not differ significantly from TD children in total number of gestures produced at 18 or 22 months of age (18 months: $t = 1.39$, $p = .17$; 22 months: $t = 0.32$, $p = .75$). But there was a marginally significant difference between the groups at 26 months ($t = 1.86$, $p = .07$), with children with PL producing an average of 75 gestures ($SD = 38.35$) and TD children producing an average of 113 gestures ($SD = 63.96$) during the 90-min session.

We next turn to our measure of gesture use: gesture types. We chose to use gesture types rather than the total number of gestures because the gesture type measure captures the diversity of meanings each child conveyed in gesture and, in this sense, is a close analog of our speech type measure. Moreover, the number of gesture types was highly correlated with the total number of gestures in our sample of children with PL: $\rho = .96$, $p < .001$ at 18 months; $\rho = .93$, $p < .001$ at 22 months; and $\rho = .96$, $p < .001$ at 26 months (Spearman rank-order correlations). Gesture types were predominantly deictic gestures for both children with PL and TD children (PL: 86% average across ages; TD: 82% average across ages). TD children and children with PL did not significantly differ in the proportion of gesture types produced with a deictic gesture ($F = 1.18$, $p = .28$).

As a group, the children with PL produced approximately the same number of gesture types as the TD children. On average, the children with PL produced 28.73 gesture types at 18 months

(*SD* = 21.89), 45.55 gesture types at 22 months (*SD* = 22.94), and 38.64 gesture types at 26 months (*SD* = 18.77). Figure 1 displays the mean number of gesture types that the children with PL produced in relation to the gesture type data from the TD children at each age. The boxes in the graph represent the interquartile range for the 53 TD children; the line in the middle of each box represents the median for the TD children and the tails represent the 5th and 95th percentiles. Note that, as a group, the children with PL were close to the median for the TD children's production of gesture types and *t* tests confirmed that there were no significant differences between groups (18 months: $t = 0.68$, $p = .50$; 22 months: $t = -0.67$, $p = .50$; 26 months: $t = 0.66$, $p = .51$).

There was, however, a great deal of variability within the group of children with PL. To explore this variability, we divided the children with PL into two groups based on their production of gesture types at 18 months: (a) Children in the LOW group fell below the 25th percentile for gesture production at 18 months in the TD group (25th percentile = 14.5 gesture types). Children in the HIGH group fell above the 25th percentile. Thus, we used the 25th percentile as a cutoff to identify children at the low end of the typical range (Thal et al., 1991). Based on these criteria, 5 of the 11 children with PL were classified into the LOW gesture group, and 6 were classified into the HIGH gesture group.

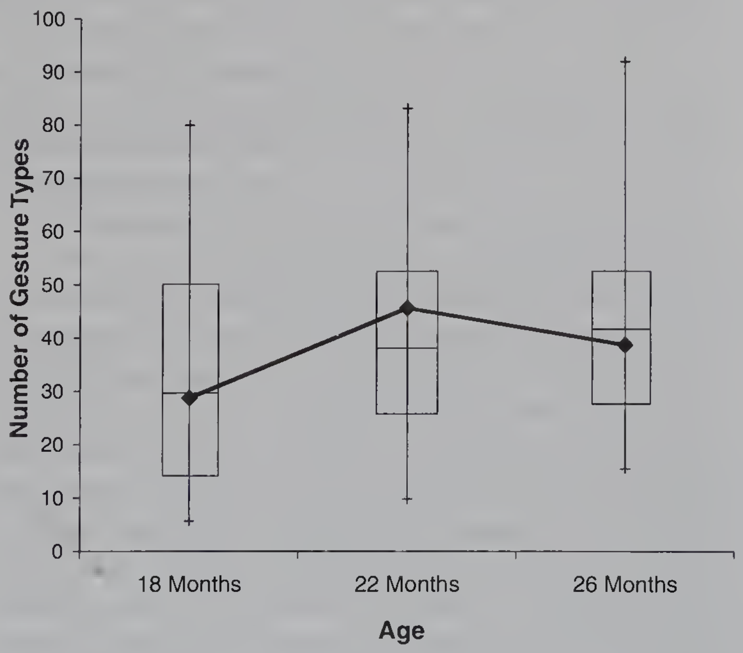

Figure 1. Mean number of gesture types that the children with pre- or perinatal unilateral brain lesions produced at each observation session.
Note. The boxes in the graph represent the interquartile range for gesture types in the typically developing (TD) children; the line in the middle of each box represents the median for TD children, and the tails represent the 5th and 95th percentiles.

Importantly, there was stability in the children's gesture use between 18 and 26 months: All 5 of the children who were assigned to the LOW gesture group on the basis of their 18-month performance fell below the 25th percentile cutoff on at least one of the other two sessions (22 and 26 months); 2 of these children fell below the cutoff on both sessions. Moreover, all 6 of the children assigned to the HIGH gesture group on the basis of their 18-month performance fell above the cutoff on both of the other two sessions. We ran permutation tests at each age (Hesterberg, Moore, Monaghan, Clipson, & Epstein, 2006) to determine whether the number of gesture types produced by the HIGH gesture group differed significantly from the number produced by the LOW gesture group. The HIGH gesture group not only produced significantly more gesture types than the LOW gesture group at 18 months (the age at which children were divided into groups, mean difference = 33.6, $p = .006$), but they also produced more gesture types at 22 months (mean difference = 39.5, $p < .001$) and at 26 months (mean difference = 30.87, $p = .002$; see Figure 2). Thus, early differences in gesture use in the children with PL were stable over time.

Does Gesture Production at 18 Months Predict Later Productive Vocabulary?

We next investigated whether gesture use at 18 months can be used to predict later speech use. On average, the children with PL produced 15.36 (*SD* = 14.64) speech types at 18 months, 56.91 (*SD* = 36.44) at 22 months, and 123.36 (*SD* = 77.23) at 26 months. Thus, as a group, the children with PL increased the number of different words they produced over time. However, there was once again a great deal of variability within the group. Can this variability be related to gesture use at 18 months?

Figure 3 presents the mean number of speech types children in the LOW and HIGH gesture groups produced at each age, displayed in relation to the speech type data from the TD children. We ran permutation tests at 18 months to determine whether the number of speech types produced by the HIGH gesture group differed significantly from the number produced by the LOW gesture group. At 18 months, the age used to divide the children into LOW and HIGH gesture groups, the HIGH group produced slightly more speech types than

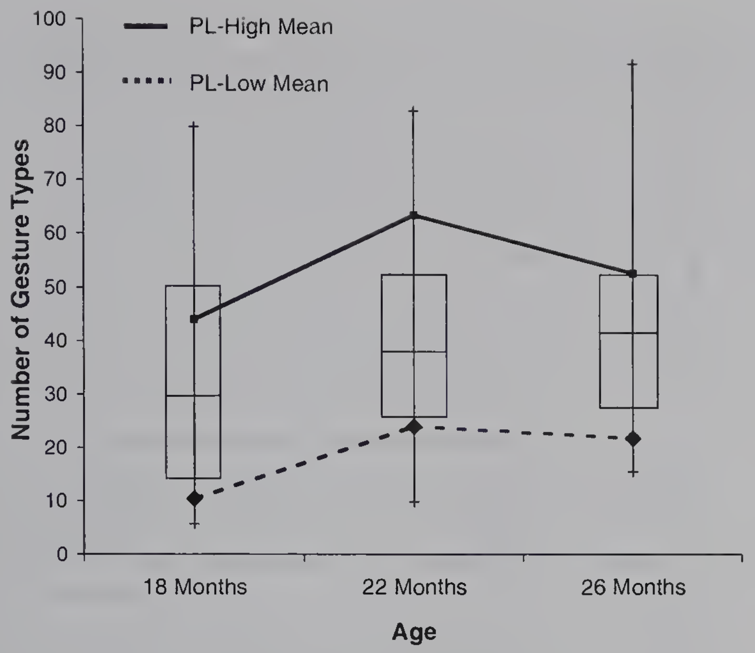

Figure 2. Mean number of gesture types produced by children with pre- or perinatal unilateral brain lesions (PL) in the HIGH and LOW gesture groups at each observation session.
Note. Children with PL were divided into gesture groups based on their production of gesture types at 18 months. The boxes in the graph represent the interquartile range for gesture types in the typically developing (TD) children; the line in the middle of each box represents the median for TD children and the tails represent the 5th and 95th percentiles.

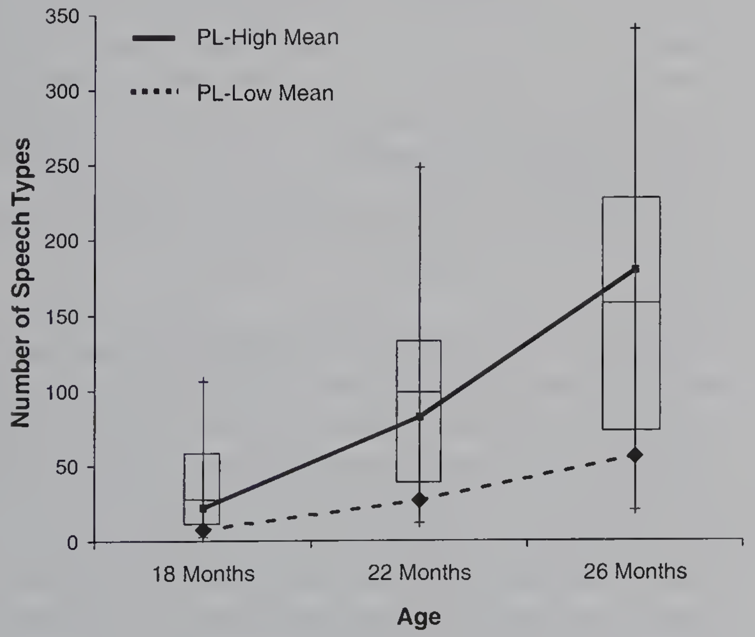

Figure 3. Mean number of speech types produced by children with pre- or perinatal unilateral brain lesions (PL) in the HIGH and LOW gesture groups at each observation session.
Note. Children with PL were divided into gesture groups based on their production of gesture types at 18 months. The boxes in the graph represent the interquartile range for speech types in the typically developing (TD) children; the line in the middle of each box represents the median for the TD children, and the tails represent the 5th and 95th percentiles.

the LOW group, but the difference was not reliable (mean difference = 14.6, $p = .112$). At 18 months, all 5 LOW gesture children fell below the TD 25th percentile for speech types, but 3 of the 6 HIGH gesture children did as well (Fisher exact probability = .12). In other words, at 18 months, it was not possible to reliably distinguish the two groups on the basis of their speech use, only their gesture use.

The interesting question, however, is whether gesture use at 18 months presages *later* speech use. We ran permutation tests at 22 and 26 months to determine whether the number of speech types produced by the HIGH gesture group differed significantly from the number produced by the LOW gesture group and found that they did. The HIGH gesture group reliably produced more speech types than the LOW gesture group at 22 months (mean difference = 55.2, $p = .003$) and at 26 months (mean difference = 123.5, $p = .005$). Moreover, at 22 months, all 5 LOW gesture children continued to fall below the TD 25th percentile for speech types but none of the 6 HIGH gesture children did (Fisher exact probability = .002). At 26 months, 4 of the 5 LOW gesture children fell below the TD 25th percentile for speech types, compared to none of the 6 HIGH gesture children (Fisher exact probability = .01). Although the sample is small, we can use gesture production at 18 months to predict which children will be below the TD 25th percentile in speech production at 22 and 26 months with some precision: At 22 months, positive predictive value for LOW gesture children to be below the TD 25th percentile was 1.00, and sensitivity was 1.00; at 26 months, positive predictive value was .80 and sensitivity was 1.00. We used categorical analyses (rather than regression analyses) to test whether later speech production can be predicted from early gesture use because our data do not meet the assumptions for linear regression. However, it is worth noting that 18-month gesture does significantly correlate with productive vocabulary at both 22 and 26 months (22 months: $\rho = .81$, $p = .002$; 26 months: $\rho = .81$, $p = .003$, Spearman's rank-order correlations).

Does Gesture Production at 18 Months Predict Later Receptive Vocabulary?

We have found thus far that differences in gesture production in children with PL at 18 months predict later differences in *productive* vocabulary. We next ask whether early gesture use also predicts later differences in *receptive* vocabulary, that is, performance on the PPVT–3. In addition to extending our language probes from production to comprehension, using the PPVT–3 has the advantage of allowing us to assess children's performance on a standardized measure of language development. Moreover, the PPVT–3 relies on a different data collection technique from our speech production measure, one that is less tightly tied to our gesture measure. Our speech and gesture production measures both come from spontaneous communication during a 90-min period. In contrast, the PPVT–3 is a normed and validated receptive vocabulary test in which the child is given a word and must select the picture he thinks the word refers to out of a distractor set. The PPVT–3 thus allows us to test the robustness of the relation between gesture and early language.

The children with PL had an average PPVT–3 standard score of 84.64 (*SD* = 21.82). This score is approximately 1 *SD* below the average score for this test (*M* = 100, *SD* = 15; Dunn & Dunn, 1997). Thus, as a group, the children with PL exhibited relatively low vocabulary comprehension. However, there was great variability in the vocabulary comprehension scores of the children with PL, ranging from a low of 45 to a high of 113. The standard deviation for the group of children with PL was 21.8, considerably higher than the standard deviation of 15 in the PPVT–3 norms. Thus, some children with PL were performing well within the average range on the PPVT–3, whereas others were falling far below that range.

Can we predict performance on the PPVT–3 at 30 months from the gestures the children produced a year earlier, at 18 months? On average, children in the LOW gesture group (*M* = 66.8, *SD* = 16.65) scored significantly lower on the PPVT–3 than children in the HIGH gesture group (*M* = 99.5, *SD* = 12.15) (*U* = 1.00, *p* = .009, Mann–Whitney). Moreover, all 5 LOW gesture children fell below the 25th percentile for the PPVT–3, whereas only 2 of the 6 HIGH gesture children did (Fisher exact probability = .045). Thus, positive predictive value for LOW gesture children to be below the 25th percentile on the PPVT–3 was 1.00, and sensitivity was .71.

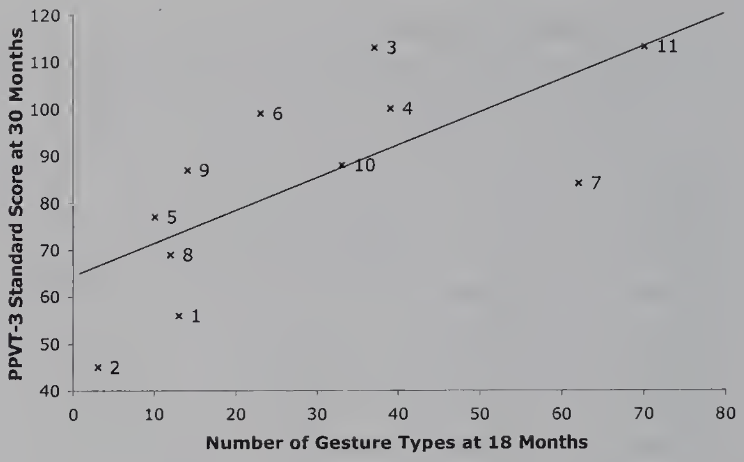

Figure 4. The relation between the number of gesture types produced at 18 months and vocabulary comprehension score on the Peabody Picture Vocabulary Test–Third Edition (PPVT–3) at 30 months in children with pre- or perinatal unilateral brain lesions.

Note. Each x represents an individual. The labels correspond to the ID numbers in Table 1. The five leftmost points (1, 2, 5, 8, 9) represent children in the LOW gesture group. The regression line on the graph is from Model 1.

Table 2

Regression Models Predicting Peabody Picture Vocabulary Test–Third Edition Scores at 30 Months Using Gesture Types and Speech Types at 18 Months in Children With Pre- or Perinatal Unilateral Brain Lesions (n = *11*)

	Vocabulary Comprehension, *B*(*SE*)	
	Model 1	Model 2
Intercept	64.77** (8.50)	61.05** (9.57)
Child gesture types at 18 months	0.69* (0.24)	0.65* (0.25)
Child speech types at 18 months		0.33 (0.37)
R^2 statistic (%)	48.1	52.8

**p* < .05. ***p* < .01.

We also explored the relation between 18-month gesture and 30-month receptive vocabulary using a continuous measure of gesture production. Figure 4 presents a scatter plot of the relation between gesture types at 18 months (*x*-axis) and receptive vocabulary (PPVT–3) at 30 months (*y*-axis); each point represents an individual child. We conducted Spearman rank order correlations between the number of gesture types a child produced at 18 months and that child's PPVT–3 standard score at 30 months, and found a significant relation between the two measures (ρ = .80, *p* = .003). Importantly, the number of speech types a child produced at 18 months did *not* significantly correlate with that child's PPVT–3 standard score at 30 months (ρ = .34, *p* = .31), presumably because there was very little variation in the number of speech types these children produced at 18 months.

We then used a linear regression model to explore whether gesture production at 18 months predicts vocabulary comprehension at 30 months (Table 2). The data meet the assumptions of linear regression required for these analyses: There is a linear relation, the residuals are normally distributed and all are within ±2, and there is no evidence that homeoskedasticity is violated. We found that number of gesture types at 18 months significantly predicted PPVT–3 scores at 30 months, accounting for 48.1% of the variance (Model 1). When we included the number of child speech types at 18 months in the regression model, the number of gesture types at 18 months continued to significantly predict 30-month word comprehension on the PPVT–3 (Model 2); in fact, it was the only significant predictor and Model 2 accounted for 52.8% of the variance in children's PPVT–3 scores. Thus, early child gesture predicts later receptive vocabulary even when controlling for early child speech.

We have found that for children with PL, variability in early gesture use predicts later variability in receptive vocabulary. But is gesture use the only measure that predicts later receptive vocabulary in these children? It is likely that the children also varied in their ability to comprehend spoken language at the early time point. Variability in early language comprehension might then be as good as, or an even better, predictor of later variability in receptive vocabulary than early gesture use. To explore this possibility, we used the 14-month MCDI language comprehension score, which was available on 7 of the 11 children (the parents of 2 of the 4 missing children did not return the MCDI; the other 2 children did not begin our study until 18 months and the age-appropriate version of the MCDI for 18-month-olds does not contain a language comprehension measure). As expected, we found that 14-month MCDI language comprehension scores were related to 14-month gesture production measures ($\rho = .75$, $p = .05$). However, 14-month MCDI language comprehension scores showed only a small, and not significant, correlation with 30-month PPVT scores ($\rho = .25$, $p = .59$). In contrast, 14-month gesture production for these 7 children showed a higher, and marginally significant, correlation with 30-month PPVT ($\rho = .63$, $p = .07$). Consistent with these findings, in analyses of the 53 TD children who served as the normative base for the current study, Rowe and Goldin-Meadow (2009b) found that 14-month language comprehension, as measured by the CDI, did *not* relate to children's 42-month PPVT scores, whereas 14-month gesture production did. Although early gesture and early language comprehension skills have *both* been found to predict later language production in previous work on late-talkers (Thal & Tobias, 1992), the power of the two predictors has not been directly compared. Our findings suggest that early gesture may be the more powerful predictor in children with PL and in TD children (Rowe & Goldin-Meadow, 2009b).

Lesion Characteristics and Gesture

We have found that early gesture use predicts later productive and receptive vocabulary in children with PL. Does gesture use vary with lesion characteristics? The small number of children in our sample of children with PL, combined with their diversity in lesion location, size, and type, makes it difficult to explore this question (see Rowe, Levine, Fisher, & Goldin-Meadow, 2009, for discussion). We therefore used nonparametric chi-square analyses to compare the distribution of children in the LOW vs. HIGH gesture groups as a function of each of the three lesion characteristics: lesion type (CV or PV), lesion size (small or large), and hemisphere (right or left). However, we stress that the findings must be considered tentative given our sample size of 11 children.

We found a significant effect for lesion type ($\chi^2 = 5.24$, $df = 1$, $p = .02$): All 4 children with PV lesions fell into the HIGH gesture group (none in the LOW gesture group), compared to only 2 of 7 children with CV infarcts (5 in the LOW gesture group). We found a trend for lesion size ($\chi^2 = 2.396$, $df = 1$, $p = .12$): One of the 5 children with small lesions fell into the LOW gesture group and 4 fell into the HIGH; in contrast, 4 of the 6 children with large lesions fell into the LOW gesture group and 2 fell into the HIGH. We did not find a significant result for lesion hemisphere ($\chi^2 = 0.749$, $df = 1$, $p = .39$): Three of the 8 children with left hemisphere lesions fell into the LOW gesture group and 5 fell into the HIGH, compared to 2 and 1, respectively, of the 3 children with right hemisphere lesions (but note that there were only 3 children in the right hemisphere lesion group).

Overall, children with small (as opposed to large) lesions and children with PV lesions (as opposed to CV infarcts) were more likely to produce gestures at a typical rate at 18 months. In turn, these children were also more likely to develop vocabulary at a typical rate than those with CV infarcts and those with large lesions, as evidenced by the significant relation between 18-month gesture and 22- and 26-month productive vocabulary and between 18-month gesture and 30-month receptive vocabulary. These findings are consistent with our previous studies including larger samples of children with PL (Rowe et al., 2009).

Discussion

Consistent with previous studies, we found that children with PL experience language delays that vary in terms of their severity and their persistence over time. Our study goes beyond previous studies of children with PL in that we observed gesture as well as language use in the children. We not only found great variability in gesture use at 18 months in children with PL, but we also found that this variability was related to later vocabulary levels—the children who produced fewer gesture types at 18 months were just the children who exhibited lower scores on productive and receptive vocabulary measures at 30 months. Most dramatically, child gesture at 18 months predicted child receptive vocabulary at 30 months, even when controlling for child speech types at 18 months.

Our findings extend previous research conducted on other child clinical groups, which report relations between gesture and language (Capone & McGregor, 2004). For example, Hill, Bishop, and Nimmo-Smith (1998) found gesture deficits in children with specific language impairment. As another example, Thal and Tobias (1992) observed communicative gesture use in 18- to 28-month-old late talkers, none of whom had been diagnosed with brain injury. The late talkers whose productive language had normalized at the 1-year follow-up had, at the earlier ages, produced significantly more communicative gestures than the late talkers whose productive language delays persisted at the 1-year follow-up. A tight relation between gesture and language has also been reported in adult Broca's and Wernicke's aphasics (Cicone, Wapner, Foldi, Zurif, & Gardner, 1979; McNeill, 1992). Taken together, these findings indicate that the relation between gesture and language is robust, found not only in samples of TD children but also in a variety of clinical populations.

Our findings have both theoretical and practical implications. In theoretical terms, the findings provide further evidence that the integrated gesture–language system found in TD children may be fundamental to the language learning process. Indeed, the diversity of our sample of children with PL underscores the robustness of this relation. Despite the fact that the children with PL varied widely in the location, size, and type of lesion they sustained, their early gestures were a reliable index of their later productive and receptive language skills. Although a larger sample is clearly needed to fully understand the relation between gesture and language, the fact that gesture and language remain linked in a population whose language functions are being carried out by a wider variety of neural substrates than is typical suggests that early gesture may be inextricably linked to the language learning process.

The theoretical question raised by our data is—why does gesture predict subsequent vocabulary development? Gesturing and word learning may draw on a common underlying cognitive skill, for example, the ability to produce and understand symbols (cf. Bates et al., 1979; Bretherton & Bates, 1984; McNeill, 1992; Werner & Kaplan, 1963). Gesturing and word learning may also be affected in similar ways by more general skills, including overall cognitive functioning (as measured by IQ tests, Levine et al., 1987) or general motor abilities (particularly given recent speculation about the importance of motor movements in language processing; e.g., Nishitani, Schürmann, Amunts, & Hari, 2005; Pulvermüller, 2005; Rizzolatti & Arbib, 1998). Indeed, previous findings have linked motor and language skills in TD individuals (Bates & Dick, 2002; Iverson & Thelen, 1999) and in clinical populations for whom some form of delay in language production is central (Bishop & Edmundson, 1987; Corriveau & Goswami, 2009; Hill, 2001; Visscher, Houwen, Scherder, Moolenaar, & Hartman, 2007). Individuals with PL, including many of the children in our sample, have hemiparesis of varying severity (Huttenlocher, 2002; Levine et al., 1987; Mercuri et al., 2004; Staudt et al., 2002; Staudt et al., 2004; Steenbergen & Gordon, 2006). Although it has not been shown that the severity of their symptoms varies systematically with their language skills, severity of hemiparesis has been shown to vary with IQ scores (see, e.g., Feldman, Janosky, Scher, & Wareham, 1994; Levine et al., 1987).

To summarize thus far, gesturing may predict subsequent vocabulary development because it is affected by cognitive or motor skills in the same way that word learning is. If so, gesture will be able to serve as a good index of vocabulary growth, but it will play no role in bringing that growth about. It is possible, however, that gesture goes beyond *reflecting* skill in vocabulary learning to actually play a role in *causing* vocabulary learning (Goldin-Meadow, 2003). Consider, for example, a child who points at a bird. Mother responds by saying, "Yes, that's a bird," thus providing a timely word-learning model for the child (see Goldin-Meadow, Goodrich, Sauer, & Iverson, 2007). In other words, gesture may be playing a role in vocabulary learning by allowing children to elicit input targeted to their level and, in this way, shape their own learning environments. Gesture could also play a role in vocabulary learning more directly by providing children with the opportunity to refer to objects whose names they are not yet able to express in speech, and to do so in a communicative context. Repeated use of gestures to refer to particular objects in an act of communication could pave the way for later acquisition of the words that refer to these particular objects (cf. Iverson & Goldin-Meadow, 2005). If so, gesture may be playing a role in the process of change by affecting learners themselves.

Our findings also have practical implications. The findings suggest that early gesture provides a way to identify children with persistent versus transient language difficulties at a time when all of the children are saying very little. Consistent with previous research with children with PL, 8 of the 11 children in our sample of children with PL fell below the 25th percentile of TD children on vocabulary production at 18 months, but only 5 children continued to be below the 25th percentile at 22 months. The striking result of our study is that these 5 were the same 5 children who were low gesture producers at 18 months. Thus, early gesture may provide clinicians with a way to identify children who may end up having persistent language difficulties *before* those difficulties appear in the children's speech. This early identification may then be useful in guiding intervention practices that may be particularly effective when employed early in development. Larger samples are clearly needed to explore gesture's use as a diagnostic indicator in clinical practice (e.g., to determine what the cutoff in gesture use ought to be to reliably distinguish children with transient vs. persistent language delays). However, our study suggests that early child gesture may be a useful indicator of subsequent language delay and thus motivates future research with both children with PL and children without PL who experience language delays.

Our results also raise the possibility that encouraging children to gesture may prove to be an effective intervention. That is, early gesture may not only precede early language but may facilitate its development. Studies of TD elementary school children have shown that the knowledge children convey uniquely in their gestures when explaining their solutions to mathematical equivalence problems is a harbinger of the knowledge that they will soon acquire (Alibali & Goldin-Meadow, 1993; Perry, Church, & Goldin-Meadow, 1988). More importantly, children who were told to gesture during a mathematical equivalence lesson retained more from the lesson than children who were told not to gesture (Cook, Mitchell, & Goldin-Meadow, 2008; see also Broaders, Cook, Mitchell, & Goldin-Meadow, 2007; Goldin-Meadow, Cook, & Mitchell, 2009), suggesting that the act of gesturing itself facilitates learning. Research on the language development of TD children suggests that gesture may play a similar role in language learning. For example, Goodwyn, Acredolo, and Brown (2000) found that encouraging children to gesture (via parent modeling) facilitates subsequent language development. Thus, gesture might serve not only as a tool for diagnosing language delay but also as a tool for early intervention.

In summary, we have found that the relation between early gesture and later language, reported in TD children, is also found in children with early unilateral brain injuries. The tight relation between early gesture and subsequent language development thus appears to be a robust aspect of language development. Our findings further suggest that early delays in gesture production can be used to identify those children with PL whose language learning is likely to be delayed in the future. If so, we may be able to offer these children interventions while their language-learning trajectory is most malleable.

Mother–Infant Interaction During the First 3 Months: The Emergence of Culture-Specific Contingency Patterns

Joscha Kärtner, Heidi Keller, and Relindis D. Yovsi
University of Osnabrück

This study analyzed German and Nso mothers' auditory, proximal, and visual contingent responses to their infants' nondistress vocalizations in postnatal Weeks 4, 6, 8, 10, and 12. Visual contingency scores increased whereas proximal contingency scores decreased over time for the independent (German urban middle-class, $N = 20$) but not the interdependent sociocultural context (rural Nso farmers, $N = 24$). It seems, therefore, that culture-specific differences in the modal patterns of contingent responsiveness emerge during the 2nd and 3rd months of life. This differential development was interpreted as the result of the interplay between maturational processes associated with the 2-month shift that are selectively integrated and reinforced in culture-specific mother–infant interaction.

Caretakers' contingent responsiveness to their infants' communicative signals is a key feature of early parenting. Mothers intuitively react to infants' signals within a short period of time, normally less than a second (Keller, Lohaus, Völker, Cappenberg, & Chasiotis, 1999; Papoušek & Papoušek, 1987). Infants, in turn, are motivated to detect these contingencies; this behavior is self-rewarding in that it gives rise to positive affect (Watson, 1985). In detecting these contingencies, infants begin to perceive themselves as causal agents whose behavior directly affects their social environment. This knowledge has fundamental implications for infants' subsequent cognitive and socioemotional developmental processes (cf. Bigelow, 1998; Keller, Kärtner, Borke, Yovsi, & Kleis, 2005; Tarabulsy, Tessier, & Kappas, 1996).

Contingent responsiveness can be regarded as a universal, evolutionarily shaped component of parenting that is realized in context-sensitive ways. Support for this assumption comes from studies that explored the universality of contingent responsiveness by looking at cross-cultural similarities and differences in caretakers' responses. The general consensus is that the overall level of contingent responsiveness is similar across cultural contexts; however, there are differences in terms of the way in which caretakers react contingently (Bornstein et al., 1992; Fogel, Toda, & Kawai, 1988; Kärtner et al., 2008; Richman, Miller, & LeVine, 1992). For example, Richman et al. (1992) found that Gusii mothers from Western Kenya were predominantly physically responsive while Euro-American middle-class mothers were predominantly verbally and visually responsive. In a similar study, Kärtner et al. (2008) compared the contingent responses of caretakers from independent, autonomous-relational, and interdependent sociocultural contexts. Kärtner et al. found that caretakers from independent sociocultural contexts addressed the infants' sense of sight significantly more often than did caretakers from autonomous-relational or interdependent contexts. Infants from interdependent contexts, on the other hand, experienced significantly more proximal contingent responses addressing the vestibular sense or the sense of touch. Kärtner et al. argued that it was the difference in the caretakers' broader sociocultural orientation and cultural embedment that led to these modal differences in contingent responsiveness. Other researchers have offered similar explanations, such as different norms of interaction (Richman et al., 1992) or differences in cultural beliefs (Fogel et al., 1988), to

---

We thank Arnold Lohaus for his cooperation in assessing the Münster data as part of a joint research project funded by the German Research Foundation (LO 337/12–1, KE 263/17–4). We are grateful and indebted to the German Research Foundation for supporting the assessment and analysis of the Nso data (KE263/41). Many thanks go to our graduate students Ute Spilker, Christina Heinrichs, Vanessa Tepe, Antje Beck, and Carmen Reinert. We are especially grateful to the infants and caretakers who participated in this study.

account for cross-cultural variation in contingent responsiveness.

There is some empirical evidence for a functional link between the dominant sociocultural orientation, actual parenting behavior, and child development. Keller, Yovsi, et al. (2004), for example, have shown that culturally informed caretaking behavior fosters desirable developmental outcomes. Specifically, Keller, Yovsi, et al. found that proximal caretaking, mainly in the form of body contact, during mother–infant interaction when infants were 3 months old led to earlier development of compliance and obedience in the toddlers' 2nd year. Both proximal caretaking and obedience of toddlers are highly valued in interdependent sociocultural contexts (Keller, 2007; Ogunnaike & Houser, 2002; Whiting & Pope Edwards, 1988). In contrast to proximal caretaking, distal parenting, mainly in the form of object stimulation and mutual gaze, led to earlier development of the toddlers' autonomous self-concept as assessed by mirror self-recognition. Both distal parenting and toddlers' autonomy are highly valued in predominantly independent sociocultural contexts (Keller, 2007; LeVine, 1994; Richman et al., 1992).

As described above, parents from interdependent and independent sociocultural contexts differ in their contingency patterns and, more generally, in their parenting behavior. For example, German middle-class families have a predominantly independent sociocultural orientation, whereas rural Nso families have a primarily interdependent sociocultural orientation (cf. Kärtner et al., 2008; Keller, 2007; Yovsi, 2003). The Nso, an ethnic group living in a mainly subsistence-based agrarian ecology in Cameroon, socialize their children toward obedience, respect for elders, cooperation, and social responsibility (Nsamenang, 1992). Obligation between kin people is an integral and institutionalized part of Nso morality and daily life (Goheen, 1996) and parents foster their children's integration into a hierarchically structured social setting (Nsamenang & Lamb, 1994).

German middle-class mothers, in contrast, socialize their children toward individuality, autonomy (Keller, 2007), and self-reliance (LeVine & Norman, 2001). Mothers value exclusive dyadic interaction and believe that children need to spend time on their own in order to become more independent (Keller, Hentschel, et al., 2004; Keller, Voelker, & Yovsi, 2005). Based on these differences in sociocultural orientation, we hypothesized that in the 3rd month of life, Nso infants would experience more proximal contingent responses addressing the sense of touch and the vestibular sense and less visual contingencies than would infants from the German middle-class sample. Across modalities, however, mothers from the two sociocultural contexts should show approximately the same amount of contingent responses to their infants' signals; that is, only the modality patterns of the contingent responses should differ between the groups.

The First 3 Months: Continuity of Culture-Specific Patterns or Differential Developmental Change?

Given that the majority of studies of contingent responsiveness focuses on infants who are at least 3 months old, it is as yet unknown whether culture-specific manifestations are present from birth or whether different patterns emerge across the infants' first few months of life. In this way, culture-specific contingency patterns could either be conceptualized as (a) a continuous behavioral response informed by broad and static cultural scripts that guide mothers' behavior or (b) the outcome of a more dynamic, culture-specific interplay of the infants' developing communicative competencies and maternal responses.

Research on the early development of contingent responsiveness is scarce and offers mixed results, partly in support of the continuity hypothesis and partly in support of the developmental change hypothesis. With respect to continuity, the assumption that mothers' contingent responsiveness is a relatively stable feature of mother–infant interaction was first discussed by Watson (1985) and Stern (1985). Both authors argued that social interaction creates default contingency levels through familiarization and that these contingency levels are subsequently reflected in infants' responses to new social stimuli. More recently, Bigelow and colleagues provided empirical evidence in support of the notion of continuity of contingent responsiveness (Bigelow, 1998; Bigelow & DeCoste, 2003; Bigelow & Rochat, 2006). The authors found that 2-month-old infants were most responsive to strangers who showed similar levels of contingent responsiveness as the infants' own mothers (Bigelow & Rochat, 2006). These results indicate that infants expected specific contingency levels, which implies that the mothers' behavior had been sufficiently continuous as to build up these expectations in their infants. Further support for the continuity hypothesis comes from Hsu and Fogel (2003), who found that from postnatal Week 4 to Week 24 there was no effect of age on maternal behavioral actions (verbal/vocal, facial expression, touch, and head movement) in response to infants' nondistress vocalizations (NDVs). Taken together, these results suggest that, at least over short periods of time, mothers' responsiveness is reasonably continuous.

Evidence for developmental change in contingent responsiveness comes from research examining the 2-month shift. The 2-month shift refers to the period near the end of an infant's 2nd month of life wherein there is a developmental change that marks a qualitative shift in the way in which the infant interacts with social partners and expresses himself or herself (Emde, 1984). Following this shift, infants spend more time in an alert active state (Wolff, 1987), their ability to maintain visual attention increases (Haith, Bergman, & Moore, 1977), and they start smiling socially (Wolff, 1987). There have been several studies that have demonstrated that these changes in infants affect mothers' responsiveness. First, Lavelli and Fogel (2005) found that mothers reacted contingently by talking and smiling in response to their infants' smiles and cooing more during the 2nd and 3rd months than in the 1st month. Second, Symons and Moran (1994) found that there was a steady increase in mothers' contingent smiles in response to infants' smiles from the 2nd to the 6th month. This result is inconclusive, however, as the authors did not report inferential test statistics for the increase. Last, Lavelli and Fogel (2002) have shown that interdyadic differences in face-to-face communication, especially in active engagement between mother and infant, were most likely to emerge during the crucial developmental transition period, that is, toward the end of the 2nd month. Based on these findings, we hypothesized that if mothers' contingency patterns change across the first 3 months, then these changes should coincide with the occurrence of the 2-month shift as indexed by the infants' awake alertness and gazing pattern (especially looks directed at their mothers).

The findings on developmental change in contingent responsiveness, as discussed above, were mostly related to distal aspects of mother–infant interaction, that is, smiling and gazing patterns. These patterns are of central importance in predominantly independent sociocultural contexts. Cross-cultural research has demonstrated that face-to-face interaction does not have the same prevalence and may not have the same meaning across different sociocultural contexts (Keller, 2007). This difference in prevalence and meaning across contexts may have significant implications for the mother's and especially the infant's behavior during early face-to-face interaction. For example, Lavelli and Fogel (2005) showed that mothers' expressions amplified and organized infants' patterns of attention and emotion in relatively stable sequences of mother–infant face-to-face communication in the 3rd month. If face-to-face interaction is less prevalent, however, the development of these stable sequences may be more characteristic of dyads from predominantly independent sociocultural contexts. The question remains as to whether the 2-month shift takes the same form in the interdependent sociocultural context, that is, whether there is a comparable increase in the infants' awake alertness and looking at their mothers. What are the implications of this result for mothers' contingent responsiveness? We addressed these two issues in the present study.

The overarching goal of the present study was to examine the development of cross-cultural modal differences in caretakers' patterns of contingent responsiveness. To do this, we examined the auditory, proximal, and visual contingent reactions that mothers from two different sociocultural contexts (independent and interdependent) show in response to their infants' NDVs in postnatal Weeks 4, 6, 8, 10, and 12. There are three specific hypotheses and two exploratory research questions. First, the overall level of contingent responsiveness should be continuous across time and should not differ between sociocultural contexts. Second, in the 3rd month, infants from the independent sociocultural context should experience more visual contingencies and less proximal contingencies than should infants from the interdependent sociocultural context. Third, contingency patterns should reflect changes associated with the 2-month shift. More specifically, the proportion of mothers' visual contingencies should increase with changes in their infants' awake alertness and gazing patterns. Furthermore, we explored whether the 2-month shift in awake alertness and infants' gazing occurred to the same degree for infants from both sociocultural contexts and whether the consequences for their mothers' contingent responsiveness were similar for the two groups. Finally, we analyzed the stability of contingent responsiveness, the provision of face-to-face context, and the infants' gazing at their mothers' faces across the infants' 2nd and 3rd months in order to learn more about the behavioral organization of early mother–infant interaction. Since little is known about this issue, we acted on the assumption that stabilities should be reasonably high in both sociocultural contexts.

In order to keep the procedure for assessing mother–infant interactions ecologically valid, mothers were not constrained to a face-to-face interaction but were free to choose a typical setting for interacting with their infants. Rochat (2001) and others (e.g., Jaffe, Beebe, Stanley, Crown, & Jasnow, 2001; Watson, 1985) argue that contingency levels are embedded in face-to-face interactions during mother–infant routines. Following this logic, we would expect infants from interdependent contexts to experience less contingent responses. Kärtner et al. (2008), however, argue that caretakers' contingent responsiveness does not presuppose face-to-face interaction. The results of their study showed that, independent of differences in the extent of caretakers' provision of face-to-face interaction, the overall contingency levels across distal (vocal/verbal, smile, facial expression) and proximal (body contact, body stimulation) modalities were similar across sociocultural contexts.

Regarding the type of infant signals that mothers respond to, a number of studies have shown that, compared to several nonverbal behaviors, infants' NDVs constitute the most salient signal for caretakers (Bornstein et al., 1992; Hsu & Fogel, 2003; Van Egeren, Barratt, & Roach, 2001). This is a consistent finding across sociocultural contexts as diverse as a rural Nso community living in the Bantu grass fields in the North Western province in Cameroon or urban middle-class families from Berlin or Los Angeles (Kärtner et al., 2008).

Method

Participants

Twenty families from Münster, a medium-sized city in Northern Germany, and 24 Nso families living in small villages around Kumbo, Cameroon, participated in the present study. In Germany, the mean age of first-time mothers was approximately 29 years and the fertility rate was 1.4 children born per woman in the last 10 years (Statistisches Bundesamt, 2008). In German middle-class families, infants spend most of their time at home with their mothers during the 1st month. Older siblings go to day-care facilities or nursery school in the mornings. The role distribution in most German families is still traditional in that it is mostly the mothers who take care of the infants while the fathers are at work (Keller, 2006; Keller, Zach, & Abels, 2005).

The Nso sample was recruited from Kikaikelaki, a village near Kumbo, Bui Division of the Northwest Province of Cameroon. In 2004, the average life expectancy in Cameroon was 48.0 years and the fertility rate was 4.6 children born per woman (Central Intelligence Agency, 2008). The mean age of first-time Nso mothers was approximately 19.8 years in 2003 (Yovsi, 2003). The majority of the Nso population live in village communities where subsistence is a combination of communal efforts and endeavors from all family members, including children (Yovsi, 2003). Men achieve high social status through the possession of *keng* (wealth) in the form of raffia palms, coffee plantations, forests, and houses. In Kikaikelaki there are denominational primary schools and most children end their education at the elementary level (Class 7) at, on average, 13–14 years. There are health centers in the villages but they lack infrastructure and most people prefer traditional medicine. Nso villages are made up of several compounds, consisting of houses grouped around a central yard. The settlement pattern is patrilocal and every male owns land within the lineage territory where he builds and settles with his family. The rural Nso have an extended family system of three or more generations. Families share everyday activities, including child care. Thus, children are socialized in a dense social network including parents, siblings, relatives, grandparents, and neighbors. Child care is a communal responsibility; after the birth of a child, everybody in the community has an obligation toward his or her care and social development (Nsamenang, 1992; Yovsi, 2003). Although the German middle-class and the rural Nso families differ in terms of the size of the social networks in which children are socialized, in both of the sociocultural groups the mother is the primary caregiver during the first 6 months of life (Yovsi, 2003).

All of the mothers were first contacted during the last trimester of pregnancy through a pediatric hospital in Münster and through the health centre in Kumbo. In the rural Nso community, mothers were informed only after the lineage heads approved participation. Interested mothers participated if their family heads consented.

There were 50 families in the original sample, however, six Nso families were excluded for equipment or procedural error ($N = 4$) or because two or more observations were lacking ($N = 2$), leaving a total sample of 44 families. Infant gender was balanced across samples (Münster: 45% girls, Nso: 54% girls). The Nso mothers were slightly younger ($M = 27.40$, $SD = 8.15$ years) than were the mothers from Münster ($M = 30.70$, $SD = 3.76$ years), $t(42) = 1.67$, $p > .10$, $d = 0.51$. All of the mothers from Münster and 33% of the Nso mothers were first-time mothers, $\chi^2 = 20.95$, $p < .01$. The Nso mothers had received less formal education ($M = 8.00$, *SD* = 1.91 years) than had the mothers from Münster (*M* = 14.35, *SD* = 3.23 years), $t(42) = 8.09$, $p < .01$, $d = 2.45$. According to our sociostructural approach to culture, these patterns of sociodemographic differences are constitutive of the different sociocultural environments (Keller, 2007).

Procedure

After the infants' birth, local research assistants made appointments with and visited mothers at home when the infants were 4, 6, 8, 10, and 12 weeks of age (± 2 days). After the assistant had explained what the study entailed, the mothers, who were the primary caretakers in all instances, were instructed in their native language (German or Lamnso) to interact with their infants as they would normally do. The mothers were free to choose a typical setting. They were, however, asked not to move around too much and not to include others in the interaction. The interaction was videotaped for 10 min (*M* = 9 min 24 s, *SD* = 48 s) using a hand-held camera with a built-in microphone at a distance of approximately 2–3 m. The research assistants made sure that the infants were awake, fed, and not crying before filming began. Assessments with the Nso mother–infant dyads were mostly done outside the house, which is reflective of their daily family routines. A questionnaire concerning sociodemographic information was also administered during the first visit.

Coding

In order to analyze the caretakers' levels and patterns of contingent responsiveness we applied an event-coding approach. In Step 1, a pair of trained students identified the onset and offset of infant sounds for the whole 10 min. A new vocalization was coded when there was a pause of more than 1 s. The identified sounds were then evaluated according to type, intensity, and, in the case of vocalizations, valence. Three types of infant sounds were differentiated: (a) vocalizations, defined as all voiced articulations; (b) vegetative sounds such as sneezes, coughs, and hiccups; and (c) effort sounds, defined as sounds that occur in combination with movements or other efforts such as grunts or motor effort sounds. The intensity of infant sounds was coded as belonging to one of three categories: (a) low, defined as sounds that were uttered with low intensity, that is, hardly audible; (b) high, defined as sounds that were subjectively perceived as loud; or (c) medium, defined as sounds that were neither low nor high in intensity. The valence of vocalizations was judged as either: (a) negative if it was subjectively perceived as negative in hedonistic tone, such as whining, fussing, crying, sighing, and other sounds of discomfort; (b) positive if it was perceived as positive in hedonistic tone, such as sounds of happiness or laughing; or (c) neutral if it was neither negative nor positive, such as a-sounds or babbling.

With respect to interrater reliability, 21% of the sample was coded by both coders. For infant sounds, the proportion of agreement for onsets relative to the total number of onsets coded by at least one of the coders, within a time tolerance of 1 s between coders, was .77. Reliabilities were medium to high for the type ($\kappa = .79$), valence ($\kappa = .79$), and intensity ($\kappa = .81$) of the infants' sounds.

In the main analysis, we focused on the infants' NDVs, defined as neutral vocalizations of low or middle intensity (cf. Hsu & Fogel, 2003; Hsu, Fogel, & Messinger, 2001). On average, infants uttered 30.3 NDVs (*SD* = 21.6) per 10 min, which had a mean duration of 1.44 s each (*SD* = 3.30) and accounted for 55% of all infant sounds. These values were similar across cultural context and age. All other sounds were excluded for theoretical and methodological reasons. Theoretically, vegetative (13.0% of all infant sounds) and effort (19.4% of all infant sounds) sounds cannot be attributed to the infant's initiative; contingent responsiveness concerns the infant perceiving himself or herself as a causal agent. Furthermore, preliminary analyses indicated that caretakers reacted differently to negative (7.4% of all vocalizations), positive (4.9% of all vocalizations), and highly intense (4.5% of all vocalizations) vocalizations. As these vocalizations were distributed unequally across dyads, ages, and cultural contexts, differences in contingency patterns between participants or cultural groups would, in part, be caused by differential distributions of valence and intensity.

Based on the fact that maternal responses are most likely to occur in the 1st second after the infants' signal (Bloom, Russell, & Wassenberg, 1987; Keller et al., 1999; Papoušek & Papoušek, 1987), we defined a latency window of 1 s for contingency (cf. Bigelow, 1998; Bigelow & Rochat, 2006; Hsu & Fogel, 2003; Kärtner et al., 2008; Keller, Yovsi, et al., 2004; Keller et al., 2008). In other words, the caretakers' response had to occur within the latency window that begins with the onset and ends 1 s after the offset of the vocalization to be considered contingent.

In Step 2, the coders coded the caretakers' contingent responses. A caretaker's action was coded as contingent if the caretaker either initiated an action that was not shown before (*addition*) or changed the rhythm or the intensity of an ongoing action (*modification*; cf. Hsu & Fogel, 2003; Keller & Schölmerich, 1987). All other cases were coded as *no reaction*. The coding was carried out separately for the different senses that the caretakers' contingent response might have addressed: (a) *auditory contingencies* addressing the infants' sense of hearing were provided by the caretakers' verbalization, vocalization, and other sounds, for example, tongue clicking; (b) *proximal contingencies* addressing the sense of touch and the vestibular sense were provided by body stimulation defined as touching or stimulating the infant with the hands (e.g., stroking or patting) or the face (e.g., kissing) or by body contact; or (c) *visual contingencies* addressing the sense of sight were provided by the caretakers' gaze, smile, or facial expression (e.g., raised eyebrows and/or mouth wide open) or by using an object (e.g., a toy).

The 1 s before the onset of each NDV served as a baseline against which the caretakers' behavior was evaluated. In all cases, auditory, proximal, and visual contingencies were coded independently. For example, a mother might modify her vocal/verbal behavior and start smiling in response to an infant's NDV. Interrater reliabilities were computed on the basis of the same 21% that were coded by both coders. Cohen's kappas were medium to high for the modalities of the caretakers' contingent responses (body stimulation: $\kappa = .87$, body contact: $\kappa = .84$, gaze: $\kappa = .76$, smile: $\kappa = .85$, facial expression: $\kappa = .72$, vocalization: $\kappa = .89$, and object stimulation: $\kappa = .92$).

Approximately 4.5% of the NDVs were excluded from further analyses because not all of the caretakers' modalities could be coded (e.g., face covered by hair). In the final analysis, we computed a proportional score that indicated the *overall* contingency experience for each infant, that is, the percentage of NDVs that were responded to contingently by addressing at least one of the infant's senses. To analyze the similarities and differences in the patterns of contingent responses across the infants' age and sociocultural context, we computed three proportional scores that indicated the percentage of all contingent responses that were *auditory*, *proximal*, or *visual*.

In Step 3, a second pair of coders coded face-to-face context and the infants' alertness and gaze. In order to do this, we used an interval coding approach based on 10-s intervals. For each 10-s interval, the coders decided whether or not mothers created a context that was favorable for face-to-face interaction for at least half of the interval. A favorable context was defined as one in which the mother turned toward the infant and positioned herself and the infant in such a way that the mother's face was situated not more than 45° off her infant's optical axis. In addition, two indicators of the 2-month shift were coded: (a) the relative number of 10-s intervals in which the infant was alert, that is, when the infant did not show any signs of sleepiness (repeated yawning and/or drooping eyelids), and (b) the infants' gazing at their mothers' faces. Onset and offset of infants' gazing at their mothers' faces were coded during episodes where mothers had established face-to-face context and infants were alert. Interrater reliabilities that were computed on the basis of 21% of the data were medium to high for face-to-face context ($\kappa = .86$), alertness ($\kappa = .72$), and infants' gaze ($\kappa = .78$). The final scores for *face-to-face context* and *alertness* were the relative frequencies (i.e., proportions) of 10-s intervals in which the coding criteria applied so that the values represent the proportion of intervals during which the mother provided a favorable face-to-face context or the infant was awake, respectively.

For the infants' gazing at their mothers' face, we computed two scores. The first score, mutual gaze$_{\text{fav}}$, was defined as the duration of infants' gazing at their mothers divided by the absolute frequency of 10-s intervals in which mothers established face-to-face context *and* infants were alert multiplied by 10 s. The latter multiplication is an approximation of the total duration of context favorable for mutual gaze, that is, episodes where mothers had established face-to-face context and infants were alert. This score (mutual gaze$_{\text{fav}}$) indicates the duration of mutual gaze relative to the duration of episodes in which mothers established face-to-face context and infants were alert. The second score, mutual gaze, is the duration of infants' gazing at their mothers divided by the duration of the full interaction episode. Because infants' gaze was only coded during sequences where mothers established face-to-face context, this score approximates the duration of mutual gaze relative to the duration of the entire episode.

Results

Plan of Analysis and Missing Data Treatment

In order to analyze differences and similarities in maternal contingency scores, the provision of face-to-face context by caretakers, and the infants' gazing at their mothers and alertness across sociocultural contexts and age, we computed repeated measures analyses of variance (ANOVAs) with age (4, 6, 8, 10, 12 weeks) as the within-subjects factor and cultural group (Münster, Nso) as the between-subjects factor. To analyze the time course of age-related changes, we have reported linear and curvilinear contrasts by age and Age × Cultural Group interactions for each analysis. Significant interactions between age and sociocultural context were clarified by subjecting the age data to separate one-way ANOVAs for each cultural group. Post hoc *t* tests were performed in the case of significant main effects of age. As neither gender nor birth rank (first- vs. later-born) was significant in any of the preliminary analyses, the data were collapsed across these factors for all subsequent analyses. In order to evaluate the stability of contingent responsiveness, the provision of face-to-face context, and indicators of the 2-month shift across ages, we averaged correlations of adjacent time points (Weeks 4 and 6, Weeks 6 and 8, Weeks 8 and 10, and Weeks 10 and 12) separately for each cultural group. To compute averaged correlations, Pearson correlations were Fisher *z*-transformed, averaged, and then back-transformed.

In the final sample, the contingency data of 15 observations (5.7% of the sample) from 12 dyads (4 from Münster) were substituted by the values for adjacent time points of those dyads (van der Kloot, 1998). There were two reasons for substituting data. First, for 5 of the 44 families (3 from Münster) only four of the five observations took place. All of the other families were visited five times as planned. Second, some observations ($N = 10$; 1 from Münster) were excluded because there were only a few NDVs. Therefore, we used an inclusion criterion of at least three NDVs. Missing values of face-to-face ($N = 5$), mutual gaze ($N = 5$), and mutual gaze_{fav} ($N = 27$) were substituted according to the same logic. There were 22 observations (10%) for which mutual gaze_{fav} could not be computed because there was no favorable context which would be tantamount to a division by zero. To test the robustness of the results, all analyses were additionally conducted on the unsubstituted data, and a data set where missing values were substituted by the individual mothers' mean score. The pattern of significant effects and the magnitudes of the effects were identical across all three analyses. It should be noted here that, compared to the ANOVAs, in all of the correlational analyses that follow, only the data gathered during actual observations, that is, unsubstituted data, were analyzed.

Overall Levels and Patterns of Contingent Responsiveness

On average, mothers responded contingently by addressing at least one of the infant's senses to about 57.5% of all NDVs; this figure did not differ between cultural groups or age groups, largest $F(1, 42) = 2.76$, $p > .10$. There was a marginally significant linear contrast for the interaction between cultural group and age, indicating that there were differences in the linear development of overall contingency across age between the cultural groups, $F(1, 42) = 3.62$, $p < .10$, $\eta_p^2 = .08$. Looking at the two cultural groups separately, separate one-way ANOVAs yielded a marginally significant main effect of age on overall contingency for the Münster sample, $F(4, 76) = 2.42$, $p < .10$, $\eta_p^2 = .11$, but no systematic change with age. For the Nso sample, there was no main effect of age on overall contingency, $F(4, 92) = 1.35$, $p > .10$, $\eta_p^2 = .06$, and a marginally significant linear decrease with age, $F(1, 23) = 3.09$, $p < .10$, $\eta_p^2 = .12$ (see Table 1).

The scores for auditory, proximal, and visual contingencies were subjected to separate mixed ANOVAs. On average, 47.2% of the mother's contingent responses to the infant's NDVs were auditory, 43.8% were proximal, and 9% were visual. Auditory and proximal contingencies were independent of cultural context and infants' age, largest $F(1, 42) = 1.28$, $p > .10$. The marginally significant linear contrast of the interaction indicated that there were differences in the linear development of the proximal contingencies with age, $F(1, 42) = 2.85$, $p < .10$, $\eta_p^2 = .06$. Looking at the two cultural groups separately, one-way (age) ANOVAs yielded a significant main effect of age on proximal contingencies for the Münster sample, $F(4, 76) = 2.63$, $p < .05$, $\eta_p^2 = .12$, that could best be explained by a linear decrease with age, $F(1, 19) = 7.15$, $p < .05$, $\eta_p^2 = .27$. There were neither differences nor any systematic changes with age in the Nso sample (see Table 1). Post hoc *t* tests indicate that Nso infants experienced significantly more proximal contingencies than did infants from Münster in Week 12, $t(42) = -2.56$, $p = .014$, $d = -0.77$.

The largest differences pertained to visual contingencies. Infants from the Münster sample experienced more visual contingencies ($M = 13.00\%$, $SE = 1.87\%$) than did infants from the Nso sample ($M = 5.80\%$, $SE = 1.71\%$), $F(1, 42) = 8.07$, $p < .001$, $\eta_p^2 = .16$. On average, these visual contingencies

Table 1

Contingency Levels (Percentage) Across Time and Cultural Context

	Week 4	Week 6	Week 8	Week 10	Week 12
Overall					
Münster	62.56 (19.06)	52.79 (17.04)	64.32 (15.15)	62.57 (13.18)	62.45 (16.56)
Nso	58.33 (17.97)	55.06 (16.67)	56.85 (14.82)	52.73 (19.57)	50.17 (21.74)
Auditory					
Münster	48.56 (16.17)	41.20 (20.32)	45.96 (11.63)	42.66 (9.48)	49.50 (13.73)
Nso	48.85 (16.67)	45.38 (19.51)	51.36 (15.91)	51.41 (25.49)	45.41 (18.34)
Proximal					
Münster	43.80 (17.85)	48.83 (21.54)	41.24 (18.89)	40.45 (22.88)	32.80 (14.01)
Nso	45.55 (18.60)	47.12 (20.76)	44.90 (16.76)	43.53 (26.11)	47.50 (22.27)
Visual					
Münster	7.64 (8.88)	9.97 (13.84)	12.80 (14.27)	16.88 (17.04)	17.70 (13.52)
Nso	5.60 (8.46)	7.50 (8.88)	3.74 (7.67)	5.06 (7.49)	7.09 (12.28)

Note. Values are M (SD). $N = 20$ for the Münster and $N = 24$ for the Nso sample. Scores are either percentage of nondistress vocalizations (overall contingency level) or percentage of mothers' contingent responses (auditory, proximal, and visual contingency). Auditory, proximal, and visual contingencies add up to 100%.

increased with age, $F(4, 168) = 2.98$, $p < .05$, $\eta_p^2 = .07$. There was, however, a significant interaction, indicating that visual contingencies changed differently with age for the two cultural groups, $F(4, 168) = 3.04$, $p < .05$, $\eta_p^2 = .07$. Looking at the two cultural groups separately, one-way ANOVAs yielded a significant main effect of age for the Münster sample, $F(4, 76) = 3.08$, $p < .05$, $\eta_p^2 = .14$, that could best be explained by a linear increase with age, $F(1, 19) = 11.96$, $p < .01$, $\eta_p^2 = .39$. In contrast, there were neither differences nor any systematic changes with age for the Nso sample. Post hoc t tests yielded significant differences between the two cultural groups from Week 8 onward, $t_{\text{week 8}}(42) = 2.55$, $p < .017$, $d = 0.77$; $t_{\text{week 10}}(42) = 2.88$, $p < .01$, $d = 0.87$; and $t_{\text{week 12}}(42) = 2.73$, $p < .01$, $d = 0.83$.

Figure 1 displays the developmental course of the three types of mothers' contingent responsiveness and the emergence of culture-specific contingency patterns in the 3rd month. Intraindividual stabilities were moderate for the total contingency score ($r_{\text{Münster}} = .36$, $p > .10$, $r_{\text{Nso}} = .54$, $p < .05$) and visual contingencies ($r_{\text{Münster}} = .45$, $p < .10$, $r_{\text{Nso}} = .51$, $p < .05$), and mixed for auditory ($r_{\text{Münster}} = .45$, $p < .10$, $r_{\text{Nso}} = -.07$, $p > .10$) and proximal ($r_{\text{Münster}} = .37$, $r_{\text{Nso}} = .16$, both $ps > .10$) contingencies.

Provision of Face-to-Face Context and the 2-Month Shift

The percentage of 10-s intervals in which mothers established face-to-face context was subjected to a 2 (cultural group; between-subjects) × 5 (age; within-subjects) ANOVA. The mothers from the

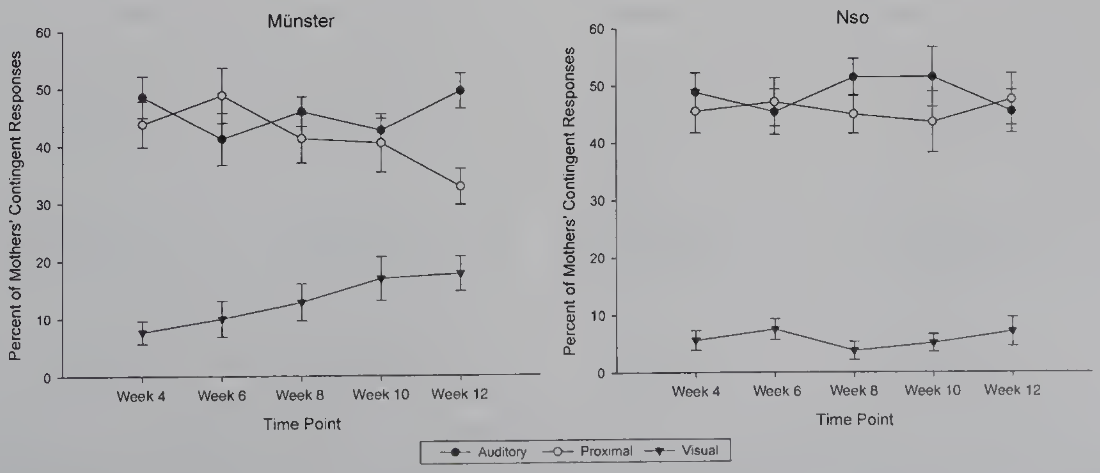

Figure 1. The developmental course of mothers' auditory, proximal, and visual contingencies for Münster and Nso infants.

Münster sample established face-to-face context significantly more often ($M = 0.82$, $SE = 0.05$), than did Nso mothers ($M = 0.49$, $SE = 0.04$), $F(1, 42) = 27.89$, $p < .01$, $\eta_p^2 = .40$. As indicated by the significant interaction, this difference increased with age, $F(4, 168) = 6.01$, $p < .01$, $\eta_p^2 = .13$ (see Table 2). Post hoc t tests indicate that mothers from Münster established face-to-face context for a significantly higher proportion of 10-s intervals than did Nso mothers in all weeks, $t_{\text{week } 4}(42) = 2.87$, $p < .01$, $d = 0.87$; $t_{\text{week } 6}(42) = 2.51$, $p = .016$, $d = 0.76$; $t_{\text{week } 8}(42) = 4.20$, $p < .001$, $d = 1.32$; $t_{\text{week } 10}(42) = 4.24$, $p < .001$, $d = 1.28$; and $t_{\text{week } 12}(42) = 8.58$, $p < .001$, $d = 2.78$.

Looking at the two cultural groups separately, one-way ANOVAs yielded a significant main effect of age for the Münster sample, $F(4, 76) = 3.24$, $p < .05$, $\eta_p^2 = .15$, that could best be explained by a linear increase, $F(1, 19) = 7.81$, $p < .05$, $\eta_p^2 = .29$. The significant main effect of age for the Nso sample, $F(4, 92) = 3.72$, $p < .01$, $\eta_p^2 = .14$, on the other hand, could best be explained by an inverted U-shaped function, $F(1, 23) = 8.64$, $p < .01$, $\eta_p^2 = .27$.

With respect to infants' alertness, there was a significant main effect of age, $F(4, 168) = 17.62$, $p < .01$, $\eta_p^2 = .30$. As indicated by the pairwise comparisons of estimated marginal means, there was a sharp increase in alertness between Weeks 6 and 8 for both sociocultural contexts; the respective mean differences for pairwise comparisons with Bonferroni adjustment ranged from −.18 to −.34, all $ps < .01$ (see Table 2).

The infants' gazing at their mothers' faces also differed between the cultural contexts and with age. During the episodes when mothers established face-to-face context (mutual gaze$_{\text{fav}}$), infants from the Münster sample looked at their mother faces, thus establishing eye contact, twice as long ($M = 0.36$, $SE = 0.04$) as did infants from the Nso sample ($M = 0.18$, $SE = 0.03$), $F(1, 42) = 14.57$, $p < .01$, $\eta_p^2 = .26$. There was a significant Cultural Context × Age interaction, $F(4, 168) = 4.21$, $p < .01$, $\eta_p^2 = .09$. Inspection of means (see Table 2) indicates that the difference between the cultural samples increased with age. Post hoc t tests yielded significant differences between the two cultural groups from Week 8 onward, $t_{\text{week } 8}(42) = 5.62$, $p < .001$, $d = 1.70$; $t_{\text{week } 10}(42) = 2.55$, $p = .015$, $d = 0.77$; and $t_{\text{week } 12}(42) = 3.06$, $p < .01$, $d = 0.93$.

The analysis of the duration of mutual gaze relative to the duration of the total interaction time (*mutual gaze*) yielded significant main effects for cultural group (Münster: $M = 0.28$, $SE = 0.03$; Nso: $M = 0.08$, $SE = 0.03$), $F(1, 42) = 24.50$, $p < .01$, $\eta_p^2 = .37$, as well as age, $F(4, 168) = 4.72$, $p < .01$, $\eta_p^2 = .10$. Furthermore, there was a significant Cultural Context × Age interaction, $F(4, 168) = 5.88$, $p < .01$, $\eta_p^2 = .12$. Looking at the two cultural groups separately, one-way ANOVAs yielded a significant main effect of age only for the Münster sample, $F(4, 76) = 5.67$, $p < .01$, $\eta_p^2 = .23$, that could best be explained by a sharp increase in mutual gaze between Weeks 6 and 8. Respective mean differences for pairwise comparisons with Bonferroni adjustment ranged between −.18 and −.23, all

Table 2

Face-to-Face Context, Alertness, and Mutual Gaze (Proportions) Across Time and Cultural Context

	Week 4	Week 6	Week 8	Week 10	Week 12
Face-to-face					
Münster	0.75 (0.26)	0.78 (0.27)	0.81 (0.20)	0.84 (0.23)	0.92 (0.10)
Nso	0.50 (0.31)	0.56 (0.30)	0.47 (0.32)	0.53 (0.25)	0.37 (0.27)
Alertness					
Münster	0.70 (0.30)	0.62 (0.35)	0.92 (0.16)	0.96 (0.12)	0.98 (0.04)
Nso	0.79 (0.35)	0.71 (0.41)	0.94 (0.20)	0.96 (0.10)	0.99 (0.02)
Mutual gaze$_{\text{fav}}$					
Münster	0.28 (0.26)	0.29 (0.25)	0.48 (0.26)	0.40 (0.33)	0.38 (0.25)
Nso	0.22 (0.22)	0.23 (0.29)	0.11 (0.15)	0.18 (0.23)	0.16 (0.22)
Mutual gaze					
Münster	0.16 (0.19)	0.16 (0.19)	0.39 (0.28)	0.36 (0.31)	0.35 (0.24)
Nso	0.09 (0.13)	0.09 (0.16)	0.06 (0.09)	0.10 (0.19)	0.08 (0.16)

Note. Values are M (SD). Scores are relative frequencies of 10-s intervals (face-to-face and alertness) or relative durations (mutual gaze and mutual gaze$_{\text{fav}}$). Mutual gaze$_{\text{fav}}$ indicates the duration of mutual gaze relative to the duration of episodes in which mothers established face-to-face context and infants were alert. Mutual gaze indicates the duration of mutual gaze relative to the duration of the entire episode. $N = 20$ for the Münster sample and $N = 24$ for the Nso sample.

ps $< .05$ (see Table 2). Post hoc *t* tests indicate that, from Week 8 on, dyads from the Münster sample established mutual gaze longer than did dyads from the Nso sample, $t_{\text{week }8}(42) = 5.18, p < .001, d = 1.57$; $t_{\text{week }10}(42) = 3.22, p < .01, d = 0.97$; and $t_{\text{week }12}(42) = 4.16, p < .001, d = 1.26$.

Intraindividual stabilities were reasonably high for the face-to-face context, $r_{\text{Münster}} = .49$, $r_{\text{Nso}} = .64$, both *ps* $< .05$, rather low for alertness, $r_{\text{Münster}} = .35$, $r_{\text{Nso}} = .17$, both *ps* $> .10$, and moderate for mutual gaze, $r_{\text{Münster}} = .33, p > .10$, $r_{\text{Nso}} = .45, p < .10$.

Contingency Patterns, Face-to-Face Context, and the 2-Month Shift

So far, the results indicate that changes in visual contingency parallel changes in the extent of face-to-face context provided by caretakers as well as changes in mutual gaze scores. For all of these scores, there was a significant increase across age for the Münster but not for the Nso sample. Within both cultural groups, averaged correlations between the two mutual gaze scores and visual contingency were significant, mutual gaze: $r = .50$, $p < .05$ for Münster and $r = .71$, $p < .01$ for Nso mothers, and mutual gaze$_{\text{fav}}$: $r = .41$, $p_{\text{one-sided}} < .10$ for Münster and $r = .64$, $p < .01$ for Nso mothers, supporting the assumption that on the dyad level, a longer duration of mutual gaze and mutual gaze$_{\text{fav}}$ was associated with a higher proportion of visual contingencies. Since, first, the two mutual gaze scores were highly correlated, $r = .95$ for the Münster sample and $r = .91$ for the Nso sample, *ps* $< .001$, and, second, there were less missing values for mutual gaze, we focused on mutual gaze in the following analyses.

For both mutual gaze and visual contingency, there were large differences between the two cultural groups from Week 8 onward. These data raise the question of whether the between-culture differences in mutual gaze and visual contingency were independent of each other or whether differences in visual contingency could, at least in part, be explained by differences in mutual gaze. The latter alternative would mean that if mothers and infants were to look at each other, mothers in both sociocultural contexts would behave similarly in terms of visual contingency. To address this issue, we computed two-step analyses separately for Weeks 8, 10, and 12 (van de Vijver & Leung, 1997). First, we computed a one-factorial (culture) ANOVA on visual contingency and, second, we computed a one-factorial (culture) ANCOVA on visual contingency with mutual gaze as the covariate. The change in η_p^2 for culture between the ANOVA and the ANCOVA gives us an indication of the extent to which differences in mutual gaze explain the cross-cultural differences in visual contingency. In all three ANOVAs, η_p^2s indicated large between-culture differences in visual contingency, smallest $F(1, 42) = 7.19$, $p < .05$, $\eta_p^2 > .14$. Entering mutual gaze as a covariate, the main effects of culture were no longer significant for any of the weeks, largest $F(1, 41) = .76$, $p > .10$, $\eta_p^2 < .04$. These findings support the hypothesis that mutual gaze largely explains cross-cultural differences in visual contingency.

These results indicate that during mutual gaze-episodes Nso mothers were as visually contingent as their Münster counterparts. The questions remain, however, as to why the Nso dyads generally engaged less in face-to-face interaction than did the Münster dyads and why the 2-month shift followed a different pattern (increase in awake alertness but not mutual gaze) in the Nso sample compared to the Münster sample. In order to address these questions, we conducted exploratory analyses of the intercorrelations between face-to-face context, mutual gaze, visual contingencies, and sociodemographic variables (e.g., mothers' education and age) that might help to explain intracultural variation. Of the sociodemographic variables that we analyzed, maternal education was the most relevant. We used a dichotomous score that differentiated between mothers who had received 7 years of formal schooling ($N = 17$) and mothers who had spent more time in school (either 9 [$N = 1$] or 12 [$N = 4$] years). Even though only five mothers had received a higher degree of formal education, averaged point-biserial correlations between education and all other scores were consistently positive, though not significant: $r = .25$ with face-to-face context, $r = .20$ with mutual gaze, and $r = .31$ with visual contingency. The correlations were highest between education and face-to-face context at 12 weeks, $r = .48$, $p < .05$; between education and mutual gaze at 4 weeks, $r = .50$, $p < .05$; and between education and visual contingency, $r_{\text{week }4} = .42$, $p < .10$; $r_{\text{week }10} = .47$, $p < .05$; $r_{\text{week }12} = .42$, $p < .10$. There were no systematic relations between education and either proximal, $r = -.26$ to $-.08$, $p > .10$ or auditory, $r = -.10$ to $.05$, $p > .10$, contingency scores.

Discussion

The purpose of this study was to analyze in detail how culture-specific contingency patterns develop during the first months of life. To address this issue, we explored how mothers' contingency patterns changed during the infants' 2nd and 3rd months of life and analyzed to what degree this development was influenced by sociocultural or other contextual factors.

As we hypothesized, there were no significant differences in the overall contingency level between cultural groups or with the infants' age. Mothers responded contingently to about 60% of their infants' NDVs. This result is very similar to Kärtner et al.'s (2008) finding of an overall contingency rate of 63% across six different sociocultural contexts. It seems, therefore, that contingent responsiveness is a universal component of intuitive parenting.

Also consistent with previous research is the finding that after 2–3 months of age, there were similarities as well as differences in the contingency patterns between the two cultural groups. Generally, mothers from both sociocultural contexts gave auditory responses far more often than they gave visual responses. Furthermore, in both samples there was no change in auditory contingencies with age. Other forms of maternal responsiveness, however, did vary across cultural contexts. As indicated by the proportional scores for auditory, proximal, and visual contingencies, 8- to 12-week-olds from the Münster sample experienced significantly more visual contingencies than did Nso infants and 12-week-olds from the Münster sample experienced significantly less proximal contingencies than did Nso infants. Within cultural contexts, 12-week-olds from the Münster sample experienced auditory contingencies more often than they did proximal contingencies, followed by visual contingencies. Twelve-week-olds from the Nso sample, in contrast, experienced proximal contingencies as often as they did auditory contingencies.

Interestingly, the modal differences in contingency patterns were not present at 4 weeks but emerged during the infants' 2nd and 3rd months. For the Münster sample, there was a linear increase in visual contingencies and a linear decrease in proximal contingencies. For the Nso sample, all contingency scores were continuous across the infants' age. Thus, these results clearly indicate differential developmental trajectories within the two sociocultural contexts.

In order to better understand this differential development, we analyzed the degree to which developmental processes were influenced by other factors, such as the provision of face-to-face context by caretakers and the infants' awake alertness and gazing pattern as indicators of the 2-month shift. As expected, mothers from the Münster sample established face-to-face context longer than did Nso mothers and this difference between the two cultural contexts increased with age. With respect to the 2-month shift, the infants' alertness increased sharply from Weeks 6 to 8 in both sociocultural contexts and reached about 100% in the 12th week.

The infants' gazing patterns are another indicator of the 2-month shift. In this respect, infants from the Münster and Nso samples were quite different. For the Münster infants, there was an age-dependent increase in the percentage of time that the infants looked back at their mothers while their mothers established face-to-face context (mutual gaze_{fav}). For the Nso infants, however, there was no change in the percentage of time that the infants looked back at their mothers. The difference in looking patterns with age between the two samples gave rise to significant differences between the samples from Weeks 8 to 12. As a consequence, the duration of mutual gaze relative to the total interaction time, a factor influenced by both the provision of face-to-face context and the infants' interest, exhibits an abrupt increase between Weeks 6 and 8 in the Münster sample but not in the Nso sample. This sharp increase in the duration of mutual gaze together with the sharp increase in alertness in the Münster sample can be taken as evidence of the 2-month shift as it is usually described in the literature (Lavelli & Fogel, 2002, 2005).

The results paint a different picture for the Nso infants since the 2-month shift seems to take a different shape: The Nso infants exhibited a similar sharp increase in awake alertness with age to the Münster infants, but the Nso infants' interest in their mothers' faces, that is, their gazing behavior, did not change with age. Across the 12 weeks, the relative duration of both face-to-face context established by the mothers and the two mutual gaze scores were continuous. Furthermore, interdyad differences remained relatively stable in the Nso context, and intercorrelations between face-to-face context, mutual gaze, and visual contingency were quite high for the Nso sample. These findings support the interpretation that each Nso mother provided a certain extent of face-to-face context and visual contingency that did not change much as the infant grew older.

In interpreting this cross-cultural developmental divergence, one has to keep in mind that most of the studies on the 2-month shift are monocultural studies from predominantly Western contexts (Emde, 1984; Lavelli & Fogel, 2002; Stern, 1985; Wolff, 1987). As indicated by the results, there was no difference in visual contingent responsiveness between the mothers from the two sociocultural contexts, per se. What differed between the two cultural contexts were the age-related changes in the provision of face-to-face context as well as the duration of mutual gaze itself. What are the possible reasons for these developmental differences in face-to-face context established by mothers and the infants' gazing behavior?

From a sociocultural perspective, we argue that caretakers hold culture-specific beliefs about parenting and follow different parenting strategies and behavioral scripts while interacting with their infants. These parenting beliefs and strategies lead to different developmental outcomes, which have an adaptive value within the specific sociocultural context. With respect to face-to-face context, there are several studies that have shown that face-to-face context and exclusive dyadic interaction play a central role in prototypically independent sociocultural contexts (Brazelton, 1977; Keller, 2007; Whiting & Pope Edwards, 1988). Furthermore, there is empirical evidence that distal parenting characterized by face-to-face interaction and object stimulation fosters the development of an autonomous self, which is one of the central developmental outcomes emphasized in independent sociocultural contexts (Keller, Kärtner, et al., 2005; Keller, Yovsi, et al., 2004). Nso mothers' parenting, in contrast, can best be described as proximal parenting with its emphasis on body contact and body stimulation (cf. Keller, 2007). According to Nso ethnotheories, these parenting strategies instill a sense of community that is characterized by obedience, deference, collective responsibility, and sharing (Goheen, 1996; Nsamenang & Lamb, 1994). Furthermore, there is empirical evidence that body contact and interactional warmth support the development of acceptance of the families' norms and values and compliance (Keller, Yovsi, et al., 2004; MacDonald, 1992).

It is important to keep in mind that, generally, infant communicative signals and mothers' behavior cannot be interpreted in isolation. Mother–infant interaction is a bidirectional process in which each partner's behavior is reciprocally influenced by the behavior of the other. Thus, the differences in the duration of gazing at the mothers' faces (mutual gaze$_{fav}$) found in this study cannot be attributed to the infants alone, even though we have described the infants' gazing as their *interest* in their mothers' faces. Rather, culture-specific scripts and behavioral standards of the mothers may have interacted with emerging behavioral potentials. Thus, in sociocultural contexts that favor face-to-face communication, mothers may enthusiastically promote mutual gaze and face-to-face interaction with their infants. Lavelli and Fogel (2005) identified positive feedback and mutual amplification as mechanisms that contribute to the consolidation of emerging behavioral patterns. In light of their results, the finding that the duration of time that the Münster infants looked at their mothers' faces while their mothers provided face-to-face context (mutual gaze$_{fav}$) increased parallel with an increase in the mothers' provision of face-to-face context may exemplify the consolidation of such an emerging behavioral pattern. For example, the more the mother establishes face-to-face context, the more probable it is that the infant will engage in mutual gaze if he or she is looking at his or her mother, which may be rewarding because of the stimulation that mothers provide during face-to-face interaction. For mothers, in turn, these experiences are rewarding because of their ethnotheoretical underpinning that mutual gaze and face-to-face interaction is a desirable way of interacting with infants. If this ethnotheoretical underpinning is missing or different, as in the Nso sample, stable and continuous development should be the consequence.

But what implications might the different ethnotheoretical underpinning of Nso mothers' caretaking have for the dynamics of mother–infant interaction? Generally, Nso mothers treat their infants as novices who need to learn compliance and subordination from early on (Nsamenang, 1992). In a qualitative analysis of the Week 12 interactions from the present study, Demuth (2008) described the prototypical Nso mother–infant interaction as characterized by rhythmic-synchronous structuring and both normative-hierarchical and socially oriented discourse. In contrast to the turn-taking sequences typical of mother–infant interaction in Münster, the Nso interactions include a large amount of repetitions and nonverbal vocalizations, which may lead to a symbiotic relationship stressing the unity between mother and infant. Repetitive patterns in Nso mother–infant interaction typically comprise musical chorusing as well as repeated addressing or greeting of the infant. These utterances were often synchronized with rhythmic body stimulation, for example, mothers rhythmically bouncing their infants. If one thinks in terms of consolidating behavioral patterns that are typical for interdependent sociocultural contexts, one may need to look beyond face-to-face interaction and toward developmental domains like affect regulation and calmness as an early precursor of proper demeanor and obedience (LeVine, 1994). However, the results of these studies point to the direction that, generally, Nso mothers take the lead and structure the interaction; that is, Nso parenting is more directive and is mother directed rather than child focused.

In the final step of our analyses, we explored to what extent other contextual factors (e.g., education) influenced the contingency patterns and dynamics of face-to-face interaction within the Nso sample. What we found was that the mothers' level of formal education (7 vs. 9 or more years) was associated with the provision of face-to-face context, the extent of mutual gaze, and the level of visual contingency. In a study on the effect of school attainment on mothers' contingent responsiveness, Richman et al. (1992) showed comparable results to ours. The higher the Mexican mothers' level of formal education (between 1 and 9 years), the more they talked and looked in response to vocalizations of their 10- or 15-month-olds. On the basis of these findings alone, it is unclear exactly how schooling affects maternal responsiveness. It seems, however, that schooling may provide women with experiences and models of social interaction that they would not acquire without schooling. These experiences may, in turn, influence the way in which they later interact with their infants. This interpretation is further supported by studies that have shown that education, with the accompanying changes in income and living standards, reorients socialization goals and parenting ethnotheories toward autonomy and independence (Laosa, 1982; LeVine, Miller, Richman, & LeVine, 1996). With regard to the Nso culture, Yovsi and Keller (2007) have shown that maternal school attainment is associated with changes in sleeping arrangements (shift from mother–infant to husband–wife cosleeping) and planned weaning date. Thus, there is evidence that formal education drives cultural change through its impact on ethnotheories, socialization goals, and norms of social interaction.

While the present study has a number of strengths in that it provided new evidence for intercultural similarities and differences in contingent responsiveness and the 2-month shift, it also has some limitations. First, due to the time-intensive coding of repeated observations, the sample sizes were relatively small. Furthermore, we substituted missing values in order to avoid listwise deletion in the repeated measures analyses. The robustness of the present findings, however, was supported by the fact that the pattern of significant results was identical regardless of whether missing values were substituted by mean scores, by adjacent values, or deleted listwise. Second, observations came from contexts that are prototypical for an independent and an interdependent sociocultural orientation: highly educated middle-class families in Münster and rural Nso farmers with only basic formal education living in a subsistence-based ecology. Based on our sociocultural approach, we argue that one has to be cautious about generalizing these data beyond the specific sociocultural contexts described. The contingency patterns that we found certainly do not apply to the country level. In order to determine whether generalizing these data to similar sociocultural contexts in the same or in other countries is appropriate, the results found here need to be replicated by further research with other prototypically independent or interdependent contexts. Last, there is evidence that Nso mothers focus more on proximal parenting; in Nso mothers' ethnotheories, mother–infant attachment is mainly defined in terms of bodily closeness, and body contact plays an important role in sensitive parenting (Otto, 2008; Yovsi, Kärtner, Keller, & Lohaus, 2009). By focusing on NDVs we tried to give justice to culture-specific emphases on face-to-face context and body contact. It is possible, however, that there are alternative mechanisms or communication systems that drive developmental change in early mother-infant communication in a way that is more typical for the Nso context.

In the present study, we could demonstrate that culture-specific contingency patterns in mother–infant interaction emerge during the 2nd and 3rd months of life. This differential development is associated with culture-specific differences in the duration of mutual gaze during social interaction, which indicates the effectiveness of broader cultural models, in this case, the prominence of face-to-face exchange in social interaction.

"My Way or Mom's Way?" The Bilingual and Bicultural Self in Hong Kong Chinese Children and Adolescents

Qi Wang and Yi Shao
Cornell University

Yexin Jessica Li
Arizona State University

This study examined the relation of language to the development of a cultural self. Bilingual children ages 8–14 from Hong Kong ($N = 125$) were interviewed in either English or Chinese. They recalled autobiographical events and described themselves, and indicated their agreement with Chinese interdependent versus Western independent values. Children interviewed in English provided more elaborate and self-focused self-descriptions and memory accounts and endorsed more strongly Western values, compared with children interviewed in Chinese. Furthermore, the endorsement of a cultural belief system mediated the effect of language on self-concept, which, in turn, mediated the effect of language on autobiographical memory. These findings offer new insight into the dynamic relations between language, culture, and the self.

The self is a multifaceted, complex, dynamic construct encompassing many interacting aspects or components (Baumeister, 1998; Neisser, 1988). Two aspects of the self—autobiographical memory and self-concept—have been underscored in contemporary theories of the self (Fivush & Nelson, 2004; Harter, 1999; Nelson, 2001). Autobiographical memory, or the "extended self," refers to memory for significant personal experiences from an individual's life. Self-concept, or the "conceptual self," refers to an individual's conceptual representations of him- or herself (Neisser, 1988). While autobiographical memory provides the materials for the constitution and maintenance of a dynamic self-concept, self-concept exerts executive control over the constructive process of autobiographical remembering in accordance with the self's current goals and motivations and thus acts to "shape both the accessibility of memories and the accessibility of their content" (Conway, 2005, p. 595; Conway & Pleydell-Pearce, 2000; Ross, 1989). More important from the current perspective, the two aspects of the self are both sensitive to social-cultural influences as they develop in a myriad of daily interactions between individuals and their immediate and distal contexts, together making up a self that integrates the framework of the culture, namely, the cultural self (see Wang, 2006a, for a review).

The Cultural Self

The development of the self is immersed in the social-cultural context constituted by cultural beliefs, symbols, artifacts, metaphors, and everyday practices (Bruner, 1990; Miller, Fung, & Koven, 2007; Wang, 2006a). These cultural factors provide an important framework based on which individuals process and represent self-related information (Kağitçibaşi, 2007; Markus & Kitayama, 1991). The belief system in European American culture that emphasizes individuality, personal uniqueness, and self-sufficiency promotes an autonomous self-concept that is primarily defined by one's inner attributes, qualities, and opinions. This autonomous self-concept may further direct cognitive resources toward elaborate processing of event information that highlights one's uniqueness and autonomy, and such information is likely to become richly represented and highly accessible during recall. In contrast, the emphasis on interdependence, group solidarity, and relational hierarchy in Confucian cultures such as Japan, Korea, and China encourages the development of a relational self-concept that is largely defined by one's position in a nexus of social relations. This relational self-concept may motivate individuals to focus on event information about group activities and interactions, which helps

them relate to significant others and the community (Wang, 2006a; Wang & Ross, 2007).

Consistent with these theoretical views, research has shown that when asked to describe themselves, European American individuals, both children and adults, tend to focus on their unique attributes, qualities, and beliefs independent of others or social contexts, whereas Japanese, Koreans, and Chinese frequently refer to their social roles, group memberships, and relationships with significant others (Cousins, 1989; Rhee, Uleman, Lee, & Roman, 1995; Trafimow, Triandis, & Goto, 1991; Wang, 2001, 2004). These different self-concepts across cultures are further related to different ways of autobiographical remembering, whereby European American children and adults often provide elaborate, lengthy accounts of personal experiences and focus on their own roles, feelings, and perspectives, whereas the memories of Koreans and Chinese are often brief and centered on shared activities and significant others (Han, Leichtman, & Wang, 1998; Mullen, 1994; Wang, 2001, 2004; Wang & Leichtman, 2000). These cross-cultural findings support the notion that the development of the self is a process of cultural adaptation (Kağitçibaşi, 2007; Miller et al., 2007; Wang, 2006a), during which individuals come to internalize cultural belief systems (e.g., independence vs. interdependence) into their own self-understanding and remembering (e.g., with an individual vs. a social orientation). Importantly, the acquisition of the cultural self may be attributed to a host of sociocultural variables, among which language as a symbolic system of culture may be central.

Language and the Self

Language lends stability to human experience and at the same time sustains flexibility adaptive to specific contexts (Nelson, 2001). Indeed, many theorists argue that the self can be viewed as developed, expressed, and reconstructed through narrative practices that occur in the realm of linguistic formulation (Bruner, 1990; Fivush & Nelson, 2004; Ochs, 1996). In particular, linguistic representation, through the structure and lexicon of the language and the social arrangement of the communicative context, may direct individuals' attention to particular cultural models of self and render certain qualities or representations of the self salient and accessible (Chiu, Leung, & Kwan, 2007; Holland & Quinn, 1987). Furthermore, as proposed within the language socialization approach, language plays an essential role in the communication of cultural content while, in the meantime, contributing to meaning construction through linguistic forms (Fernald & Morikawa, 1993; Miller et al., 2007; Ochs, 1996). Language learning is thus a powerful medium of cultural transmission that enables children to acquire both linguistic and sociocultural competence.

One important approach to understanding the relation between culture, language, and the self is to study bilingual individuals. Given that cultural practices and meanings are so deeply embedded in language, the acquisition of a second language often entails the establishment of a new cognitive system—schemata, mental models, or representations—that reflects new ways of constructing the self and its relation to the social and physical world (Ochs, 1996; Schrauf, 2000; Valsiner, 2001). As a result, bilingual individuals may possess separate self-structures associated with different languages. Studies with bilingual adults have provided some evidence. Ross, Xun, and Wilson (2002) interviewed, in either Chinese or English, Chinese-born bilingual young adults living in Canada. They asked participants to describe themselves and to rate statements reflecting Chinese cultural values (e.g., "Modesty leads to success, pride leads to failure"). Those who participated in Chinese described themselves in more collective terms and endorsed Chinese values more strongly than did those surveyed in English. Similarly, when bilingual young adults from Hong Kong were asked to describe themselves, those who responded in Chinese used more collective and fewer individual terms than those who responded in English (Kemmelmeier & Cheng, 2004; Trafimow, Silverman, Fan, & Law, 1997). In addition, in a study of autobiographical memory in Russian English bilingual adults, Marian and Kaushanskaya (2004) found that memories recalled in English tended to be more self-focused, whereas memories recalled in Russian were more other oriented. These effects of language on self-concept and memory directly parallel the findings of cross-cultural studies (Han et al., 1998; Mullen, 1994; Wang, 2001, 2004; Wang & Ross, 2005).

From a developmental perspective, it is of great importance to examine whether the acquisition of different languages in children is accompanied by different modes of self-understanding and remembering. Furthermore, although the findings with adults suggest that language can bring self-concept and autobiographical memory in line with cultural belief systems, the specific mechanisms underlying the language effects are yet to be fully explicated. According to the constructivist view, language may serve as a cue or prime for associated cultural constructs and thus increase the accessibility of relevant beliefs, self-concepts, and autobiographical information (Ross et al., 2002; Schrauf, 2000; Trafimow et al., 1997). More important from the current perspective, these language effects may not reflect simultaneous processes. Conceivably, the use of a particular language (e.g., Chinese) may activate a specific cultural frame or belief system (e.g., Confucian values) to which this language is chronically connected in everyday life. The cultural belief system may, in turn, activate culturally promoted self-concepts (e.g., a relational self), which may further increase the accessibility of relevant autobiographical event information (e.g., social interactions). In other words, the activated cultural belief system may mediate the effect of language on self-concept. In turn, given its executive role of modulating access to long-term memory (Conway, 2005; Conway & Pleydell-Pearce, 2000), the working self-concept may further mediate the effect of language on autobiographical memory. Figure 1 depicts the hypothesized direct effects and mediations. Alternatively, the cultural accommodation theory suggests that language may create a "response bias," where individuals provide responses deemed appropriate or desirable by the culture in which the language is used (Bond & Yang, 1982). Thus, the use of a particular language may elicit associated culturally desirable beliefs, self-concept, and autobiographical recall. Such effects should appear in parallel and the unidirectional mediations will not be expected. This study addresses these theoretical issues by examining self-concept and autobiographical memory in bilingual children and adolescents from Hong Kong.

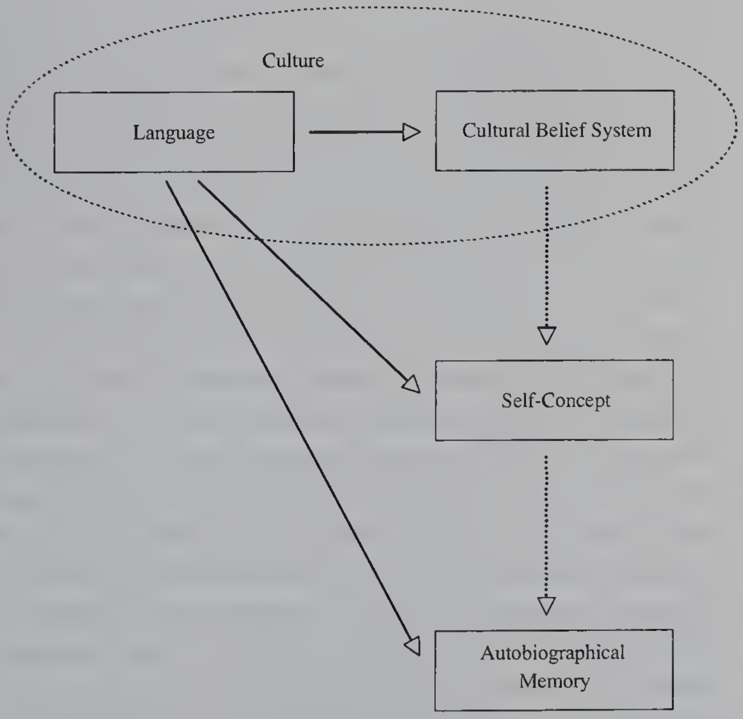

Figure 1. The effects of language.
Note. The solid arrows represent the direct effects of language predicted by both the constructivist view and the cultural accommodation theory. The dashed arrows represent hypothesized mediations according to the constructivist view.

The Language and Culture of Hong Kong Children

Because of its 100-year reign by England that lasted until 1997, Hong Kong is a culturally dynamic place where Western and Chinese values intertwine and where modernity and tradition coexist. Historically, the British colonial and metropolitan authorities in Hong Kong promoted English-language education (vis-à-vis Chinese education). The policies and practices embrace both the promotion of Western education through the medium of English and the teaching and learning of English as a language subject (Tung, Lam, & Tsang, 1997). After its handover back to China, Hong Kong maintains its cultural ties to the Western world under the Chinese government's "one country, two systems" policy (Hong, Morris, Chiu, & Benet-Martinez, 2000). Both Chinese and English are official languages. Many schools that were in place during the British reign have remained relatively unaffected, and English continues to be an important language to be learned starting even before formal schooling.

On the other hand, the Hong Kong society is conscious of preserving Chinese traditions, where Confucian ethics such as respect for the elderly, humility, and a sense of shame are highly prized. Children are exposed to traditional Chinese culture early on and come to learn and speak Chinese (Cantonese or Mandarin, depending on their family background) in their daily lives at home and in the community. Some parents also send their children to take additional Chinese classes outside school. Consequently, many children become proficient bilinguals from an early age. Furthermore, constant transition in everyday life between different cultural contexts such as home and school often requires full cultural competency in both (Hong et al., 2000; Kemmelmeier & Cheng, 2004). Many children thus grow up bicultural, living with their families in a city that has established traditional Chinese teachings and a rich cultural history, while seeking out Western friends, music, movies, toys and cuisine that are readily available to them (Deeds, Stewart, Bond, & Westrick, 1998; Feldman

& Rosenthal, 1991). The bilingual and bicultural characteristics of Hong Kong children thus present us with a unique opportunity to test the relation of language to the development of a cultural self.

The Present Study

In the present study, bilingual 8- to 14-year-old children and adolescents from Hong Kong were interviewed in either English or Chinese. They were asked to recall autobiographical events and provide self-descriptions, and to indicate their agreement with Chinese interdependent versus Western independent values. We expected that, consistent with previous research with adults (Marian & Kaushanskaya, 2004; Ross et al., 2002; Trafimow et al., 1997), children interviewed in English would report higher agreement with Western independent values and lower agreement with Chinese values than those interviewed in Chinese, regardless of age. Also, across all age groups, children interviewed in English were expected to provide lengthier and more self-focused descriptions of themselves and their personal experiences, compared with those interviewed in Chinese whose memories and self-descriptions would be less elaborate and more socially oriented. Furthermore, in line with the constructivist view, we expected that the language of interview would prime the associated cultural belief system, which would then activate the self-concept consistent with the belief system and further shape the retrieval of autographical event information. Thus, the endorsement of a cultural belief system would mediate the effect of language on self-concept, which, in turn, would serve as a mediator for the effect of language on autobiographical memory.

Furthermore, including different age groups would help to reveal possible interactions between age, language, and cultural identification. Extant cross-cultural studies on the development of self-concept and autobiographical memory have focused on preschool and early grade school children (Han et al., 1998; Wang, 2004), included only one age group (Stigler, Smith, & Mao, 1985; Wang, 2006b; Wang & Leichtman, 2000), or not examined age effect in analysis (e.g., Hart, Lucca-Irizarry, & Damon, 1986). In Wang (2004) that included 4-, 6-, and 8-year-olds from European American and Chinese cultural backgrounds, it was found that older children in both cultures provided more self-descriptions and lengthier memories than younger children, which reflects children's increasing cognitive skills with age. Accordingly, compared with younger children, older children described more personal as well as social themes in their memory recall and self-descriptions. Moreover, there were interactions between culture and age such that cultural differences, while identified in all age groups, appeared to become larger with age, suggesting the increasing enculturation as children grow older. It would be interesting to see whether similar patterns of results with the younger, monocultural children would be found in the older, bicultural children in the present study. However, given that there is no extant research on relevant topics with bilingual children in middle childhood and early adolescence, we made no priori predictions about effects related to age.

In addition, we examined gender effects because literature has suggested that across cultures, females often exhibit greater interdependence, whereas males often exhibit greater independence (Cross & Madson, 1997; Fivush & Buckner, 2003). Such gender differences might be reflected in children's value orientations and self-knowledge such that, independent of language of interview, girls would endorse more strongly interdependent as opposed to independent values and provide more socially oriented self-descriptions and memory accounts, when compared with boys.

Method

Participants

The participants were 125 children from Hong Kong, including thirty-three 8-year-olds ($M = 7.62$, $SD = 0.76$, $Mdn = 7.80$; 20 girls), thirty-two 10-year-olds ($M = 10.02$, $SD = 0.48$, $Mdn = 10.00$; 13 girls), twenty-eight 12-year-olds ($M = 12.02$, $SD = 0.58$, $Mdn = 12.03$; 14 girls), and thirty-two 14-year-olds ($M = 14.58$, $SD = 0.98$, $Mdn = 14.47$; 22 girls). All children were ethnic Chinese and were proficient speakers of both English and Chinese (Mandarin or Cantonese). Based on initial conversations with the children, research assistants rated each child's proficiency in both languages, respectively, in comparison with native speakers, on a 10-point scale of 1 (*very poor*) to 10 (*excellent*). The average Chinese proficient score was 9, and the average English proficient score was 8. There was no age difference in either score ($Fs < 1$, *ns*). Children were recruited from elementary and middle schools in primarily middle- and upper-middle-class communities. All parents gave informed consent. Fifty percent of the children's mothers had a college education or beyond, 38% had a high school education, 2% received postgraduate professional training, and

Table 1
Mean Ages (Standard Deviation; % Girls) by Interview Condition

Age group (years)	Chinese	English
8	7.57 (0.71; 61)	7.71 (0.90; 60)
10	9.97 (0.45; 42)	10.17 (0.56; 38)
12	11.93 (0.69; 47)	12.12 (0.42; 54)
14	14.51 (1.20; 71)	14.63 (0.81; 67)

Note. Within each age group, there was no significant difference in age or gender distribution between the two language conditions.

10% did not provide the information. Children were randomly assigned to the Chinese or English interview condition, being matched as closely as possible on the basis of age and gender. Table 1 displays the mean ages and gender distributions of the children by interview condition. The Chinese interviews were conducted in Mandarin (11%) or Cantonese (89%), whichever dialect the child was most comfortable with.

Procedure

Trained bilingual research assistants visited children at home and conducted the interview in a quiet room without the presence of parents or other family members. The interview procedure followed previous research on children's autobiographical memory and self-concept (Han et al., 1998; Wang, 2004). At the beginning of the interview, the interviewer first chatted with the child to establish rapport. When the child seemed relaxed and comfortable, the interviewer told the child, "You and I are going to play a fun game. It's called a question-and-answer game. I'm going to ask you some questions. You can reply in any way you want. There are no right or wrong answers. You'll see it's really fun. Are you ready?"

The first set of questions was about children's memories of personal experiences. Children were asked to recount four past events, including: one thing they did recently that was special and fun, a recent time when they argued with someone at school, a recent time when they did well on a school assignment, and their earliest childhood memory. After each memory question, the interviewer used standard prompts such as "What else happened?" and "Can you tell me more about it?" until the child indicated by speech or gesture that the memory was finished.

Following the memory questions, children were asked to describe themselves in response to open-ended questions (Keller, Ford, & Meacham, 1978; Wang, 2004). The interviewer told the child: "(Child's name), I would like to write a story about you, to write a story that will tell about (child's name). What's the first thing I should put in the story?" She prompted the child after each response, "And what else should I write to tell about you?" until the child indicated by speech or gesture that he or she was finished.

The last set of questions tapped upon children's identification with or endorsement of Chinese cultural values such as interpersonal harmony, group solidarity, social compliance, and humility, versus Western independent values such as individual autonomy, personal sufficiency, and pride. The questions were adapted from Ross et al. (2002), the Self-Construal Scale (Singelis, 1994), and the Ethnic Identity Scale (Umaña-Taylor, Yazedjian, & Bámaca-Gómez, 2004) and modified to be age appropriate. The interviewer posed to children 20 pairs of opposing statements that described a variety of behaviors, preferences, and emotional reactions pertaining to important others, social situations, and cultural artifacts. For example, children were asked, "If you get the highest grade in class, will you tell people about it or keep it to yourself?" and "When you have a big decision to make, do you ask your parents for advice or make your own plans?" Children responded by making a forced choice for each pair of the statements.

The order of the tasks was fixed across all children in order to test the hypothesized mediations in the most stringent way because any possible sequence effects (i.e., autobiographical recall → self-descriptions → culture beliefs) would work against the mediations (i.e., culture beliefs → self-descriptions → autobiographical recall). Each interviewer–child session lasted approximately 30 min. Children received small gifts for their participation. All interviews were audio tape-recorded and then transcribed verbatim onto paper for coding.

Coding

Endorsement of cultural values. Children's responses to the cultural value questions were scored 1 whenever they agreed with Chinese values (e.g., asking parents for advice) and scored 0 whenever they responded in accordance with Western independent values (e.g., making one's own plans). Reliability analysis showed that six items had negative correlations with the total scale (rs = −.04 to −.38) and they were therefore excluded. The remaining items formed a reliable scale (Cronbach's α = .70), and their scores were aggregated to index the children's endorsement of Chinese values (maximum score 14). Note that because the total number of items was fixed (i.e., 14 items), a low score on the scale (e.g., 3) would indicate low agreement with Chinese interdependent values (i.e., responding to 3 items in accordance with Chinese values) and high agreement with Western independent values (i.e., responding to 11 items in accordance with Western values). In other words, if each child were to receive two separate scores, one for the number of responses in accordance with Chinese values and one for the number of responses in accordance with Western values, the two scores would be perfectly correlated at −1 and they would yield identical results in analysis, only in different directions.

Self-concept. Children's self-descriptions were coded as referring to personal versus social aspects of the self, following previous research (Trafimow et al., 1991; Wang, 2001, 2004). Proposition, defined as a subject–verb construction (in Chinese, 主谓结构), was used as the coding unit (Fivush, Haden, & Adam, 1995). Each unique or implied verb in an independent clause forms a propositional unit (e.g., ''I normally go to the library''). The total number of self-descriptions each child provided was first tabulated. Then self-descriptions were coded as *personal* whenever children referred to personal qualities, attitudes, beliefs, and behaviors that were not related to other people (e.g., ''I am honest'' and ''I enjoy books''). Self-descriptions were coded as *social* whenever children referred to their social roles, demographic categories, and group memberships (e.g., ''I live in Hong Kong'' and ''I am a student.''), or important others, relationships, and sensitivity to the viewpoints of others (e.g., ''I have many friends,'' ''My sister is at high-school,'' and ''I like to help other people''). The two codes were exclusive and exhaustive. A ''personal-to-social self-description'' ratio was then calculated for each child to form a composite score of *autonomous self*, which controlled for the effect of the total number of self-descriptions. Some children did not provide any social self-descriptions, a constant 1 was therefore added to the denominator. The ratio scores were later submitted to analysis. Two trained research assistants, both blind to the hypotheses, first coded 20% of the data for reliability estimates, which ranged from 81% to 88%. Disagreement was resolved through discussion between the coders. One assistant then coded the rest of the data.

Autobiographical memory. Following previous studies (Han et al., 1998; Wang, 2004), the length of children's memories was first coded by counting the total number of English words or Chinese characters children used in each memory. Memory content was then coded, using proposition as the coding unit (Fivush et al., 1995; e.g., ''Yesterday I went to fetch my award''). Propositions were coded as *personal* whenever children referred to their own emotions, actions, thoughts, preferences, and agency in their memories (e.g., ''I was happy'' and ''I wanted to drink Coca Cola''). Propositions were coded as *social* whenever children referred to social interactions, group activities, and the roles of others (e.g., ''We traveled'' and ''My father bought a Game Cake for me''). The two codes were exclusive but not exhaustive. A ''personal-to-social'' ratio was then calculated for each memory to index the degree of *memory self-focus* while controlling for the effect of memory length. A constant 1 was added to the denominator because some children did not describe any social content in their memories. The ratio scores were later submitted to analysis. Two trained research assistants first coded 20% of the data for reliability estimates, which ranged from 82% to 96%. Disagreement was resolved through discussion, and one assistant then coded the rest of the data.

Results

In connection with the hypotheses, results pertaining to the endorsement of cultural values, self-concept, and autobiographical memory are first presented. Across all the variables, 2 (interview language: Chinese vs. English) × 2 (gender: boys vs. girls) × 4 (age: 8-year-olds vs. 10-year-olds vs. 12-year-olds vs. 14-year-olds) analyses of variance (ANOVAs) were conducted. Power analysis ($\alpha = .05$, power = 0.80, and effect size $f = 0.30$) indicated that the current sample size was adequate to test the three-factor model (Rosenthal & Rosnow, 1991). Children's responses to the four memory questions showed overall consistent patterns; the analyses of memory variables were therefore performed based on the mean frequencies across the four memories. Mediation analyses were then conducted to test the hypotheses that the language use would activate the associated cultural belief system, which would mediate the effect of language on self-concept. Self-concept, in turn, would serve as a mediator for the effect of language on autobiographical memory. Some children did not answer every question; thus, the degrees of freedom varied slightly across tests.

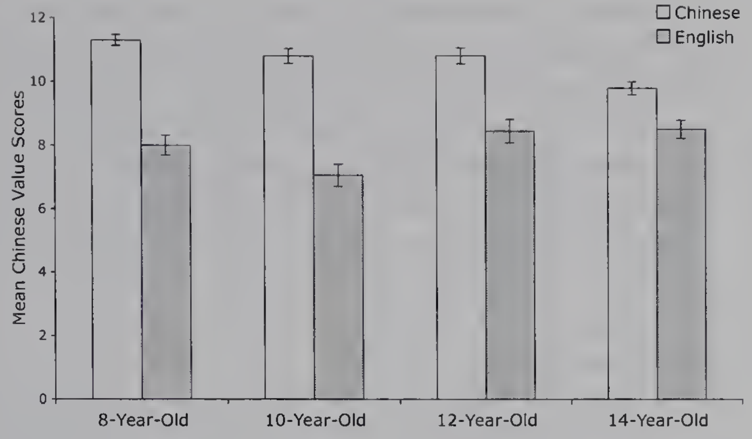

Figure 2. Mean Chinese value scores as a function of age and language of interview.

Endorsement of Cultural Values

Children on average scored 9.76 (*SD* = 2.47) for their endorsement of Chinese values. If responding in Chinese activates Chinese interdependent values and responding in English activates Western independent values, children in the Chinese interview condition should evidence higher agreement with Chinese values and children in the English interview condition should evidence higher agreement with Western values. Consistent with the hypothesis, children answering in Chinese ($M = 10.78$, $SD = 1.95$) reported higher agreement with Chinese interdependent values, and thus lower agreement with Western independent values, than did children answering in English ($M = 8.16$, $SD = 2.35$), $F(1, 109) = 43.29$, $p < .0001$, $\eta_p^2 = .28$. Figure 2 illustrates the mean Chinese value scores as a function of age and language of interview. In addition, girls ($M = 10.17$, $SD = 2.22$) reported greater endorsement of interdependent values than did boys ($M = 9.24$, $SD = 2.67$), $F(1, 109) = 7.81$, $p = .006$, $\eta_p^2 = .07$. There was no significant main effect or interaction related to age.

Self-Concept

Children on average provided 4.46 (*SD* = 8.67) self-descriptions. Inspection of the distribution showed that 3 children in the English interview condition were high-influence outliers, where the number of self-descriptions they provided (76, 34, and 32, respectively) were more than 3 *SD* above the group mean. When the 3 children were excluded from analysis, the average number of self-descriptions of the entire sample was 3.27 (*SD* = 3.57). A further ANOVA revealed that children in the English interview condition ($M = 4.60$, $SD = 3.77$) on average provided more self-descriptions than did children in the Chinese interview condition ($M = 2.42$, $SD = 3.20$), $F(1, 92) = 7.90$, $p = .006$, $\eta_p^2 = .08$. There were no significant effects pertaining to age or gender.

Next, the autonomous self score, that is, the ratio of personal-to-social self-descriptions ($M = 1.20$, $SD = 1.55$), was analyzed as a function of language, gender, and age. Because the ratio score controlled for variations in the total number of self-descriptions children provided, the 3 outlier children were included in the analysis. Consistent with the prediction, children interviewed in English ($M = 1.81$, $SD = 1.79$) exhibited a greater sense of autonomous self than did children interviewed in Chinese ($M = 0.78$, $SD = 1.20$), $F(1, 95) = 13.93$, $p = .0003$, $\eta_p^2 = .13$, regardless of gender or age. For example, a child interviewed in English responded that her story would include, "I like to play tennis . . . um, that I like to dance and um, I have a twin . . . that I like to do my homework and I like to swim . . . and I like, um, I have a favorite actor and singer." In comparison, a child interviewed in Chinese responded that in the story about her, she would "Write about my family; write about my mommy, daddy, and brother; my family lives in Jiulongtang." Figure 3 illustrates the mean autonomous self scores as a function of age and language of interview. No other main effect or interaction neared significance. Boys ($M = 1.37$, $SD = 1.68$) scored higher than girls ($M = 1.05$, $SD = 1.43$) on the autonomous self, although the difference was not significant.

Autobiographical Memory

The average length of children's memories was 37.62 (*SD* = 31.87). Analysis revealed a main effect of language, $F(1, 95) = 21.26$, $p < .0001$, $\eta_p^2 = .18$. As expected, children interviewed in English ($M = 51.32$, $SD = 27.12$) provided lengthier

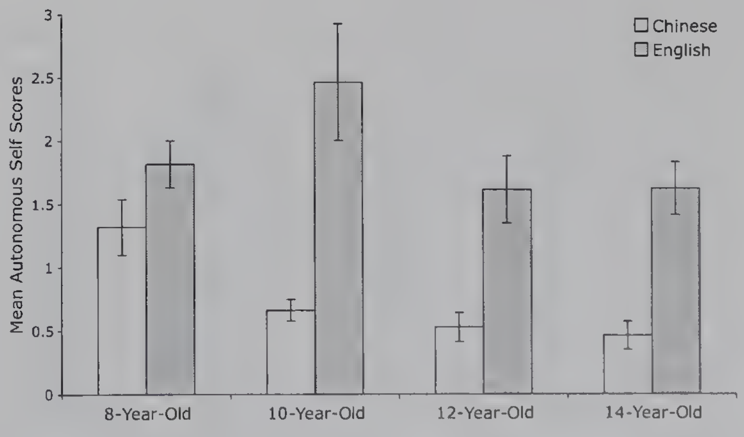

Figure 3. Mean autonomous self scores as a function of age and language of interview.

memories than did children interviewed in Chinese ($M = 28.28$, $SD = 31.67$). There were no significant effects pertaining to age or gender.

Analysis of the degree of self-focus in children's memory ($M = 1.10$, $SD = 0.65$), that is, the ratio of personal-to-social memory content descriptions, further revealed a main effect of language, $F(1, 95) = 5.25$, $p = .02$, $\eta_p^2 = .05$. Children interviewed in English ($M = 1.30$, $SD = 0.72$) provided more self-focused memories than did children interviewed in Chinese ($M = 0.97$, $SD = 0.58$), regardless of gender or age. Figure 4 illustrates the mean memory self-focus scores as a function of age and language of interview. There was no other significant main effect or interaction. Boys ($M = 1.12$, $SD = 0.70$) scored higher than girls ($M = 1.09$, $SD = 0.61$) on memory self-focus, although the difference was not significant.

The following two memory examples, both about a social conflict, further help illustrate the effects of language on memory retrieval. The first memory, provided by a child in the Chinese interview condition, focused on social interactions, group activities, and the roles of others, whereas the second memory, provided by a child in the English interview condition, highlighted the child's own roles, opinions, and perspectives.

> *Memory 1*: Once, my classmates and I were making a poster. One classmate wanted us to use his design. The rest of us didn't really like his idea. We didn't know what to do and argued with him. We all screamed, and the Head teacher had to come. In the end, even the Head teacher thought that he was wrong. So we started designing the poster all over again.

> *Memory 2*: Well, usually I argue with people because that's just sort of my nature. I like arguing. And recently I won this science competition thing at school and when I got the award I told one of my friends. Then he just didn't believe it so then I got a bit angry because he's supposed to believe it . . . well, basically, then I thought he was getting a bit selfish and stuff so I decided to just ignore him for a couple of days.

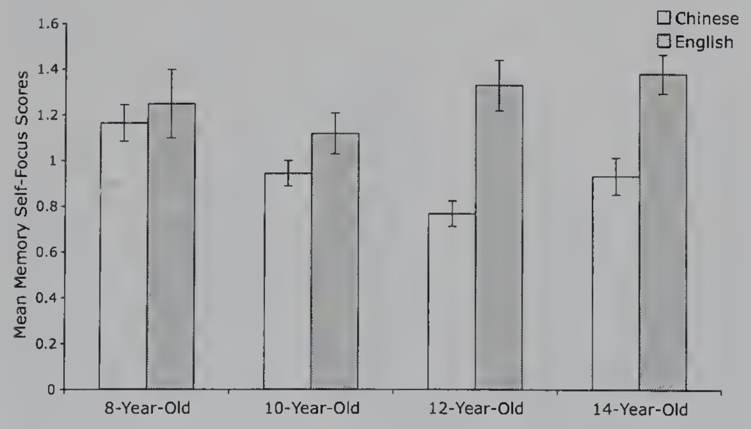

Figure 4. Mean memory self-focus scores as a function of age and language of interview.

Mediation Effects

To test the predicted mediation effects, two mediation analyses were conducted (Baron & Kenny, 1986; MacKinnon, Warsi, & Dwyer, 1995). Figure 5 illustrates the results from the analyses. The first analysis tested whether the effect of language on self-concept was mediated by the activation of cultural value systems (see Figure 5a). To establish the conditions for mediation, language (i.e., the predictor) was first regressed on Chinese value scores (i.e., the mediator) and autonomous self scores (i.e., the criterion), respectively (language was coded 1 for Chinese and 0 for English). The effects were significant in both cases, $t = 6.76$, $p < .0001$, and $t = -3.63$, $p = .0004$. A further regression confirmed that Chinese value scores had a significant effect on autonomous self scores, $t = -2.03$, $p = .04$, independent of language. Furthermore, when both language and Chinese value scores were simultaneously regressed on autonomous self scores, the independent contribution of language was substantially reduced, $t = -2.16$, $p = .03$,

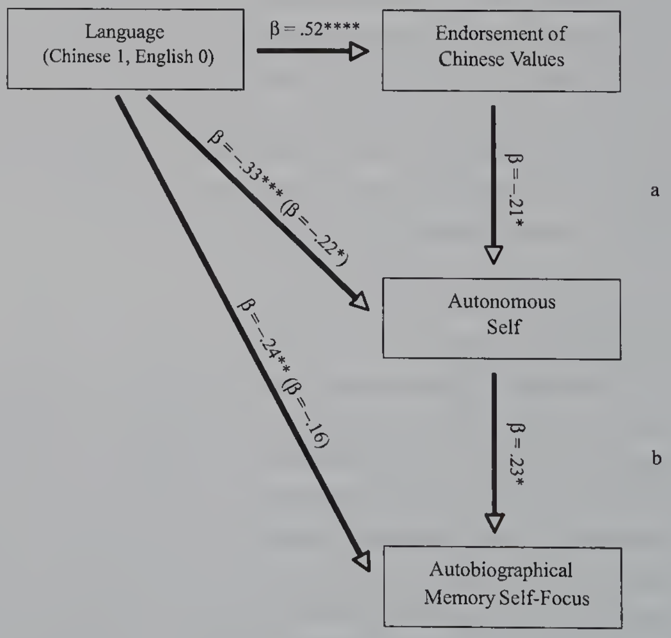

Figure 5. Mediation analyses.
Note. Language was coded 1 for Chinese and 0 for English. The coefficients in parentheses are from regressions when the mediator was included in the equation.
$^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$. $^{****}p < .0001$.

whereby the standardized regression coefficient (β) of language decreased in both size and significance. The reduction was significant by the stringent Sobel (1982) test for mediation, $Z = -1.95$, $p = .05$. Thus, the activated cultural beliefs system is indeed a potent mediator for the effect of language on self-concept.

The next mediation model tested whether the working self-concept mediated the language effect on autobiographical memory (see Figure 5b). Language was a significant predictor of autonomous self scores, $t = -3.63$, $p = .0004$, and memory self-focus scores, $t = -2.62$, $p = .01$. Autonomous self scores were also related to memory self-focus scores, $t = 2.37$, $p = .02$, independent of language. Furthermore, the independent contribution of language to memory self-focus was reduced to a nonsignificant level by the effect of the mediator, the autonomous self, $t = -1.69$, $p = .09$. The reduction was significant by the Sobel (1982) test, $Z = -1.98$, $p = .05$. Thus, the activated autonomous self mediated the effect of language on memory self-focus.

Note that children were first tested for autobiographical recall, followed by the self-description task and then the cultural value questions. Were there any effects of the task sequence such that retrieving certain autobiographical information might lead children to adopt self-concepts consistent with such information, which in turn, might shape their endorsement of cultural values? To answer this question, we tested alternative models of the above analyses. We tested in the first model (Figure 5a) whether the autonomous self mediated the language effect on the endorsement of Chinese values instead. Then, we tested in the second model (Figure 5b) whether memory self-focus mediated the language effect on the autonomous self. In both alternative models, when language and the mediator were simultaneously regressed on the criterion, the effect of language was not significantly reduced compared with when language alone predicted the criterion, Sobel (1982) test $Z = 1.77$, *ns*, and $Z = -1.76$, *ns*, respectively. Thus, there were no mediations due to the task sequence. In addition, we tested a third model with language being the predictor, Chinese value scores being the mediator, and memory self-focus being the criterion. It was found that Chinese value scores did not relate to memory self-focus scores, $t = -0.94$, $p = .35$. The conditions for mediation were therefore not met (Baron & Kenny, 1986). Thus, the activation of culture belief systems did not have a direct effect on autobiographical memory, nor did it mediate the effect of language on memory.

Discussion

The present study is the first to test the effects of language on the cultural self among children. Two aspects of the self, namely, self-concept and autobiographical memory, were examined in bilingual children and adolescents from Hong Kong. Consistent with the predictions, across all age groups, children interviewed in English gave lengthier accounts about themselves and their personal experiences, and they focused more on unique personal attributes and qualities when describing themselves and talked more frequently about their own roles and perspectives in their autobiographical recall, compared with children interviewed in Chinese who provided less elaborate and more socially oriented self-descriptions and memory accounts. In addition, children responding in Chinese reported higher agreement with Chinese interdependent values and lower agreement with Western independent values than did those responding in English, regardless of age. Furthermore, the activation of cultural belief systems mediated the effect of language on self-concept, which, in turn, mediated the effect of language on autobiographical memory. Thus, linguistic usage (i.e., Chinese vs. English) triggered specific cultural belief systems (i.e., interdependence vs. independence), which further shaped the children's conceptions of self and autobiographical memory.

These findings suggest that bilingual children possess different modes of self associated with different languages. They support the theoretical notion that language as a representational medium of culture, represents, maintains, and further expresses the self through linguistic and conceptual configurations (e.g., syntax, grammar, vocabulary) and, perhaps more importantly, the associated (cultural) ways of thinking (Chiu et al., 2007; Holland & Quinn, 1987; Schrauf, 2000). Furthermore, as embedded practices, language learning and narrative interactions more generally take place in culturally organized communicative contexts that transmit to children not only linguistic and communicative skills but also cultural knowledge and competence (Fernald & Morikawa, 1993; Miller et al., 2007; Ochs, 1996). For instance, when sharing memories with their young children, European American mothers often focus on the child's roles and predilections in the past event and encourage the child to elaborate on his or her own perspectives. This child-centered, elaborative style facilitates children's detailed remembering of personal experiences that highlight their uniqueness and socialize children into an autonomous sense of self. In contrast, Chinese mothers often focus on shared activities, important others, and social norms and expect the child to answer pointed questions without elaboration. This group-oriented, pragmatic style helps children develop a sense of belonging and social compliance, and yet downplays the construction of elaborate personal stories and, further, a unique individual identity (Miller et al., 2007; Wang, Leichtman, & Davies, 2000). Through such joint activities, children gradually internalize culture-specific ways of defining themselves and remembering personal experiences (Wang, 2004, 2006a). Language is thus critical to the development and maintenance of a cultural self. For bilingual children, learning to speak two different languages equips them with multiple tools of constructing the self in relation to the sociocultural world. And developing different representations of the self in relation to different languages may further provide them with the flexibility to respond effectively to myriads of cultural and linguistic contexts that they transition in and out in everyday life (Ross et al., 2002; Schrauf, 2000).

The current findings are further provocative in terms of the specific mechanisms underlying the effect of language on the self. According to the cultural accommodation theory (Bond & Yang, 1982), the use of a language may create a ''response bias'' in the direction valued by the culture associated with that language, a process that may take place as either conscious self-presentation or unconscious automatic association. Although this theoretical view can account for the language effects on the children's agreement with Chinese versus Western independent values and their self-descriptions and memory recall, it does not predict the mediation effects. Alternatively, the constructivist view within a social-cognitive framework suggests that the use of a language may serve as a cue that makes salient and accessible the cultural belief system chronically associated with that language. The activated cultural belief system may further activate self-concepts congruent with the belief system. In turn, the currently operative working self-concepts may modulate retrieving of confirmatory autobiographical event information (Schrauf, 2000; Wang, 2008; Wang & Ross, 2005). The results from the mediation analyses lend support for this view, whereby responding in Chinese (vs. English) activated Chinese interdependent (vs. Western independent) values, which mediated, at least partially, the effect of language on the autonomous self. In turn, the autonomous self mediated the effect of language on the degree of self-focus in memory recall. These mediation effects were particularly notable given that the order of the tasks was arranged in a way that would work against the mediations. Indeed, the tests of alterative models showed that the mediations did not occur in opposite directions in spite of possible sequence effects among the tasks. It would be interesting to test in future studies if the expected mediation effects will become more potent when the task order is in favor of the mediations.

This ''chain of reactions'' has important implications for cross-cultural differences in self-concept and autobiographical memory (e.g., Cousins, 1989; Mullen, 1994; Rhee et al., 1995; Wang, 2001, 2004). In the daily life, language, no matter whether it is used privately in thinking or overtly in communication, may serve as a constant reminder of cultural knowledge and beliefs, which can further lead individuals to adopt self-concepts consistent with these knowledge structures. The culturally endorsed self-concepts, or cultural self-construals (Kağitçibaşi, 2007; Markus & Kitayama, 1991), may remain chronically active, salient, and accessible given the constant reinforcement of the linguistic-cultural context in which individuals reside. In turn, they may drive cognitive resources into the privileged processing and retrieving of autobiographical information that confirms the goals and motivations associated with the self-concepts (Conway & Pleydell-Pearce, 2000), thus giving rise to culture-specific ways of autobiographical remembering (Wang & Ross, 2007).

Notably, the activation of culture belief systems did not have a direct effect on autobiographical memory, nor did it mediate the effect of language on memory. This might seem counterintuitive given the cross-cultural findings that people in different cultures, upholding different cultural beliefs (e.g., independence vs. interdependence), tend to remember their autobiographical experiences in different ways (e.g., being self-focused vs. being socially oriented) consistent with their cultural beliefs (Han et al., 1998; Mullen, 1994; Wang, 2001, 2004; Wang & Leichtman, 2000). However, recent research examining specific mechanisms in individual social-cognitive processes that give rise to cultural differences suggests that culturally endorsed self-concepts function as a potent mediator or predictor in explaining cultural effects on autobiographical memory (Wang, 2006b, 2008; Wang & Ross, 2005). Similarly, the current study showed that the activation of culture belief systems indirectly influenced memory through the currently activated cultural self-concepts. These findings are consistent with general cognitive theories that emphasize the executive role of the conceptual self in modulating the constructive process of autobiographical remembering in line with the self's current goals and motivations (Conway, 2005; Conway & Pleydell-Pearce, 2000; Ross, 1989).

As expected, language effects were observed in children of all age groups. This, coupled with prior findings with adults (Kemmelmeier & Cheng, 2004; Marian & Kaushanskaya, 2004; Ross et al., 2002; Trafimow et al., 1997), suggests that the mechanisms underlying the language effects may operate similarly across age groups. On the other hand, unlike previous cross-cultural findings with preschool and early grade school children (Han et al., 1998; Wang, 2004), age effects and age-related interactions did not emerge in the current sample of children in middle childhood and early adolescence. This might be related to the nature of the tasks that had been previously used with younger children (Han et al., 1998; Wang, 2004, 2006b) and were therefore simple enough for older children and adolescents to give readily responses, thus eliminating age effects due to developmental differences in cognitive skills. Furthermore, the variables of interest might not differentiate among the children and adolescents of the limited age range of 8–14 years, who, at least in the current sample, showed similar levels of bilingual proficiency and might therefore have similar degrees of bicultural identification (Schrauf, 2000). Future research that includes children and adolescents of a wider age range is called for.

In line with the predictions, girls endorsed more strongly value systems emphasizing interdependence as opposed to independence than did boys, and their memories and self-descriptions appeared to be more socially oriented than those of boys, although the latter differences did not reach significance. These gender-related findings are consistent with the notion that gendered value orientations and self-knowledge emerge early though different family socialization practices and societal expectations (Cross & Madson, 1997; Fivush & Buckner, 2003). One important question to pursue further in this line of research is to examine differing developmental processes and consequences for boys and girls when gender norms and cultural norms coincide or clash.

The current findings have further implications for the development of the self in the immigration context. Many immigrant children and adolescents in the United States, for instance, are often exposed to contrasting cultural values and practices across various contexts of home, school, community, and the larger society (Mahalingam, 2006). Research has shown that developing a bicultural self, where immigrant individuals identify with both the host culture and their culture of origin, lends flexibility to cognition and behavior and is positively associated with psychological well-being (Kim & Omizo, 2006; Ryder, Alden, & Paulhus, 2000). In line with language socialization theories (Chiu et al., 2007; Miller et al., 2007; Ochs, 1996), findings from this study and previous studies with bilingual immigrant adults further suggest that bilingual proficiency may facilitate both the preservation of the ethnic culture and the adoption of the host culture, and may be a critical factor for the construction of a bicultural self among immigrants (Marian & Kaushanskaya, 2004; Ross et al., 2002; Schrauf, 2000). It should be noted, however, that different from the bilingual–bicultural children in Hong Kong, immigrant children may face unique obstacles as they strive to sustain their ethnic culture and language often without broader societal encouragement or recognition to do so, and this can make the development of a bicultural self an ever challenging task. Further longitudinal research is required to examine systematically how immigrant children come to develop a bicultural self in the process of acquiring the first and second languages and what important individual, familial, and societal factors are involved in this process.

George Miller once commented that "no general theory of psychology will be adequate if it does not take account of language" (Miller, 1990, p. 7). Applied to the self, it may follow that no theory of self-development will be adequate if it does not take account of language socialization. Our findings suggest that language is a powerful device for activating and reinforcing associated cultural constructs and plays a critical role in the construction, maintenance, and expression of a dynamic cultural self. In the process of becoming proficient speakers of their languages, children come to acquire cultural knowledge and culturally promoted self-views and are further socialized into competent members of their society.

When Do Children Exhibit a "Yes" Bias?

Mako Okanda and Shoji Itakura
Kyoto University

This study investigated whether one hundred and thirty-five 3- to 6-year-old children exhibit a yes bias to various yes–no questions and whether their knowledge status affects the production of a yes bias. Three-year-olds exhibited a yes bias to all yes–no questions such as *preference-object* and *knowledge-object* questions pertaining to objects, and *knowledge-face* questions pertaining to facial expressions. Four-year-olds tended to say "yes" only to knowledge-object questions. Five-year-olds did not show any strong response tendency. Six-year-olds exhibited a *nay-saying* bias to knowledge-face questions. Also, 3-year-olds could indicate the correct option when asked questions with 2 response options. It suggested that 3-year-olds tended to inappropriately say "yes" to yes–no questions, although they knew the answers to the questions. The mechanism of a yes bias was discussed.

A large number of studies in developmental psychology often use questioning of children in their research methodology. Researchers question children in experimental tasks in order to obtain conclusions about the children's social and cognitive development (e.g., Fritzley & Lee, 2003; Waterman, Blades, & Spencer, 2004); however, children sometimes exhibit a response bias to questions. A response bias is seen when children tend to give inappropriate responses by providing the same answer such as saying "yes" to yes–no questions (i.e., a yes bias).

A response bias is most often observed when children are asked closed questions like forced-choice and yes–no questions (e.g., Flavell, Flavell, & Green, 1983; Flavell, Green, & Flavell, 1986; Flavell, Zhang, Zoui, Dong, & Qi, 1983; Gopnik, Sobel, Schulz, & Glymour, 2001; Siegal & Surian, 2007; Steffensen, 1978), with yes–no questions being the most problematic type for preschoolers (see also Fritzley & Lee, 2003). In fact, a yes bias was stronger when 3- to 5-year-olds were asked yes–no questions as compared to open-ended questions (i.e., wh questions; Peterson, Dowden, & Tobin, 1999) or forced-choice questions (Peterson & Grant, 2001). Five- to 9-year-old English-speaking children could say "I don't know" to unanswerable wh questions, whereas they were reluctant to say it and attempted to provide "yes" or "no" responses to unanswerable yes–no questions (Waterman, Blades, & Spencer, 2001; Waterman et al., 2004). Similarly, 5-year-olds tended to say "yes" to bizarre yes–no questions such as "Is milk bigger than water?" (Hughes & Grieve, 1980).

Given the possibility that children exhibit a yes bias to yes–no questions, several studies investigated children's yes bias in simulated interviews about staged or experienced events (Peterson & Grant, 2001; Peterson et al., 1999), in simple experimental situations (Fritzley & Lee, 2003; Okanda & Itakura, 2008), and in daily conversations (Okanda & Itakura, 2007; see also Steffensen, 1978). Fritzley and Lee (2003) found that 2- and 3-year-olds exhibited a yes bias to simple yes–no questions pertaining to the properties and functions of objects. Okanda and Itakura (2008) replicated the study and found that 2- to 4 year-old Japanese and Vietnamese children exhibited a yes bias to the same type of yes–no questions.

This research was supported by the research fellowship of the Japan Society for the Promotion of Science (JSPS) for young scientists to Mako Okanda, by the grants from the JSPS (20330150) and the Nissan Science Foundation to Shoji Itakura, and by the Global COE Program "Revitalizing Education for Dynamic Hearts and Minds," MEXT, Japan. We are grateful to the teachers in the kindergartens and the nursery schools, the parents of the children, and especially to the children who participated in this study. We are also grateful to the two anonymous reviewers and to Kazuo Fujita, Makoto Takahashi, Yusuke Moriguchi, Tara Callaghan, and Kang Lee for their constructive and valuable comments on experiments and/or drafts.

A yes bias appears to be a common phenomenon among young preschoolers who are living in different countries and speak different languages. Three main reasons have been advanced to account for a yes bias. The first relates more to perceived social factors, and the second and third to cognitive development.

First, children might feel social pressures that they have to provide an answer when questioned by adults (Cassel, Roebers, & Bjorklund, 1996; Moston, 1990) because they might believe that (a) adults prefer a "yes" response (Brady, Poole, Warren, & Jones, 1999), (b) it would be in agreement with adults (Peterson & Biggs, 1997), and (c) it would display compliance (Peterson & Biggs, 1997) with the interviewer's intentions, especially when he or she is not a family member (Krähenbühl & Blades, 2006; Zajac, Gross, & Hayne, 2003; Zajac & Hayne, 2003). In addition to these social pressures, children might be likely to affirm interviewers' intentions because yes–no questions are highly suggestive (Ceci & Bruck, 1993; Peterson et al., 1999). The social pressure research typically examines children's answers to experimenters, and thus, the question arises as to whether children provide inappropriate answers to yes–no questions because the interviewers are unfamiliar adults. However, Okanda and Itakura (2007) found that 2- and 3-year-olds exhibited a yes bias to their own mothers. The issue of the social pressure of compliance still remains in this case, but it is clear that a stranger effect does not explain fully why children show a yes bias.

The second and third possibilities are that young preschoolers may be unable to appropriately answer questions due to cognitive factors that impact their ability to understand conversations or pragmatics with the experimenter, or their inhibitory control. Related to the second possibility, Lee and Eskritt (1999) suggested that understanding the contexts of questions, such as what an interviewer would like to know, is considerably important in order to appropriately answer questions. Children may have learned that saying "yes" is better than saying "no" in day-to-day questions (e.g., "Could you close the door?"), and thus, they tend to say "yes" to yes–no questions without fully understanding the contexts of the questions. Similarly, Fritzley and Lee (2003) suggested that children's yes bias and conversational or pragmatic understanding might be related. The third possibility suggests that a "yes" response could be a dominant response that is difficult to inhibit for young preschoolers (Okanda & Itakura, 2007). Moriguchi, Okanda, and Itakura (2008) indicated that the dominance of "yes" responses may be achieved simply because adults rarely ask young children questions for which the answers are "no" and so children may have more experience in saying "yes" than in saying "no." Evidence that supports the idea that these are mitigating cognitive factors suggests that children who have lesser verbal ability and inhibitory control displayed a stronger yes bias (Moriguchi et al., 2008).

In this study, we hypothesized that cognitive factors play a role in a yes bias and examined the following three issues that have not been investigated thus far in previous studies: (a) Do children exhibit a yes bias when asked yes–no questions about their preferences? (b) Do children display a yes bias to yes–no questions pertaining to knowledge of objects as well as to different domains, such as questions about knowledge of facial expressions? (c) Do children exhibit a yes bias even when they actually know the answer?

The first research question investigates whether children exhibit a yes bias to yes–no questions pertaining to their preference. Previous research only considered questions that pertain to what the children knew, did, or witnessed; this is probably because most of the previous studies were concerned with the accuracy of children's responses to questions in forensic interviews. For example, Peterson et al. (1999) questioned children after they were shown staged events. Waterman et al. (2001) narrated short stories and questioned children about these stories. Although Fritzley and Lee (2003) did not employ a simulated forensic interview style, they asked questions only pertaining to the properties and functions of objects. Thus, the questions used in the previous studies were all knowledge questions that demanded objective judgments and that evaluated children's knowledge.

In Study 1, we asked children "preference" yes–no questions pertaining to objects (e.g., "Do you like this?" or "Do you dislike this?"; i.e., *preference-object yes–no questions*) that demanded binary but subjective decision making. Such questions are clearly different from the questions asked in the previous studies pertaining to the properties and functions of objects (i.e., *knowledge-object yes–no questions*) because here children were allowed to answer "yes" or "no" depending on their preferences, and there were no particular correct answers. More importantly, children should have more experiences with preference than knowledge questions in daily conversation, and thus, the former may be easier for children to answer appropriately than the latter. It is worth comparing these two types of questions. In addition, although the word *dislike* is an unfamiliar word in English, the word meaning *dislike* in Japanese, *kirai*, is a very familiar word for Japanese preschoolers. We chose *dislike* rather than *hate* which may be familiar to English-speaking preschoolers, because the English *hate* is too extreme to use for the Japanese *kirai*.

The second research question investigates whether children exhibit a yes bias to yes–no questions pertaining to social entities. In Study 2, we asked children simple yes–no questions pertaining to facial expressions (i.e., *knowledge-face yes–no questions*) in order to compare their response tendencies to knowledge-based questions. Fritzley and Lee (2003) asked children simple questions about objects, but they did not ask questions about social entities. Although other studies have questioned children about events, environments, and people, these studies were simulated forensic interviews with a delay between the events and interviews that might introduce memory issues (e.g., Peterson & Biggs, 1997; Peterson & Grant, 2001; Peterson et al., 1999). Questions about facial expressions are a special type of knowledge question, one that taps children's social emotional knowledge.

The last issue we considered was to examine whether children's knowledge status influences the production of a yes bias. In Study 3, we confirmed what children's knowledge status was and then asked children choice questions that had two options (i.e., ''Which is X?'' and ''Which is for X?''). We presented children with two objects or cards that had been used in the first two studies in this study, as well as items from the study conducted by Okanda and Itakura (2007). We investigated the possibility that children might say ''yes'' when asked yes–no questions, despite knowing the answer.

In addition, we examined whether Japanese children give ''I don't know'' and ''no answer'' responses in Study 1 and Study 2 because Okanda and Itakura (2008) reported that Asian children, in contrast to North American children, do show these responses to yes–no questions.

Study 1

In this study, we investigated whether children show a yes bias to preference-object questions that have no correct answer, framed in a social context to examine children's attitudes. Children's responses to the preference-object questions were compared with those to knowledge-object questions that have correct answers.

Method

Participants

Participants of this study were 61 Japanese children: twenty 3-year-olds (M = 43.3 months, SD = 2.70, range = 37–47 months; 8 boys and 12 girls), twenty 4-year-olds (M = 54.1 months, SD = 3.69, range = 48–59 months; 9 boys and 11 girls), and twenty-one 5- to 6-year-olds (M = 72.4 months, SD = 3.76, range = 64–79 months; 11 boys and 10 girls). An additional 3-year-old child was investigated but excluded from further analysis because she refused to participate in the experiment. The children were selected from kindergartens and nursery schools in Kyoto and Kobe, Japan.

Materials and Procedures

We followed the procedure and materials used by Fritzley and Lee (2003) and Okanda and Itakura (2008). Objects used in the present study were identical to those used by Okanda and Itakura (2008). The familiar objects included a blue cup, a red apple, and a picture book, and the unfamiliar objects included a plastic coffee filter, a shoehorn, and a CPU. Children's object familiarity to these items was confirmed in Okanda and Itakura (2008). The familiar objects were known to be familiar, and the unfamiliar objects were known to be unfamiliar for Japanese 2- to 5-year-old children.

In the experiment, each child was interviewed individually in a classroom at the nursery school in which he or she was studying. Each child was asked 36 questions, with six questions pertaining to each object (the list of the questions asked is provided in Appendix A). Four of the six questions were knowledge-object yes–no questions that inquired about the properties and functions of objects, and the other two were preference-object yes–no questions that asked whether the child liked or disliked the object. Two of the four knowledge questions were yes questions (i.e., the correct answer was ''yes''), and the other two questions were no questions (i.e., the correct answer was ''no''). The two preference questions had no correct answer, and each child could provide any answer that he or she felt to be appropriate. For every object, each child was asked both like and dislike questions (i.e., ''Do you like this? ''Do you dislike this?") to confirm whether children appropriately and consistently showed their preferences. That is, if the children liked the object, they were required to answer "yes" to the like question and "no" to the dislike question.

Half of the children were first asked questions about a familiar object. An experimenter randomly chose one of three familiar objects as the first target object and subsequently asked six questions. The six questions, both preference and knowledge questions with regard to each object, were presented to each child in a random manner. The experimenter then randomly chose one of three unfamiliar objects as the second target object and asked six questions. The following target objects alternated between the remaining familiar and unfamiliar objects. For the other half of the children, the first target object was an unfamiliar object, and the subsequent target objects were alternately chosen from familiar and unfamiliar objects. Children did not always need to know the exact names and functions of the objects to answer the yes–no questions. For example, some questions asked about color or shape of the objects. The experimenters explained the purpose and method of the study to the directors of the nursery schools prior to the experiments.

Scoring

Knowledge response bias scores. We modified Fritzley and Lee's (2003) scoring method to examine the response bias score for the knowledge yes–no questions for each child (a knowledge response bias score). First, for all yes questions the children scored 1 if their response was "yes" (a correct answer) and −1 if their response was "no" (an incorrect answer). The scores were added to obtain a yes score. Similarly, for all no questions, the children scored 1 for all "no" responses (a correct answer) and −1 for all "yes" responses (an incorrect answer). Thereafter, the scores were added to obtain a no score. Both "no answer" (when they were posed and said nothing) and "I don't know" responses were scored as zero. To derive a proportional yes score, the yes score was divided by the total number of yes questions. A proportional no score was derived in a similar manner. Subsequently, the proportional no score was subtracted from the proportional yes score and a knowledge response bias score was obtained. The score range was 1 to −1, with a positive response bias score indicating a yes bias and a negative response bias score indicating a nay-saying bias (a response tendency to say "no"). The knowledge response bias score for a child who did not have a response bias would be zero.

Preference response bias scores. The calculation of a response bias score for the preference yes–no questions (a preference response bias score) was modified based on the calculation of the knowledge response bias scores. In order to examine whether each child's responses corresponded with each other in both the like and dislike questions for each object, the children were given 1 for every "yes" response and −1 for every "no" response. Thereafter, the mean scores were considered as the preference response bias score. The preference response bias score for a child who did not have a response bias was zero (i.e., a child who was able to answer "yes" to like questions and "no" to dislike questions, or vice versa). A positive preference response bias score implied that the child tended to respond with a "yes" to both the like and dislike questions, and a negative preference response bias score suggested that a child tended to respond with a "no" to both questions. Both the knowledge and preference response bias scores were separately calculated for familiar and unfamiliar objects.

Results

Figure 1 shows the children's response bias scores in each age group. We conducted a preliminary analysis on the 5- and 6-year-olds because the age range of the 5- to 6-year-olds was 64–79 months and the 6-year-olds were actually younger

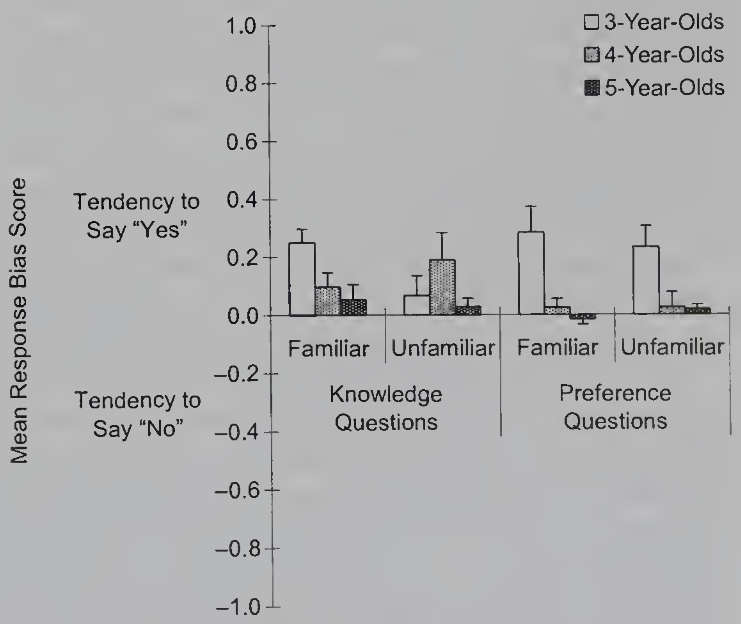

Figure 1. Children's mean knowledge response bias scores and mean preference response bias scores on knowledge and preference questions.
Note. T-bars represent standard errors.

6-year-olds. There was no main effect of age between 5- and 6-year-old children; hence, we combined them into one group. Subsequently, a 3 × 2 × 2 mixed-design analysis of variance (ANOVA; age: 3 years, 4 years, 5–6 years; familiarity: familiar, unfamiliar; question type: knowledge, preference) was conducted. The main effect of age was significant, $F(2, 58) = 7.94$, $p < .01$, partial $\eta^2 = .22$. Post hoc Tukey honestly significant difference (HSD) tests revealed that 3-year-olds showed a significantly stronger yes bias than did the 4- ($p < .05$) and 5-year-olds ($p < .01$). Furthermore, the Age × Familiarity interaction was significant, $F(2, 58) = 3.22$, $p < .05$, partial $\eta^2 = .10$, and the Age × Question Type interaction was marginally significant, $F(2, 58) = 2.93$, $p = .061$, partial $\eta^2 = .09$.

One-sample t tests were conducted to confirm these interactions and to examine whether the response bias scores were significantly above or below zero. The mean knowledge and preference response bias scores of each age group within each condition was compared to a score of zero (a zero implied that there was no response bias). With regard to the knowledge questions, 3-year-olds exhibited a strong yes bias with respect to familiar condition, $t(19) = 5.31$, $p < .01$, and 4-year-olds tended to display a yes bias for both familiar and unfamiliar items, $t(19) = 1.91$, $p < .10$, and $t(19) = 2.01$, $p < .10$, respectively. In addition, the one-sample t tests indicated that the mean knowledge response bias score of 5- to 6-year-olds was significantly higher than zero with respect to familiar condition, $t(20) = 2.80$, $p < .05$, although the raw knowledge response bias score was almost zero ($M = .053$). The knowledge response bias scores of 5- to 6-year-olds were significantly lower than those of 3-year-olds. Japanese 5- to 6-year-olds could have a yes bias, but the tendency was very weak. With regard to the preference questions, only 3-year-olds exhibited a strong yes bias with respect to both familiar and unfamiliar conditions, $t(19) = 3.21$, $p < .01$, and $t(19) = 3.19$, $p < .01$, respectively.

In addition, the frequency of "I don't know" and "no answer" response was also calculated. For the knowledge yes–no questions, the children were more likely to provide other responses ("I don't know") or not respond when they were asked unfamiliar questions (12 times) than when they were asked familiar questions (6 times). For the preference yes–no questions, all the children responded to the questions. There was no difference in the "I don't know" responses for familiar and unfamiliar objects; the frequency of the "I don't know" responses was 9 versus 11, respectively.

Discussion

In this study, we investigated whether 3- to 6-year-old Japanese preschoolers exhibit a yes bias to preference-object and knowledge-object yes–no questions. The results revealed that 3-year-olds had strong tendency to exhibit a yes bias to both preference and knowledge questions. Four-year-olds were able to appropriately answer preference questions but showed a yes bias to knowledge questions. Five- to 6-year-olds did not show a response bias to preference questions but showed very weak tendency to say "yes" to knowledge questions regarding familiar objects.

First, the results with regard to the knowledge questions in this study were mostly consistent with those obtained in a similar study by Okanda and Itakura (2008). Second, the most important finding in this study was that 3-year-olds exhibited a yes bias to both knowledge and preference questions, but 4- to 6-year-olds displayed a yes bias only to knowledge yes–no questions. Knowledge and preference questions might be equally difficult for 3-year-olds; however, knowledge questions might be more difficult than preference questions for 4- to 6-year-olds. Hence, the older children were likely to display a yes bias to difficult yes–no questions. This result may indicate that 3-year-olds show a yes bias automatically regardless of the question type, but older children may have different reasons for responding with a "yes" in certain questions. It is possible that some social factors may affect older children's yes bias; however, a weak yes bias in 5- to 6-year-olds in this study must be treated with caution because the previous study did not report such a tendency (Okanda & Itakura, 2008).

Third, object familiarity did not influence the children's yes bias with respect to preference questions. In contrast, it might be important with regard to the knowledge question because the children's yes bias differed between questions regarding familiar and unfamiliar objects. One possible reason why object familiarity influenced a yes bias only for knowledge questions is that the children were in a test situation where their knowledge was being examined. In this kind of a situation, the children were sensitive to whether they were knowledgeable or ignorant about the questions and thus it affected their answers. Our result indicates that knowledge and preference questions differ in terms of their inherent characteristics.

Finally, Japanese children in this study were likely to show a stronger yes bias to familiar objects than to unfamiliar objects, as Okanda and Itakura

(2008) reported. This tendency was exactly opposite to that obtained by Fritzley and Lee (2003) when they examined North American children. However, this tendency was not robustly observed in this study, and we need to further examine the object familiarity effect and cross-cultural differences in future research.

In this study, we found that 3-year-olds display a yes bias to both knowledge and preference questions, but older children exhibited a weak yes bias only to knowledge questions. In Study 2, we examined whether children exhibit a yes bias to knowledge questions from the social domain.

Study 2

In this study, we investigated whether children exhibit a yes bias to yes–no questions pertaining to the facial expressions of schematic faces. It is important to note that while a question about facial expressions is a type of knowledge question, it pertains to social entities. Children's responses to knowledge-face questions were compared with their responses to knowledge-object questions.

Method

Participants

Participants of this study included 74 Japanese children, none of whom participated in Study 1: twenty-seven 3-year-old children (M = 41.1 months, SD = 3.57, range = 36–47 months; 14 boys and 13 girls), twenty-two 4-year-old children (M = 54.1 months, SD = 3.24, range = 48–59 months; 15 boys and 7 girls), twelve 5-year-old children (M = 67.1 months, SD = 3.53, range = 60–71 months; 9 boys and 3 girls), and thirteen 6-year-old children (M = 76.5 months, SD = 3.73, range = 72–83 months, 9 boys and 4 girls). The children were selected from kindergartens and nursery schools in Kyoto and Ashiya, Japan.

Materials and Procedures

For the object condition, we used four familiar objects. Three objects were exactly the same as those used in Study 1 (i.e., a blue cup, a red apple, and a picture book), and the fourth object was a spoon. For the face condition, four schematic faces were used. Two cards were used for each face: One showed the face smiling and the other showed it crying; a total of eight cards were used.

In the experiment, each child was tested individually. A child was asked 32 questions: 16 object questions and 16 face questions. For the object condition, two of four questions were yes questions (i.e., questions whose correct answers were "yes") and the other two questions were no questions (i.e., questions whose correct answers were "no"). For the face condition, each card had two questions: a yes question and a no question (see Appendix B).

Half of the children were first asked object questions, and the remaining half of the children were first asked face questions. For the former group, an experimenter randomly chose one of the four objects and asked the children four questions. The order of four questions was randomized. Thereafter, the experimenter randomly chose objects sequentially from the remaining objects and asked four questions per object accordingly. For the latter group, the experimenter randomly chose one of the eight facial expression cards, showed it to the child, and asked two questions in random order. The experimenters explained the purpose and method of the study to the directors of the nursery schools prior to the experiments.

Results

The response bias scores of the object and face conditions were calculated separately. The scoring method used in this study was exactly the same as that used in Study 1. Age range of the 5- and 6-year-olds in this study was 60–83 months. A preliminary analysis revealed that the 5- and 6-year-olds exhibited extremely different response bias patterns; hence, we analyzed them under different age groups. We conducted a 4 × 2 × 2 mixed-design ANOVA (age: 3 years, 4 years, 5 years, 6 years; entity: object, face; order: object questions first, face questions first) to examine whether there was an order effect between the groups who received the object versus face condition first. There was no order effect, $F(1, 66) = .06$, $p = .81$, partial $\eta^2 = .01$, and no interaction between order and entity was revealed, $F(3, 66) = 1.05$, $p = .36$, partial $\eta^2 = .05$.

A 4 × 2 mixed-design ANOVA (age: 3 years, 4 years, 5 years, 6 years; entity: object, face) was then conducted on the children's response bias scores (see Figure 2). The main effect of age was significant, $F(3, 70) = 10.43$, $p < .01$, partial $\eta^2 = .31$. Post hoc Tukey HSD tests revealed that the 3-year-olds' mean response bias scores were significantly higher than that of 4- ($p < .01$), 5- ($p < .01$), and 6-year-olds ($p < .01$). Furthermore, the main effect of entity was also significant, $F(1, 70) = 22.77$, $p < .01$,

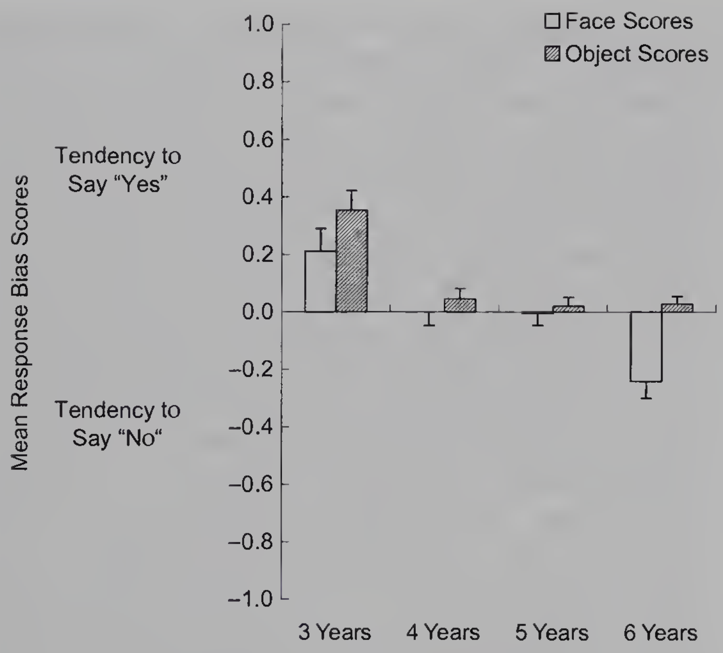

Figure 2. Children's mean knowledge response bias scores on object and face questions.
Note. T-bars represent standard errors.

partial $\eta^2 = .25$. The children exhibited a stronger yes bias to object questions than they did to face questions. No interaction between age and entity was revealed, $F(3, 70) = 2.10$, $p = .11$, partial $\eta^2 = .08$.

One-sample t tests were conducted to confirm whether response bias scores were significantly above or below zero. The mean response bias score of each age group and each condition was compared to a score of zero, which indicated no response bias. Three-year-olds exhibited a strong yes bias in the object condition, $t(26) = 5.25$, $p < .01$, and the face condition, $t(26) = 2.63$, $p < .05$, whereas 6-year-olds displayed a nay-saying bias in the face condition, $t(10) = -4.06$, $p < .01$.

Neither face questions nor object questions elicited a large number of "I don't know" and "no answer" responses. Only one 4-year-old child displayed a high frequency of not responding to the questions.

Discussion

Study 2 investigated whether the type of question (object vs. face) influenced children's yes bias. As in Study 1, the results confirmed that 3-year-olds exhibited a strong yes bias to various yes–no questions and showed further that the tendency to say "yes" was stronger to object questions than to face questions. In addition, 6-year-olds displayed a nay-saying bias to face questions.

First, 3-year-olds exhibited a strong yes bias to both knowledge-objects and knowledge-face questions, and their yes bias was the strongest among all age groups. This suggests that 3-year-olds display a yes bias to yes–no questions regardless of the entities to which the questions pertain. It is possible that 3-year-olds automatically exhibit a yes bias when asked yes–no questions.

Second, entities to which the questions pertained possibly influenced the strength of children's response bias. Overall, children in Study 2 said "yes" more frequently to object questions than they did to face questions. This result is partly consistent with the result of Study 1, which revealed that older children tended to say "yes" to object questions but not to preference questions. One possible reason why the entities to which the questions pertained affected the children's yes bias might be the difficulty level of the questions. Both questions tested children's knowledge; however, responding to face questions, which tap social knowledge, may be easier than responding to object questions.

Six-year-olds already seemed to understand a variety of facial expressions and they were likely to insist on accurately expressing their opinions. For example, they sometimes said "No, he is smiling" to the card with happy face when asked "Is he glad?" and vice versa. This attention to specificity in their answers might explain why 6-year-olds tended to say "no" to face questions. They might understand that the experimenter was asking the questions to assess their knowledge, and they wanted to demonstrate a high level of knowledge. Thus, these children might understand the question interview context more deeply than the younger children..

Finally, the children in this experiment did not often respond with "I don't know" or with no response. One possibility is that we used object questions involving only familiar objects and face questions regarding highly familiar emotional expressions, and thus Japanese children were capable of answering these familiar questions (see also Okanda & Itakura, 2008). That the children were comfortable with the familiarity of these items is supported by the finding that the 5- and 6-year-olds in Study 2 did not display a yes bias to yes–no questions to familiar objects, in contrast to that found for children at this age in Study 1.

In this study, we have found that 3-year-olds exhibited a yes bias to both types of yes–no questions (object, face); however, the question that still remains unanswered is whether children tend to say "yes" to yes–no questions despite knowing the answer or because they do not know the answer. In

Study 3, we confirmed whether or not the 3-year-olds who participated in Study 2 had prior knowledge of the target entities of the questions.

Study 3

In this study, we investigated whether 3-year-old children knew the answer or did not know the answer to the yes–no questions when they responded with a "yes" response, and whether children's level of knowledge about the entity influenced their yes bias. The 3-year-old children were asked questions with two response options and were asked to indicate the correct answer.

Method

Participants

Participants of the study included twenty-two 3-year-old Japanese children (M = 40.6 months, SD = 3.39, range = 36–47 months; 11 boys and 11 girls) who had participated in Study 2.

Materials and Procedures

Each child was asked 18 choice questions relevant to objects and face stimuli from Study 1 and Study 2 and previous studies (Fritzley & Lee, 2003; Okanda & Itakura, 2007, 2008). The target objects included six familiar objects (i.e., blue cup, red apple, green apple, book, spoon, and toothbrush) and the eight face cards that were used in Study 2. Two objects or two cards were shown to the children, and they were instructed to indicate the correct answer from the two response options by pointing. The questions were based on the object condition or the face condition; the former had 10 questions and the latter had 8 questions.

Each child was tested individually. The conditions were counterbalanced and the order of questions was randomized. The experimenter chose one of the two conditions, object or face, and showed two objects or two face cards to the child. The experimenter then instructed the child to indicate one of the two options and asked the questions appropriate to the item (i.e., "Which is X?" or "Which is for X?"; Appendix C provides the list of questions asked in Study 3). The same two face cards were always presented together. The other condition followed the first condition using the same procedure. In order to avoid order effects, half of the children began Study 2 first, and the other half began Study 3 first. The one study immediately followed the other study.

Results

Each child received a score of 1 for a correct answer and a score of 0 for an incorrect answer. Subsequently, the proportional correct score of the choice questions was obtained by calculating the average of the scores, and thus, the overall scores of the responses to object and face choice questions were in the range 0.0–1.0. The children's face choice question mean scores were .98 (SD = .05), and object choice question mean scores were .97 (SD = .06).

The children's correct scores for the yes–no questions asked in Study 2 were also obtained in this study. The children received a score of 1 for a correct answer and score of 0 for an incorrect answer. Subsequently, the proportional score of the yes–no questions was obtained by calculating the average of the scores, and thus the overall scores of the responses to object and face yes–no questions were in the range 0.0–1.0. The children's face yes–no question scores were .43 (SD = .09) and object yes–no question scores were .38 (SD = .08).

A 2 × 2 within-design ANOVA (entity: object, face; question type: choice, yes–no) was conducted. The main effect of entity was significant, $F(1, 21) = 5.78$, $p < .05$. The children's performance was better when they were asked face questions than object questions. The main effect of question type was also significant, $F(1, 21) = 1367.77$, $p < .01$. The children gave significantly more correct answers to choice questions than to yes–no questions.

One-sample t tests were conducted to investigate whether the children were better able to choose the options or answer the yes–no questions correctly. The mean correct scores of the object and face conditions for the choice and yes–no questions were compared to a chance level (0.5). The children's mean scores for correct responses to the choice questions were significantly higher than the chance level: object condition, $t(21) = 35.14$, $p < .01$, and face condition, $t(21) = 46.81$, $p < .01$. The children were able to choose the correct answer from the two options. The children's mean scores for correct responses to the yes–no questions were significantly lower than the chance level: object condition, $t(21) = -7.37$, $p < .01$, and face condition, $t(21) = -3.69$, $p < .01$. Thus, the children were unable to correctly answer yes–no questions.

Discussion

Study 3 investigated whether children exhibited a yes bias even if they know the correct answer, and whether their level of knowledge about the entity influences their yes bias. Three-year-olds were able to provide correct answers when they were asked questions in the choice question format, and their knowledge about the entity seemed to influence their yes bias.

Our finding suggests that even though the children knew the answer, they tended to say "yes"; that is, they answered inappropriately only to yes–no questions. In addition, the children were found to be more knowledgeable about facial expressions than objects. The level of knowledge with regard to the entity could partly explain why children exhibited a weaker yes bias to questions about facial expressions, which they are more knowledgeable about, than they did to questions about objects.

General Discussion

The present study investigated whether 3- to 6-year-old Japanese preschoolers exhibit a yes bias to yes–no questions from two knowledge domains, and whether 3-year-olds possess sufficient knowledge about the subject of the questions. It is important to note that this was the first study, to our knowledge, that investigated whether children display a yes bias to questions about one's own preferential attitude and about the social entity of facial expressions. In Study 1, 3-year-olds exhibited a yes bias to both knowledge-object and preference-object questions, but 4-year-olds displayed a yes bias only to knowledge-object questions. Five- to 6-year-olds tended to exhibit a very weak yes bias that needs a further investigation. In Study 2, only 3-year-olds exhibited a yes bias to both knowledge-object and knowledge-face questions, and 6-year-olds showed a nay-saying bias to knowledge-face questions. In Study 3, 3-year-olds were able to answer choice questions that measured their knowledge of the objects, and level of knowledge about the entity might be found to influence their yes bias.

First, let us address the yes bias among 3-year-olds, who exhibited a strong yes bias to every yes–no questions even when they were knowledgeable about the entities to which the questions pertained. These results are partly consistent with earlier studies that revealed that 2-year-olds were unable to express what they know even when they have sufficient knowledge (e.g., Berthier, DeBlois, Poirier, Novak, & Clifton, 2000; Hood, Carey, & Prasada, 2000; Kloos, Haddad, & Keen, 2006). In these studies, 2-year-olds failed to find a ball on the ramp that was stopped by a barrier behind one of several opaque screens even though they seemed to have knowledge of solidity. Similarly, the children in this study might have failed to express their knowledge of objects and facial expressions and tended to inappropriately say "yes" to all questions.

Why do 3-year-olds exhibit a strong yes bias to yes–no questions? Understanding the context of questioning formats with adults and inhibitory control ability are considered plausible factors. Attention to the precise context of the question is needed to correctly answer the yes–no format of questions (Lee & Eskritt, 1999); however, 3-year-olds might not pay close attention to these contexts. Also, as Moriguchi et al. (2008) indicated, a "yes" response could be a dominant response because adults may not often ask children questions that require saying "no." Three-year-olds might not be able to inhibit their dominant "yes" response, and they automatically exhibited a yes bias (Moriguchi et al., 2008; Okanda & Itakura, 2007). However, it is also possible that the knowledge of 3-year-olds might not be as consolidated as that of older children. Choice questions probably required less knowledge than yes–no questions did because two options of the answer were presented in the choice questions but no such options in the yes–no questions. As the result, the children could perform well on the choice questions. Also, the issue of compliance is still a potential factor in accounting for children's yes bias. Children may be likely to say "yes" because adults are authoritative interviewers for them. In future research, we need to investigate whether children exhibit a yes bias to other children's yes–no questions. Children may not feel the same division of authority to children about the same age as they do with adults, and they may not show a yes bias to their peers.

Second, why do 4-year-olds and some older children exhibit a yes bias only to object questions? As discussed in Study 1, one possible explanation is that older children tend to display a yes bias to more difficult yes–no questions, and knowledge questions regarding objects appeared to be the most difficult type of the questions. Another possible explanation is that object questions which present a knowledge-testing situation may not be familiar to young children; hence, it might be difficult for the children to answer correctly. In fact, the children's yes bias was stronger when they were asked object questions than when they were asked face questions. Lee and Eskritt (1999) suggested that it is difficult for children to adjust their responses if they are asked questions in a context that violated daily conversations (see also Cordón, Saetermoe, & Goodman, 2003, 2005). It is likely that in day-to-day life, children come across questions regarding facial expressions and preferences more than they come across questions about objects. For example, mothers may often ask their children questions about a character's facial expression, or whether they like the character and contents, when they read a picture book. However, object yes–no questions used in the present and previous studies (Fritzley & Lee, 2003; Okanda & Itakura, 2007, 2008) asked children questions in an unusual manner. It may be rare for mothers to ask their children "Is this green?" while showing a red apple.

Third, we found that 6-year-olds exhibited a nay-saying bias to questions about facial expressions. They tended to insist on precisely expressing their opinions as accurately as possible and denied the interviewer's questions when asked face questions; however, they did not display the same tendencies to object and preference questions. A possible difference among these yes–no questions is that face questions might have several possible correct answers, but object and preference questions had very clear answers and were too easy for 6-year-olds to attempt to give more precise answers. Thus, one possible interpretation of this finding is that 6-year-olds might be able to understand the context of the question, that is, the interviewer wanted to know their knowledge, and they were likely to show the response tendency when asked questions that had several possible answers.

Fourth, object familiarity was not important for preference questions, but might be important for knowledge questions. In contrast, Okanda and Itakura (2007) found that object familiarity was not important for 2- to 3-year-olds when their own mothers asked them object yes–no questions. These results indicate that object familiarity may be important only when yes–no questions involving object knowledge are asked by a stranger.

Fifth, we did not find strong evidence that Japanese children tended to show "I don't know" and "no answer" responses to yes–no questions, similar to findings reported by Okanda and Itakura (2008). One possible reason might be that we mainly used familiar yes–no questions, and Japanese children are likely to avoid a binary yes–no decision when asked yes–no questions pertaining to unfamiliar issues (Okanda & Itakura, 2007, 2008). Moreover, our findings suggest there may be a cross-cultural difference with Japanese children's developmental pattern of a yes bias. While Fritzley and Lee (2003) reported that North American 4- and 5-year-olds did not show a yes bias, Japanese 4- to 6-year-old children sometimes showed a weak tendency to say "yes" (Okanda & Itakura, 2008; Study 1 in this article). We only found this tendency in Study 1, but not in Study 2, so it must be treated with caution; however, it is possible that Japanese children's yes bias disappears later than that of North American children. In Japanese culture, saying "yes" is much more polite than saying "no" in adult community. Possibly, some older children might have already adopted this Japanese attitude.

The present study provided new evidence for understanding the mechanism of a yes bias. Three-year-olds said "yes" to both types of yes–no questions, including testing-context yes–no questions (i.e., knowledge-object questions) and social-context yes–no questions (i.e., preference-object and knowledge-face questions). At the same time, we reported that 3-year-olds actually knew the answers to the questions when asked in the choice format and only failed to answer questions appropriately in the yes–no format. Underdeveloped cognitive abilities such as inhibitory control, ability to understand the context of the questions, and unconsolidated knowledge might be plausible explanations for a yes bias in 3-year-olds. In contrast, 4-year-olds and older children might have social reasons, such as sensitivity to interviewers' intentions and compliance, to show a yes bias. We conclude that there may be both cognitive and social reasons in the production of a yes bias, and its mechanism varies depending on the child's age.

On a practical level, and given that a yes–no question is the most common questioning method in developmental psychology (Fritzley & Lee, 2003), our results suggest that researchers should consider alternative methodologies in their experiments. Using yes–no questions for preschoolers is not suitable because they are likely to show different response tendencies to yes–no questions for different types of domains.

Appendix A: Objects Used and Test Questions in Study 1

Familiar object condition		Unfamiliar object condition	
Object	Questions	Object	Question
Blue cup	Is this blue?	Coffee filter (plastic)	Is this used for making coffee?
	Is this used for drinking?		Is this empty?
	Is this made of glass?		Is this used for making cake?
	Is there water in this?		Is this made of paper?
	Do you like this?		Do you like this?
	Do you dislike this?		Do you dislike this?
Red apple	Is this hard?	Shoehorn	Is this used for wearing shoes?
	Is this for eating?		Is this found at the entrance?
	Is this rotten?		Is this worn on the head?
	Is this green?		Is this soft?
	Do you like this?		Do you like this?
	Do you dislike this?		Do you dislike this?
Book	Is this full of pictures?	CPU	Is this square-shaped?
	Is this used for reading?		Is this used with a computer?
	Is this small?		Is this made of wood?
	Is this round?		Is this circular?
	Do you like this?		Do you like this?
	Do you dislike this?		Do you dislike this?

Appendix B: Objects and Cards Used and Test Questions Asked in Study 2

Face condition		Object condition	
Target face	Questions	Target object	Questions
Face 1 smiling	Is it joyful?	Blue cup	Is this blue?
	Is it sad?		Is this used for drinking?
Face 1 crying	Is it annoyed?		Is this made of glass?
	Is it pleased?		Is there water in this?
Face 2 smiling	Is it happy?	Red apple	Is this hard?
	Is it lonely?		Is this for eating?
Face 2 crying	Is it crying?		Is this rotten?
	Is it smiling?		Is this green?
Face 3 smiling	Is it joyful?	Picture book	Is this full of pictures?
	Is it sad?		Is this used for reading?
Face 3 crying	Is it unpleasant?		Is this small?
	Is it joyful?		Is this round?
Face 4 smiling	Is it happy?	Spoon	Is this blue?
	Is it lonely?		Is this used for eating?
Face 4 crying	Is it crying?		Is this made of paper?
	Is it smiling?		Is this square?

Appendix C: Objects and Cards Used and Test Questions Asked in Study 3

Condition	Object/cards	Question
Familiar object	Blue cup/red apple	Which is used for drinking? Which is blue?
	Red apple/green apple	Which is red? Which is green?
	Picture book/red apple	Which is used for reading? Which is for eating?
	Spoon/picture book	Which is used for eating? Which has pictures?
	Toothbrush/spoon	Which is used for brushing teeth? Which is placed in the bathroom?
Face	Face 1 happy/sad	Which is joyful? Which is displeased?
	Face 2 happy/sad	Which is pleased? Which is sad?
	Face 3 happy/sad	Which is crying? Which is smiling?
	Face 4 happy/sad	Which is happy? Which is lonely?

Although there has been extensive research on children's moral knowledge about lying and truth-telling and their actual lie- or truth-telling behaviors, research to examine the relation between these two is extremely rare. This study examined one hundred and twenty 7-, 9-, and 11-year-olds' moral understanding of lies and their actual lying behaviors in a politeness situation. Results revealed that as age increased, children increasingly evaluated others' lying in politeness situations less negatively and were more inclined to tell lies in such situations themselves. Contrary to previous findings, children's sociomoral knowledge about lying was significantly related to their actual behaviors, particularly when children's rationales underlying their moral judgments were consistent with their motives for actual lie- or truth-telling in the politeness situation.

Lying is a common social phenomenon. It occurs regularly in various social contexts for a multitude of purposes. For children, there are two types of lies that are of great importance during their socialization. One type is the lies that violate moral rules as they are typically told to benefit oneself at the expense of others. As a result of the antisocial nature of this type of lie, it is universally discouraged by children's caregivers and teachers from a very early age. The other type of lies are those that are told with an intention to help, not harm, another individual (e.g., faking liking an undesirable gift in front of a gift-giver) and are thus prosocial in nature. Although philosophers and theologians have long debated about whether prosocial lies should be morally sanctioned (Bok, 1978), in everyday practice, such lies are told frequently (DePaulo & Bell, 1996; DePaulo & Kashy, 1998) and often entail positive values (Nyberg, 1993). Some theorists such as Sweetser (1987) have even suggested that in some situations prosocial lies are not only socially acceptable but also are not lies at all.

There has been extensive research on the development of lying that dates back to the beginning of developmental psychology (e.g., Binet, 1896; Darwin, 1877; Piaget, 1932). This long-standing interest in this topic is a result of the fact that lying can serve as a window into many aspects of children's developing minds, for example, intelligence (Binet, 1896; Lewis, 1993), theory of mind (Chandler, Fritz, & Hala, 1989; Leekam, 1993; Peskin, 1992; Peterson, 1995; Peterson, Peterson, & Seeto, 1983; Polak & Harris, 1999; Sodian, 1991; Talwar, Gordon, & Lee, 2007), moral understanding (Piaget, 1932), personality and character formation (Hartshorne & May, 1928), and children's competence as witnesses in the courts of law (Goodman et al., 2006; Lyon, 2000; Strichartz & Burton, 1990; Talwar, Lee, Bala, & Lindsay, 2002, 2004; for a review, see Lee, 2000).

Research on Antisocial Lying

To date, most studies have focused on the development of antisocial lies and can be divided into

two major streams. One stream investigates children's conceptions and moral judgments of antisocial lies. Extensive research has revealed that children from very early on are taught explicitly or implicitly about the negative moral implications associated with antisocial lies. They are also strongly discouraged from telling this type of lie (Cameron, Chen, & Lee, 2001; Wilson, Smith, & Ross, 2003). Perhaps for this reason, the conceptual understanding of antisocial type of lies emerges as early as 3 years of age (Siegal & Peterson, 1998; Talwar et al., 2002). With regard to children's moral judgments of lying, evidence shows that even preschoolers understand that antisocial lies entail negative moral implications (Bussey, 1992, 1999; Talwar et al., 2002).

The other stream of research, pioneered by Binet (1896), Darwin (1877), and Hartshorne and May (1928), examines children's lying behavior for trickery, personal protection, or benefit (Chandler et al., 1989; Lewis, Stanger, & Sullivan, 1989; Peskin, 1992; Polak & Harris, 1999; Talwar & Lee, 2002a). It has been found that even preschoolers tell lies with intent to deceive (Chandler et al., 1989; Peskin, 1992). Young child lie-tellers are generally skilled in masking their nonverbal behaviors (e.g., making eye contact while lying; Lewis et al., 1989; Talwar & Lee, 2002a) but poor at concealing their deception in their verbal statements (e.g., blurting out the name of a toy that they claimed not to have peeked at: Polak & Harris, 1999; Talwar & Lee, 2002a, 2008; Talwar, Gordon, et al., 2007).

Research on Prosocial Lying

In contrast to the extensive literature on antisocial lying, there is very limited research on the development of lie-telling for politeness purposes. Research on this issue should offer a unique perspective for understanding social development in children owing to the multifaceted nature of prosocial lie-telling. More specifically, to take an appropriate action in a politeness situation, one must assess, and reason about, both moral and social conventional rules regarding interpersonal interaction. Turiel and his colleagues (Helwig & Turiel, 2002; Nucci & Turiel, 2000; Smetana & Turiel, 2003; Turiel, 2002) have found that moral and social conventional rules are distinctive domains in the realm of social life and social thought. Moral rules are concerned with what is right and what is wrong as well as regulating how individuals ought to behave toward each other based on the principles of welfare and justice. In contrast, social conventional rules are concerned with uniformities that define social expectations regarding appropriate behaviors within a specific society and serve functions of social coordination. Typically, these rules deal with individuals' social thoughts and actions in their respective domains. For example, moral rules prohibit killing of another human being, whereas social conventional rules may require one to dress properly at a formal social gathering.

Politeness, however, cuts across both domains. In the politeness situation, one must assess, and reason about, the applicability of various moral and social conventional rules to take a morally and socially appropriate action. More significantly, the politeness situation brings to the fore the inherent contradictions in the rule system in either the moral or social conventional domains, respectively. In the moral domain, the concern for others' well-being and the need to avoid harm should motivate one to tell a prosocial lie (e.g., "I really like your gift" or "You look great in that dress") rather than telling the blunt truth (e.g., "I do not like your gift" or "You look fat in that dress"). However, lying, or making a false statement with an intent to deceive, has long been considered to be a serious moral transgression by philosophers and theologians, such as St. Augustine (1952), Kant (1949), and Bok (1978), because lying impinges on the lie recipient's right to information and freedom of choice (Grice, 1980; Krupfer, 1982). Children have also been socialized to take this view of lying from very early on in life (Cameron et al., 2001; Wilson et al., 2003).

In the social-conventional domain, there are also contradictory rules concerning interpersonal communication, particularly in the case of politeness are clearly demonstrated. On one hand, Grice (1980) suggested that one of the most fundamental conventions governing interpersonal communication is the Maxim of Quality. This maxim requires speakers to inform, not misinform, their communicative partners, which is commonly assumed to be the case when individuals enter into a conversation. Prosocial lies clearly flout this maxim. On the other hand, Lakoff (1973) proposed that interpersonal communications must also adhere to the Rule of Politeness that requires speakers to be amicable to their communicative partners. In the politeness situation, this rule calls for individuals to not tell the blunt truth to establish or maintain an amicable relationship with another.

The existing evidence suggests that many adults have little difficulty in resolving the conflicts evoked by the politeness situation. Typically, they allow that the need to be polite and to avoid hurting others overrides the need to be truthful. For this reason, adults not only endorse prosocial lies (Lee & Ross, 1997) but tell them regularly (DePaulo & Bell, 1996; DePaulo & Kashy, 1998). In contrast, for children, the politeness situation poses a challenge to children who are still in the process of acquiring moral and social-conventional rules of their society. Resolving conflicts between these rules places additional demands on them. Although the politeness situation may be a challenge for developing children, it offers a naturalistic opportunity for developmental researchers to understand whether children are capable of making strategic trade-offs when facing social situations where rules are in conflict as well as how they select and apply rules adaptively in different social situations.

To date, there are only three studies that have examined children's actual behavior in a politeness situation. Talwar and Lee (2002b) used a Reverse Rouge task in which the experimenter had a conspicuous mark of lipstick on the nose. The child was asked to take a picture of the experimenter, but before the picture was taken, the experimenter asked, "Do I look okay for the picture?" Results showed that 89% of children between 3 and 7 years of age stated that the experimenter looked okay. However, when the experimenter left, children told another adult that the experimenter actually did not look okay. Thus, the researchers concluded that young children can tell prosocial lies in a politeness situation. However, because children were not probed about why they told such a lie, it is unclear whether the children in the study considered the contradictory rules evoked by the situation when deciding to lie. Furthermore, among the children who lied, it was unclear as to whether they told lies to spare the feelings of the experimenter (a prosocial lie) or to avoid potential negative consequences if the truth was told (a self-protective lie).

In another study (Fu & Lee, 2007), Chinese children aged between 3 and 6 years were asked to rate pictures that were poorly drawn by confederates. Most children, except for the youngest ones, gave the drawings more positive ratings in front of the confederates than when the confederates were absent. Thus, like Western children, Chinese preschoolers appeared also to refrain from telling the blunt truth to others (i.e., the pictures were poorly drawn). However, because the children were not probed about their motivation for inflating their ratings, it is not clear whether they did so for the benefit of the confederate (e.g., sparing the feelings of the confederate) or for themselves (e.g., avoiding negative consequences if the truth was told).

In the third study, Talwar, Murphy, and Lee (2007) used a disappointing gift paradigm to examine children's prosocial lie-telling. Children played a game where they were promised a gift from a gift basket that contained a range of different toys and gifts. After the task, children received an undesirable gift of soap instead of a toy and were questioned by the gift-giver about whether they liked the gift. In this situation, children had to reconcile their desire for a better gift with the competing social and moral requirement to be polite. When asked if they liked the gift, the majority of children told the gift-giver untruthfully that they liked the disappointing gift, despite having told their parents that they did not like the gift. School-aged children were more likely to lie than were preschool children. However, this study also did not systematically probe children's justifications for their lies. Thus, it is again not clear whether some children were more motivated to lie for self-protection (e.g., avoiding negative responses from the gift-giver if the truth was told) or to be polite and protect the gift-giver's feelings.

In contrast to the paucity of research on children's actual prosocial lie-telling behaviors, there is some, albeit limited, research on children's conceptual understanding of prosocial lies. With regard to children's concept of prosocial lies, Lee and Ross (1997) found that adolescents aged between 12 and 14 years and college students were less inclined to classify untruthful statements as lies when told with the intent to help another individual than when told to harm. Their results confirmed Sweetser's (1987) theoretical contention that untruthful statements deliberately told to help another individual and to be polite may not be considered lies. In contrast, Bussey (1999) reported that most children aged between 4 and 11 years classify all types of untruthful statements as lies regardless of their anti- or prosocial nature. This finding suggests a possible developmental change in terms of the concept of prosocial lies during adolescence.

With regard to moral judgments, Bussey (1999) found that children during preschool and elementary school years tended to give negative ratings to prosocial lies. Nevertheless, beginning from 4 years of age, their ratings of prosocial lies were not as negative as those given to trickery or antisocial lies. Broomfield, Robinson, and Robinson (2002) further found that children aged between 4 and 9 years would suggest that a story character should tell a lie about liking an unwanted gift to make the giver believe the gift was liked. The children also judged that the gift-giver would be happy when hearing the lie. The results of Broomfield et al. (2002) were replicated in China (Zeng, 2004). However, Walper and Valtin (1992) found that children only began to give prosocial lies positive evaluations at the end of the elementary school years. These findings taken together suggest that children's conceptual understanding of prosocial lies begins in preschool years and develops throughout the childhood. They appear to be able to consider the contradictory rules evoked by the politeness situation when evaluating prosocial lies, but only in late childhood do children appear to allow the need to be polite and avoid hurting another's feelings override the need to be truthful. It should be noted that this conclusion is tentative because these studies did not probe children about the underlying rationales for their evaluations.

No studies have examined the relation between children's conceptions of prosocial lie-telling and their actual lying behavior. Research on the general relation between children's social and moral conceptions and their actual behaviors is of significant importance because the ultimate purpose of socialization is to ensure that children not only know morally what is right or wrong and conventionally what is appropriate or inappropriate, but that they also act accordingly. Existing studies with children and adults concerning Kolhbergian moral dilemmas as well as antisocial lying have shown either weak or no linkages between individuals' moral knowledge and moral action (Arnold, 1989; Blasi, 1980; Talwar et al., 2002, 2004; Thoma & Rest, 1986). Multiple theories have provided a variety of explanations as to why individuals fail to act according to their conceptual knowledge about moral or social rules (Arsenio & Lemerise, 2004; Crick & Dodge, 1994; Huesmann, 1998; Rest, 1986; Walker, 2002), including situations involving aggression (Crick & Dodge, 1994; Huesmann, 1998) or prosocial behaviors (e.g., Rest, 1986). A major factor contributing to this disconnection is the difference in the interpretation of hypothetical situations used to assess moral and social *knowledge* and interpretations of actual situations that call for morally and socially appropriate *behavior*. This is particularly true for situations where contradictory moral and social rules may apply. For example, in a politeness situation, individuals may interpret the need to be polite and to avoid hurting another to be the primary concern and thus advocate hypothetically that one should tell a prosocial lie in such a situation. However, when encountering the same situation in reality, they may interpret the situation to require only for the fulfillment of the need to be truthful and thus tell the truth. Alternatively, individuals could interpret the hypothetical situation to be concerned with the need to the truthful but the real-life situation to be concerned with the need to be polite and to avoid hurting another. In both cases, a disconnection between conceptual knowledge and action results.

Thus, to examine empirically the relation between children's *conceptual knowledge* about prosocial lie-telling and their *actual* lying behavior, two methodological measures must be taken. First, one must examine children's interpretations of hypothetical politeness stories that are used to assess their understanding of prosocial lie-telling. Second, one must also obtain children's interpretations of their own actions in the politeness situation. Such methodological measures were not taken in the previous studies, which leaves gaps in our knowledge about: (a) the age at which children begin to understand the politeness situation to be a situation where one needs to consider the need to be truthful and the need to be polite and avoid hurting another, (b) the age at which they begin to tell lies for prosocial reasons, and most importantly, (c) whether children's conceptual understanding of prosocial lie-telling is related to their actual behaviors in the politeness situation. This study was conducted to bridge the gap in the literature and to address these three important questions.

In the present study, we assessed 7-, 9-, and 11-year-old Chinese children's conceptual understanding of prosocial lie-telling and blunt truth-telling in a politeness situation. The three age groups were chosen because existing studies have shown that children's conceptual knowledge about prosocial lie-telling appears to undergo systematic changes during this period (e.g., Broomfield et al., 2002; Bussey, 1999; Walper & Valtin, 1992; Zeng, 2004). Also, this developmental trend appears to be similar between Western and Chinese children (see Broomfield et al., 2002; Zeng, 2004). The Chinese children were read stories in which story characters encounter politeness situations (e.g., receiving an undesirable gift). The story characters either made truthful or untruthful statements. Children were asked to classify the statements as lies or truths. Also, they were asked to evaluate the statements either positively or negatively and to justify their ratings. Children were also asked to respond to control stories in which a story character receives a desirable gift and likes it and tells the truth or lie about it. The use of these control stories was to ensure that children's categorizations and moral judgments of lie- or truth-telling about undesirable gifts would not be simply responses to truthful and untruthful statements in general.

Furthermore, we placed the children in a real-life situation where they themselves must decide whether to tell the truth or lie. In this situation, children were given an undesirable gift and then asked by the gift-giver whether they liked the gift. This method was a modified version of the undesirable gift paradigm pioneered by Saarni (1984) and Cole (1986) to examine children's expressive display rule use, and adapted for examining children's lie-telling by Talwar, Murphy, et al. (2007). The undesirable gift situation was chosen because this is a situation that occurs commonly in children's lives (e.g., receiving a poorly fitting knitted sweater from grandparents as a birthday gift), and children are socialized from early on to dissemble their true feeling of disliking in such situations. Indeed, from 4 years of age, children are already able to dissemble their nonverbal (Cole, 1986; Saarni, 1984) or verbal behaviors (Talwar, Murphy, et al., 2007) to appear pleased about receiving an undesirable gift.

Given the previous findings, we expected children in our study would also dissemble verbally and tell the gift-giver a prosocial lie that they liked the undesirable gift. This tendency to lie would increase with age. With regard to children's concept of prosocial lie-telling, based on the results of Bussey (1999) and Lee and Ross (1997), we predicted that children in general would classify untruthful statements told for prosocial purposes as lies and this tendency would decrease with age. With regard to children's evaluations of prosocial lie-telling, based on the results of Bussey (1999) and Walper and Valtin (1992), as age increased, children would be more inclined to rate prosocial lies less negatively than lies told for nonprosocial reasons. Also, with increased age, children would increasingly weigh the relative importance of being truthful versus being polite and avoiding hurting another when making evaluations and use the latter rather than the former to justify their ratings. Finally and most importantly, a significant relation between children's conceptions of prosocial lies and their actual behavior was expected. We hypothesized that this possible relation can be established when children's motives for their actions are consistent with the rationales underlying their moral judgments. For this reason, after children in this study told either the truth or a lie, they were asked about the reasons for their actions. We expected that the relation between children's conceptual understanding of prosocial lie-telling and their actual behavior would be stronger when the concerns for politeness and avoidance of hurting others motivated both their evaluations and their actions.

Method

Participants

A total of 120 Chinese children participated: forty 7-year-olds (M = 7.30 years, SD = 0.19; 20 boys), forty 9-year-olds (M = 9.18 years, SD = 0.14; 20 boys), and forty 11-year-olds (M = 11.21 years, SD = 0.13; 20 boys). The children were recruited from a large elementary school of close to 1,000 students in a southeastern city in P.R. China (population: 10 million). The school was chosen because it was highly representative of an elementary school in the city in terms of its ethnic composition as well as parental income, occupation, and educational levels according to the school records. Student admission to the school was determined by the location of the neighborhood where the children and their family lived rather than other criteria (e.g., parental professional standing, job affiliation, or the child's scores of entrance examination). The neighborhood from which the children came was highly diverse in terms of parental income, occupation, and educational levels. The children were Han Chinese, which represents 98% of the population in the city and 90% of the P.R. China population. We did not measure the socioeconomic status of the participants' family because no reliable and accurate measures were available. The children were selected from their classes based on the following factors: guardian consent, home classroom teacher's consent, the children's own verbal assent, and the requirement to balance the numbers for boys and girls per age group.

Materials and Procedures

Children were seen individually in a quiet room in their school. They participated in two sessions: One session examined whether children would tell a prosocial lie (undesirable gift procedure), and the other assessed children's conceptual understanding of lies and truths in politeness situations (moral story procedure). The two sessions were separated by 10 days and counterbalanced between subjects. Half of the children participated in the undesirable gift procedure first followed by the moral story procedure, and the other half did the opposite.

Moral story procedure. Experimenter 1 introduced herself as a student teacher from a local university and read children four stories accompanied by pictures. Before beginning the stories, children were first trained about how to use a 7-point Likert scale. The positive, neutral, and negative ratings were symbolized by red stars, a circle, and black crosses as follows: very very good (three stars), very good (two stars), good (one star), neither good nor bad (a circle), bad (one cross), very bad (two crosses), and very very bad (three crosses). Children's verbal responses were then converted into a 7-point numeric scale from −3 to 3 with 3 representing *very very good*, 0 representing *neither good nor bad*, and −3 representing *very very bad*.

In the stories, a child protagonist interacted with a teacher from the school. The stories were modified from those used in the previous studies on prosocial lie-telling (Bussey, 1992; Lee & Ross, 1997; Walper & Valtin, 1992). In one story, a child receives a gift that he dislikes but tells his teacher, the gift-giver, that he likes the gift (the prosocial lie-telling story). In the second story, a child receives an undesirable gift and tells the teacher the truth (the blunt truth-telling story). In the third story, a child receives a desirable gift but states falsely that she does not like the gift (the control lie-telling story). In the fourth story, a child receives a desirable gift and states truthfully that she likes the gift (the control truth-telling story). Existing studies (e.g., Bussey, 1992; Talwar et al., 2002) have consistently shown that children from preschool years tend to rate lying depicted in the control lie-telling story very negatively and truth-telling in the control truth-telling story very positively. Children's ratings for these two stories thus could be used to be compared to their ratings for the prosocial lie-telling and blunt truth-telling stories, respectively. The presentation of the stories was counterbalanced across subjects. The moral story procedure lasted about 10 min.

The actual stories are described in the following.

1. *Prosocial lie-telling story*: This is Ming Ming. He did very well in a math competition. His teacher gave him a pencil box as a gift. But Ming Ming already had many pencil boxes at home. He did not want any more of this kind of pencil box. So Ming Ming didn't like the gift his teacher gave him. The teacher asked him: "Do you like the pencil box?" Ming Ming said: "Yes, I like it very much."
2. *Blunt truth-telling story*: The final exam was finished and Xiao Qiang did very well. The teacher gave a book to Xiao Qiang as a gift when she distributed the grade report. When Xiao Qiang received the book, she found she already had this book at home. She already knew the book very well and wanted to read a new book. So Xiao Qiang didn't like the gift that the teacher gave to her. The teacher asked Xiao Qiang, "Do you like the book?" Xiao Qiang answered, "No, I don't like it."
3. *Control lie-telling story*: The teacher knew that many students in the class would celebrate their birthdays. Today is Xiao Hao's birthday. So she gave Xiao Hao an eraser as a birthday gift. Xiao Hao received the eraser and thought it looked cute. He liked the eraser. The teacher asked Xiao Hao, "Do you like the gift?" Xiao Hao said to the teacher, "No, I don't like the eraser."
4. *Control truth-telling story*: The teacher brought some landscape color pictures from home as a gift to give to the students in the class. Li Li thought these pictures were beautiful. Li Li was a representative of the class and went to the office to turn in the students' homework after class. The teacher wanted to know if the students liked the pictures. She had asked many of her students, but hadn't asked Li Li. So the teacher stopped Li Li and asked, "Do you like the picture I give you?" Li Li said, "Yes, I like it."

After being told each of the stories, the participants were asked the following questions: (a) Question 1 (categorization question): "Is what XXX (the name of the protagonist) said a lie or not a lie?" (If the participant replied "not a lie," they were asked "Is what XXX said the truth or not truth?"); (b) Question 2 (moral evaluation question): "Is what XXX said very very good, very good, good, neither good nor not bad, bad, very bad, or very very bad?" Children were asked to indicate their responses on the Likert scale they had been trained on. Finally, children were asked to justify their ratings (rating justification question): "Why do you think it is XXX (the child's rating)?"

The coding system of children's justifications was developed in the following manner. First, the potential types of responses were obtained based on the reports and discussions of the several existing studies (Bussey, 1999; Peterson et al., 1983; Walper & Valtin, 1992). Second, all types of responses provided by participants were reviewed by the research team members to obtain additional types of responses if any existed. Third, because participants did not provide a diverse array of justifications, the final coding system only contained the following types of response categories. The first type referred the need to be polite and protect another person's feelings as justification (politeness justification; e.g., ''It is not polite if I say I don't like it'' or ''It would not be nice'' or ''It would be embarrassing''). The second type made reference to the need to be truthful (honesty justification; e.g., ''He didn't like it'' or ''You should tell the truth''). The third type made reference to both politeness and honesty justifications (both justifications; e.g., ''Saying liking it will make the teacher feel better, but it is lying''). We also created an ''other'' category for responses (e.g., ''I don't know'') that did not fall into one of the three categories. Two graduate students who were naïve to the hypotheses of the study were trained to code children's responses according to these categories.

Undesirable gift procedure. In the procedure, children were seen individually by Experimenter 2 in a quiet room in their school. The child's teacher introduced the experimenter as a student teacher from a local university. The experimenter brought children to a quiet room in their school. She told the participants that they were going to take two memory tests. If they did well on both tests, they would receive a gift selected from a gift box. Children were shown each item from the box. They were ball-point pens, stickers, coloring books, flash cards, and pencils. Pilot testing showed that school-aged children liked the attractive and colorful pens, stickers, and coloring books, but disliked the plain-looking flash cards and pencils. Children were asked which item they would like to receive as a gift and which they would not like to receive (the Gift Preference Assessment). Consistent with the findings of the pilot study, no child liked the flash cards and pencils. Upon identifying the liked and disliked gift items, children were told that they would receive the gift item they liked the most if they passed the tests. Then, the experimenter administered a short-term memory test (a subtizing task) in which a number of pencils were shown briefly and children were asked to report how many pencils they saw. To ensure all children succeed in the test, the number of pencils shown was smaller than what would be expected to be remembered by children at the same age as the participants, which was determined by pilot testing. After all participants passed the test, they were praised. The experimenter told the children that she just remembered that she had to finish unspecified business and had to leave the room for a few minutes. Their own teacher would have to administer the second test and give them the gift if they also passed the second test.

After the participants' own teacher entered the room, the experimenter left. The teacher administered a digit span test similar to the subscale in Wechsler Intelligence Scale for Children, Fourth Edition (WISC). Based on the norms of the WISC, only those test items that were known to be easy for the participants' age were chosen. After all the participants passed the second test, the teacher said to the children: ''You did very well on both tests, so I am going to give you a gift.'' She pointed to the gift items in the gift box and said: ''The student teacher bought some of the gifts (pointing to the attractive ones). I bought these gifts (pointing to the unattractive ones). Let me give you the one I bought as a gift.'' Then, she handed over an unattractive gift to the child. After the child had the opportunity to inspect the gift, the teacher asked: ''Do you like the gift I have given to you?'' (Liking Question 1).

After the children received the gift and responded to the Liking Question 1, the experimenter returned. The teacher told the experimenter that the children did very well on the second test and therefore received a gift (pointing to the gift). She also informed the experimenter whether the children said that they liked the gift or they did not like the gift. The teacher then made an excuse and left the room. At this point, if children said that they liked the gift, the experimenter asked the children: ''I just heard that your teacher said that you told her you liked this gift but you told me earlier that you didn't like the gift. So, do you really like the gift or not?'' (Liking Question 2). If the children responded that they did not like the gift, the experimenter asked: ''Why did you tell your teacher you liked the gift?'' (action justification question). If the children responded directly to their teacher that they did not like the gift, the teacher also informed the experimenter of the children's response. After the teacher left, the experimenter also asked the children to justify their response: ''Why did you tell your teacher you didn't like the gift?'' After this question, the children were told that they could exchange their gift if they wished to do so. All children opted to do so. They were thanked for their participation in the study. The undesirable gift procedure lasted about 10 min. All experimenters and teachers were women. They were trained about how to carry out the procedures prior to interviewing children. The experimenters were randomly assigned to be Experimenter 1 or 2.

The children's responses to the "why" question were coded according to a coding system developed ad hoc based on the responses because no previous studies had coded such responses. Once the research team members reviewed the responses, it became clear that although children who told the truth consistently made reference to the need to be truthful or made a statement of the fact (e.g., "You should tell the truth" or "I don't like it"), among children who told a lie to conceal their disliking of the undesirable gift, some were not motivated to lie out of prosocial concerns. Thus, the following categories emerged for the children who lied: (a) the prosocial lie-tellers who justified their lying by referring to the need to be polite or to avoid hurting the feelings of their teacher, and (b) nonprosocial lie-tellers who gave a variety of responses unrelated to prosocial concerns such as referring to the need to avoid negative consequences to themselves (e.g., the teacher being angry at them if truth be told) or deserving the gift even though they did not like it, or other miscellaneous responses unrelated to politeness (e.g., "I don't know" or "I can find another use for it"). The same two graduate students were trained to categorize children into three categories: blunt truth-tellers, prosocial lie-tellers, and nonprosocial lie-tellers based on whether the children told the truth or lie and their responses to the "why" question.

Results

In the following, we will first report results about children's knowledge of lie- and truth-telling as assessed by the moral story procedure, followed by results about children's actual lie- or truth-telling behavior in the undesirable gift procedure, and finally results about the relations between children's knowledge and behavior. Preliminary analyses revealed that the order of the moral story procedure and undesirable gift procedure and the sex of participants did not significantly affect the results of this study. Thus, the data for these two factors were combined for the subsequent analyses.

Moral Story Procedure

Children's classifications of the statements made by the story characters as lies or truth or neither (i.e., their responses to the categorization question) were analyzed using multiple chi-square analyses. Neither the age group nor the story type effect was significant. Overall, 98% of the children categorized prosocial lies as lies, and 100% categorized the untruthful statements in the control lie-telling story as lies. Also, 98% categorized the blunt truths as the truth, and 100% categorized the truthful statement in the control truth-telling story as the truth.

Figure 1 shows the means and standard errors of 7-, 9-, and 11-year-olds' moral evaluations of the truthful or untruthful statements made by the story characters (i.e., their responses to the moral evaluation question). An omnibus 2 (truthfulness: truth vs. lie) × 2 (setting: prosocial vs. control) × 3 (age: 7, 9, and 11 years) analysis of variance (ANOVA) was performed on the moral evaluation data for the truth- and lie-telling stories.

Age, truthfulness, and setting main effects were significant, $F(2, 117) = 3.12$, $p < .05$, $\eta^2 = .05$; $F(1, 117) = 264.82$, $p < .0001$, $\eta^2 = .69$; and $F(2, 117) = 14.25$, $p < .0001$, $\eta^2 = .11$, respectively. Children overall gave positive ratings to truth-telling and negative ratings to lie-telling. Also, children's ratings changed with age and setting. The mean effects were qualified by significant Age × Truthfulness and Truthfulness × Setting interactions, $F(2, 117) = 3.57$, $p < .05$, $\eta^2 = .06$, and $F(1, 117) = 106.95$, $p < .0001$, $\eta^2 = .49$, respectively. These effects were qualified by a significant Age × Truthfulness × Setting interaction, $F(2, 117) = 5.15$, $p < .001$, $\eta^2 = .08$. Simple effect tests with Sidak adjustments for multiple comparisons were performed to examine the significant three-way interaction. This effect was because of the fact that 7-year-olds were significantly different from 9- and 11-year-olds, whereas the two older groups' ratings of blunt truth-telling did not differ from each other. Seven-year-olds

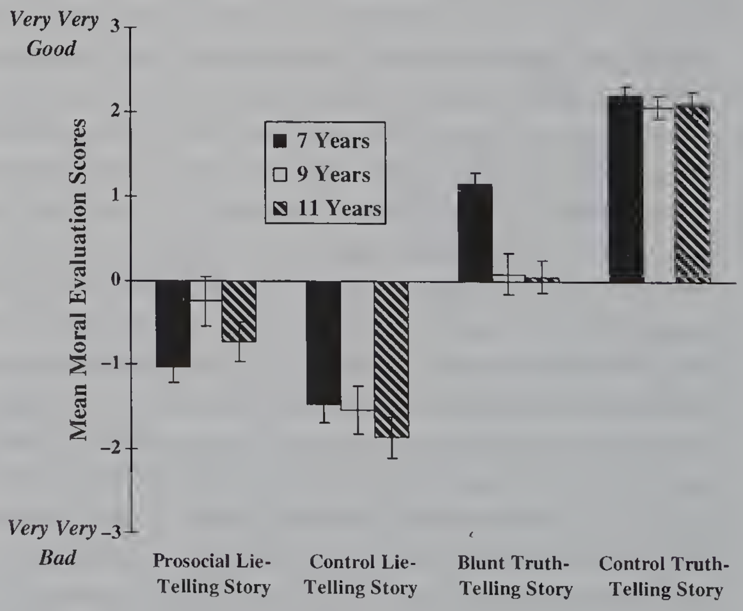

Figure 1. Means and standard errors of children's positive and negative evaluations of the story characters' statements by age.

gave significantly more positive ratings to blunt truth-telling than older children. In contrast, no age differences were found for control truth- and lie-telling and prosocial lie-telling. Overall, they gave very positive ratings to control truth-telling and very negative ratings to control lie-telling. They gave significantly less negative ratings to prosocial lie-telling than control lie-telling.

With regard to children's justifications of their evaluations, overall, participants did not provide a diverse array of justifications. For the control lie- and truth-telling stories in which the protagonist receives a desirable gift, all children justified their ratings to the former by referring to the negativity of dishonesty and the latter by referring to the positivity of honesty (the interrater reliability was 100%). Owing to the ceiling effect, the explanation data were not analyzed further. For the prosocial lie-telling and blunt truth-telling stories, the interrater reliability was also high, $\kappa s = .93$ and .85, respectively. The children's justifications fell into three types of responses: politeness justification, honesty justification, and both justification (see Table 1). No children gave ''I don't know'' responses.

A multinomial logistic regression analysis was performed with the age as the predictor and the type of justifications (politeness, honest, and both) for the prosocial lie-telling story as the predicted. The model (i.e., the age effect) was significant, $\chi^2(4, N = 120) = 19.41, p < .01$, Nagelkerk $R^2 = .17$. A priori comparisons with the honesty justification type as the reference for the predicted variable category and 7-year-olds as the reference for the predictor variable category were performed. As shown in Table 1, 9- and 11-year-olds used significantly more the ''both'' justification for their moral evaluations than did the 7-year-olds, $\beta = 1.82$, Wald = 6.18, $p < .01$, odds ratio = 9.90, and $\beta = 2.28$, Wald = 13.02, $p < .001$, odds ratio = 9.80, respectively. Thus, 9-year-olds were 6.18 times, and 11-year-olds were 9.8 times, more likely to use the both justification than 7-year-olds. No significant age differences were found for the politeness justification.

Table 1

Percent (Frequency) of Types of Justifications Made by Children at Each Age Group About Their Moral Judgments

	Politeness	Honesty	Both
Prosocial lie-telling			
7 years	20 (8)	70 (28)	10 (4)
9 years	20 (8)	43 (17)	38 (15)
11 years	10 (4)	38 (15)	53 (21)
Blunt truth-telling			
7 years	30 (12)	60 (24)	10 (4)
9 years	33 (23)	48 (19)	20 (8)
11 years	15 (6)	28 (11)	58 (23)

Another multinomial logistic regression analysis was performed with the age as the predictor and the type of justifications (politeness, honesty, and both) for the blunt truth-telling story as the predicted. The model (i.e., the age effect) was significant, $\chi^2(4, N = 120) = 24.68, p < .001$, Nagelkerk $R^2 = .21$. A priori comparisons with the honesty response type as the reference for the predicted variable category and 7-year-olds as the reference for the predictor variable category were performed. As shown in Table 1, 11-year-olds, but not 9-year-olds, used significantly more of both justifications for their moral evaluations than did the 7-year-olds, $\beta = 2.53$, Wald = 15.02, $p < .001$, odds ratio = 12.55. In contrast, no significant age differences were found for the politeness justification.

Two hierarchical linear regression analyses were performed with children's moral evaluation scores of prosocial lies and blunt truths as the predicted variable and age entered first as a predictor followed by the type of justifications, which was dummy coded as Predictor 1 (both vs. the other two responses) and Predictor 2 (honesty vs. the other two responses). After partialing out the effect of age, the type of justifications was significantly related to children's moral evaluation scores for prosocial lies and blunt truths, $F_{change}(2, 116) = 30.67$, $R^2_{change} = .34$, $p < .001$, and $F_{change}(2, 116) = 15.69$, $R^2_{change} = .20$, $p < .001$, respectively. Regardless of age, those children who used the both response to justify their ratings tended to give positive ratings to prosocial lies ($M = 0.45$, $SD = 1.54$) and negative ratings to blunt truths ($M = -0.49$, $SD = 1.27$). Those children who used the politeness response to justify their ratings gave moderately negative ratings to both prosocial lies ($M = -0.30$, $SD = 1.81$) and blunt truths ($M = -0.10$, $SD = 1.38$). In contrast, those children who used the honesty response to justify their ratings gave highly negative ratings to prosocial lies ($M = -1.53$, $SD = 0.81$) but highly positive ratings to blunt truths ($M = 1.31$, $SD = 1.50$).

Children's Truth- or Lie-Telling Behaviors in the Undesirable Gift Procedure

Children were coded as lie-tellers if they responded to their own teacher that they liked the gift she gave them (i.e., the Liking Question 1) but told the experimenter that they really did not like the gift (i.e., the Liking Question 2). If they responded that they did not like the gift to both questions, they were coded as blunt truth-tellers. Forty percent of 7-year-olds, 50% of 9-year-olds, and 60% of 11-year-olds were categorized as lie-tellers. A binary logistic regression analysis was performed with the age as the predictor and the child behavior (lie-telling vs. blunt truth-telling) as the predicted. The model (i.e., the age effect) was significant, $\chi^2(2, N = 120) = 10.72$, $p < .001$, Nagelkerk $R^2 = .12$. A priori comparisons with the 7-year-olds as the reference showed that 11-year-olds, but not 9-year-olds, differed significantly from 7-year-olds in terms of their tendency to tell a lie in the politeness situation, $\beta = 1.62$, Wald = 9.02, $p < .05$, odds ratio = 5.17 (11-year-olds were statistically 5.17 times more likely to lie than 7-year-olds).

With regard to children's responses to the question as to why they told the truth or lied, among the truth-tellers, their responses were highly similar. All of them either cited that they must tell the truth or simply said that they just did not like the gift. They were all coded as blunt truth-tellers by the two independent coders. Among the lie-tellers, one group of children were coded as prosocial lie-tellers because they justified their lying by referring to the need to be polite or the potential negative impact of their statement on the lie recipient if truth was told. Another group of lie-tellers (12 children in total) justified their lies by referring to the need to avoid negative consequences to themselves (e.g., the teacher being angry at them if truth be told). Yet another group of lie-tellers stated that they deserved the gift even though they did not like it (5 children in total). Another group (5 children in total) simply said: "I don't know." The rest gave miscellaneous responses unrelated to politeness (e.g., "I can find another use for it"). These children who gave these nonprosocial justifications were coded as nonprosocial lie-tellers. The intercoder reliability was high, $\kappa = .88$. Figure 2 shows the percentages of the three groups of children per age group.

A multinomial logistic regression analysis was performed with age as the predictor and the child behavior (blunt truth-telling, prosocial lie-telling, and nonprosocial lie-telling) as the predicted. The model (i.e., the age effect) was significant, $\chi^2(4, N = 120) = 11.27$, $p < .05$, Nagelkerk $R^2 = .10$. A priori comparisons were performed with 7-year-olds as the reference for the predictor variable and the blunt truth-tellers as the reference for the predicted variable. As shown in Figure 2, the proportion of the children who told a nonprosocial lie did not change with age. However, as age increased, more children told prosocial lies. Among the prosocial lie-tellers, 11- but not 9-year-olds differed significantly from 7-year-olds in terms of their tendency to tell a lie for prosocial purposes, $\beta = 1.67$, Wald = 4.13, $p < .05$, odds ratio = 4.75. That is, 11-year-olds were statistically 4.75 times more likely than 7-year-olds to tell a prosocial lie.

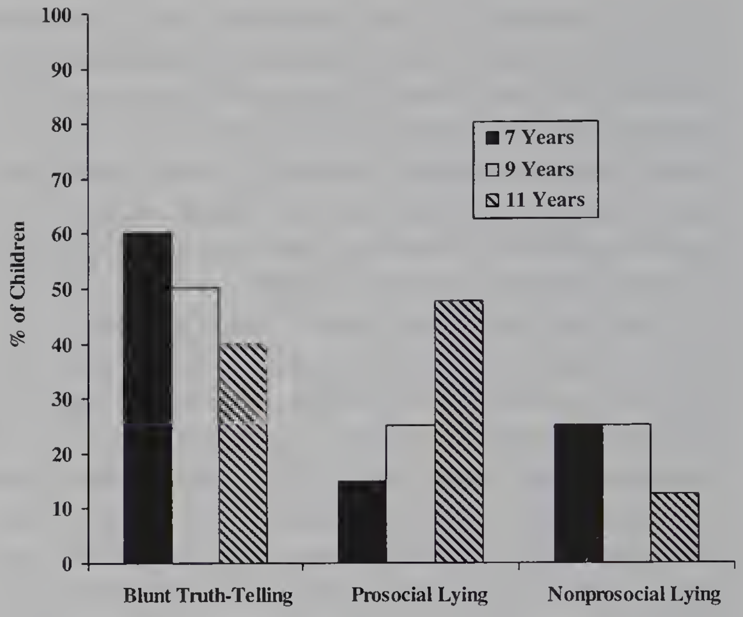

Figure 2. Percentage of prosocial lie-tellers, nonprosocial lie-tellers, and blunt truth-tellers by age.

Relations Between Children's Behavior and Moral Judgments

A 3 (age: 7, 9, and 11 years) × 3 (child behavior: prosocial lie-telling, nonprosocial lie-telling, and blunt truth-telling) ANOVA was performed on children's moral evaluation scores of the prosocial lie-telling story (see Table 2). Only the child behavior effect was significant, $F(2, 111) = 3.76$, $p < .05$, $\eta^2 = .06$. A priori contrast with prosocial lie-telling as the reference showed that both blunt truth-telling and nonprosocial lie-telling children's moral evaluation scores were significantly more negative than those of the prosocial lie-telling children ($ps = .025$ and $.013$, respectively).

Another 3 (age: 7, 9, and 11 years) × 3 (child behavior: prosocial lie-telling, nonprosocial lie-telling, and blunt truth-telling) ANOVA was performed on children's moral evaluation scores of the blunt truth-telling story. The effects of both age and child behavior were significant, $F(2, 111) = 4.78$, $p < .05$, $\eta^2 = .08$, and $F(2, 111) = 8.06$, $p < .01$, $\eta^2 = .13$, respectively. For the significant age effect, a priori contrast with 7-year-olds as the reference

Table 2
Means (Standard Deviations) of Children's Positive or Negative Evaluations of the Story Characters' Statements by Age and Behavioral Type (Minimum Score = −3, Maximum Score = 3)

Behavior type	Prosocial lie-telling story	Control lie-telling story	Blunt truth-telling story	Control truth-telling story
Blunt truth-tellers				
7 years	−1.29 (1.12)	−1.58 (0.72)	1.25 (1.29)	2.13 (0.80)
9 years	−0.25 (1.77)	−1.45 (1.50)	0.40 (1.50)	2.20 (0.77)
11 years	−0.87 (1.09)	−1.75 (1.07)	0.19 (1.56)	2.37 (0.96)
Prosocial lie-tellers				
7 years	0.33 (1.51)	−1.00 (0.63)	0.83 (1.47)	2.17 (0.75)
9 years	0.00 (2.16)	−1.00 (2.00)	−1.10 (1.29)	1.70 (1.16)
11 years	−0.37 (1.50)	−1.68 (1.29)	−0.63 (1.01)	1.68 (1.00)
Nonprosocial lie-tellers				
7 years	−1.20 (0.63)	−1.50 (0.97)	1.10 (1.29)	2.30 (0.68)
9 years	−0.50 (1.90)	−2.20 (0.79)	0.60 (2.22)	2.10 (0.74)
11 years	−1.60 (2.19)	−2.80 (0.45)	2.20 (1.30)	2.60 (0.55)

showed that 11-year-olds', but not 9-year-olds', moral evaluation scores of the blunt truth-telling story were significantly less positive than those of the 7-year-olds ($p < .05$). For the significant child behavior effect, a priori contrast with prosocial lie-telling as the reference showed that both blunt truth-telling and nonprosocial lie-telling children's moral evaluation scores were significantly more positive than those of the prosocial lie-telling children ($ps < .001$ and .01, respectively). In other words, those children who told a prosocial lie also tended to view blunt truth-telling in less a positive light than the other two groups of children.

To examine the relation between children's moral evaluation justifications (both, honesty, and politeness) for the prosocial lie-telling story and the child behavior (blunt truth-telling, prosocial lie-telling, and nonprosocial lie-telling), a multinomial logistic regression analysis was performed with the child behavior as the predictor and the type of justifications as the predicted. The model (i.e., the child behavior effect) was significant, $\chi^2(4, N = 120) = 15.36$, $p < .01$, Nagelkerk $R^2 = .14$. A priori comparisons with prosocial lie-telling as the reference for the predictor and the honesty justifications as the reference for the predicted were performed. Those children who gave the both justification were significantly (8.84 times) more likely to tell prosocial lies than nonprosocial lies, $\beta = 2.18$, Wald = 9.02, $p < .01$, odds ratio = 8.84, and (3.13 times) more likely to tell prosocial lies than the blunt truth, $\beta = 1.14$, Wald = 5.85, $p < .05$, odds ratio = 3.13. In other words, children who considered both the honesty and politeness issues when judging the prosocial lie story were more inclined to tell a prosocial lie than those who focused solely on either honesty or politeness. Consistent with this result, those children who gave the politeness justifications for their moral judgment scores of the prosocial lie-telling story were equally likely to tell prosocial lies, nonprosocial lies, or the blunt truth.

Another multinomial logistic regression analysis was performed with the child behavior as the predictor and the type of justifications for the blunt truth-telling story as the predicted. The model was also significant, $\chi^2(4, N = 120) = 31.72$, $p < .001$, Nagelkerk $R^2 = .26$. A priori comparisons with prosocial lie-telling as the reference for the predictor and the politeness justifications as the reference for the predicted were performed. Those children who gave the both justification to their moral judgment scores of the blunt truth-telling story were significantly (11.07 times) more likely to tell prosocial lies than nonprosocial lies, $\beta = 2.41$, Wald = 10.24, $p < .01$, odds ratio = 11.07, and (9.09 times) more likely to tell prosocial lies than the blunt truth, $\beta = 2.21$, Wald = 16.40, $p < .001$, odds ratio = 9.09. In other words, children who considered both the honesty and politeness issues when judging the blunt truth-telling story were more inclined to tell a prosocial lie than those who only focus on either honesty or politeness. Consistent with this result, those children who gave the politeness justifications to their moral judgment scores of the blunt truth-telling story were equally likely to tell prosocial lies or nonprosocial lies or the blunt truth.

Discussion

This study examined children's prosocial lie-telling behavior in a politeness situation and its relation to their moral understanding of lie- and truth-telling. Overall, almost all children were able to identify lies and the truth correctly in the story procedure. Contrary to our hypothesis, no age differences were found. Unlike Lee and Ross (1997) who tested participants 12 years and above, but similar to Bussey (1999) who tested younger children, all the children in our study identified untruthful statements told with the intent to help another individual as lies. Our findings taken together with those of Bussey (1999) suggest that young children do not adhere to the suggestion that prosocial untruthful statements may not be lies at all (Sweetser, 1987). However, it may be that as children develop into adolescence and adulthood their conceptions of prosocial lies change (Lee & Ross, 1997). Future studies are needed to examine this possible developmental shift in the conception of prosocial lies.

The moral evaluation results are consistent with and complement previous findings (Bussey, 1999; Walper & Valtin, 1992) that children's evaluations of prosocial lies become less negative between preschool and elementary school age. Children in this study, who were all elementary school age, gave less negative moral evaluations for prosocial lie-telling than for control lie-telling. They also gave less positive ratings to blunt truth-telling than control truth-telling. In addition, whereas children between 7 and 11 years of age similarly gave negative yet near-neutral ratings to prosocial lies, 7-year-olds were more likely to give positive ratings to blunt truth-telling than 9- and 11-year-olds whose ratings were at the neutral level.

This tendency to rate prosocial lie- and blunt truth-telling around the zero point (neither good nor bad) may reflect children's increasing awareness of the fact that politeness situations involve two contradictory sets of rules that must be weighed against each other. This is demonstrated by children's justifications of their ratings. Older children were significantly more inclined than younger children to raise the issues of honesty and politeness simultaneously when justifying their ratings of prosocial lies and blunt truths. Furthermore, children who recognized both issues to be applicable to the politeness situation were more inclined to let the concern for politeness override the need to be truthful. As shown by the results of the multiple regression analyses, regardless of age, those children who used the both responses to justify their ratings tended to rate prosocial lies positively and blunt truth negatively. In contrast, those who used the politeness justifications rated both prosocial lies and blunt truths moderately negatively, suggesting that they might be ambivalent about whether the concern for politeness should determine the appropriate course of action for the situation. Not surprisingly, children who used the honesty justifications gave prosocial lies highly negative ratings whereas blunt truths were given highly positive ratings.

In terms of children's actual behavior in the politeness situation, 40% of 7-year-olds, 50% of 9-year-olds, and 60% of 11-year-olds told a lie. They told the gift-giver that they liked the undesirable gift but later told the experimenter that they did not really like the gift. The age pattern is generally in line with the findings of Talwar, Murphy, et al. (2007), who also found a significant increase in lie-telling between 3 and 11 years of age in a similar undesirable gift situation. However, because Talwar, Murphy, et al. did not probe children's motives for lying, the extent to which their children truly told prosocial lies for prosocial purposes was not clear.

Unlike Talwar, Murphy, et al. (2007), this study questioned children's motives for lying. When children were asked about why they had lied to the teacher, a developmental difference emerged between younger and older children. Although most younger lie-tellers were motivated to lie for nonprosocial reasons such as to avoid negative consequences for themselves (e.g., the gift-giver being mad at them), the majority of older lie-tellers were motivated to lie for prosocial reasons such as avoiding hurting the feelings of the gift-giver. These findings suggest that although the tendency for children to tell a lie increases with age in the politeness situation, their motives for telling such lies also change with age, from more self-serving at the younger age to more prosocial at the older age. Thus, the significant age effect seen in this study and perhaps that in Talwar, Murphy, et al. reflects a developmental change in children's tendency to tell a truly prosocially motivated lie.

It should be noted that the rate of lying in this study (50%) was substantially lower than the rate of lying (about 80%) in situations where children tell lies to conceal their own transgression (e.g., Talwar & Lee, 2002a). The exact nature of this discrepancy is unclear. One possibility is that children's tendency to lie may be more significantly influenced by their self-interests than by the need to help others as suggested by Talwar et al. (2004). Consistent with this suggestion, they found that although most children aged between 3 and 11 years refused to lie to conceal their parents' transgression, when their own responsibility for the transgression was absolved, approximately half of the children would lie for their parents. This possibility is also in line with the present finding that more than half of the 11-year-olds and the majority of the younger children told the truth so that they would not miss the opportunity to obtain a desirable gift. Furthermore, even among the children who lied, more than a half of the 7- and 9-year-olds and 20% of the 11-year-olds lied for nonprosocial reasons.

Another major finding of our study is that children's actual lying or truth-telling behaviors in the politeness situation were consistently related to their moral evaluations and justifications of the prosocial lie-telling or blunt truth-telling stories. Prosocial lie-tellers were more likely to rate others' prosocial lie-telling more positively and blunt truth-telling more negatively than did nonprosocial lie-tellers and blunt truth-tellers. The same children also tended to mention both the politeness and honesty rules when justifying their evaluations of a story character's prosocial lie-telling or blunt truth-telling in a politeness situation. These results suggest that the prosocial lie-tellers were aware of both the need to be polite and to avoid hurting others as well as the need to be truthful. Nevertheless, they decided to be polite and therefore tell a prosocial lie themselves in the situation. These findings are inconsistent with the existing studies with children that involved the Kolhbergian moral dilemmas or antisocial lying. These studies tended to show either weak or no linkages between individuals' moral knowledge and moral action (Arnold, 1989; Blasi, 1980; Talwar et al., 2002, 2004; Thoma & Rest, 1986).

As mentioned earlier, the disconnection was likely because of the mismatch between children's interpretations of the two situations. One places them in an everyday situation in which they must choose an action. The other uses stories to depict a situation about which they must make a moral evaluation. Thus, to avoid this kind of mismatch and to reveal a relation between children's moral knowledge and action, we must directly assess children's interpretations of both the situations. By implementing such a strategy in this study, we were able to identify two different types of lie-tellers: prosocial and nonprosocial lie-tellers. Both types of children lied in the undesirable gift situation but for different reasons. Nonprosocial lie-tellers told a lie either out of fear or could not justify their lies and showed the classic dissociation between moral knowledge and action. They evaluated prosocial lies negatively and blunt truths positively but failed to act according to their moral knowledge. In contrast, prosocial lie-tellers told a lie for politeness purposes and were consistent in their knowledge and action because they not only told prosocial lies in the undesirable gift situation themselves but also evaluated such lies positively and blunt truths negatively.

It should be noted that these children were apparently aware that the concern for both politeness and honesty were applicable to the situation. However, the concern for politeness seemed to play a more significant role in prosocial lie-tellers' decisions to lie than the concern for honesty. Also, the former seemed to override the latter when prosocial lie-tellers made moral evaluations of prosocial lies and blunt truths. Blunt truth-tellers were also consistent between their moral knowledge and behavior as they evaluated prosocial lie-tellers highly negatively and blunt truth-tellers highly positively, and acted accordingly themselves. Blunt truth-tellers appeared to identify both the undesirable gift situation they themselves encountered and the same situation depicted in the stories as a situation calling for honesty and thus displayed consistency between moral knowledge and action.

The present assessment of children's justifications to their moral judgments and the reports of their motives for their own actions not only highlight the importance of seeking out such information for methodological purposes but also raise a theoretical question about children's interpretative theories of mind and action. Chandler and his colleagues (Chandler, Sokol, & Hallett, 2001; Chandler, Sokol, & Wainryb, 2000) have argued that children's beliefs about rightness (i.e., morality) should be studied together with their beliefs about mental life; the separation of the existing developmental research on the two issues is both incomplete and arbitrary because beliefs about rightness are intimately related to beliefs about mental states such as beliefs and intentions. This approach has received some empirical support. For example, Wainryb, Brehl, and Matwin (2005) examined children's narrative accounts and moral evaluations of their own interpersonal conflicts with others. They found that children gave qualitatively different interpretations when events were viewed from the victim's or perpetrator's perspectives, and hence different moral judgments. Although Wainryb et al. did not directly study children's actual moral behavior, they suggested that "by integrating, within the study of moral development, children's interpretations of the social interactions that are at the basis of moral thinking, this approach brings us a step closer to conceptualizing the study of children's moral behavior" (p. 80).

The findings of this study suggest that this interpretative approach may indeed be fruitful for research on moral development in general and the relation between children's moral judgment and actual action specifically (see also Arsenio & Lemerise, 2004). Although this study revealed a significant relation between children's evaluations of prosocial lies and blunt truths and their actual behavior, the relation was strengthened and clarified when both children's justifications about their evaluations and their own behavior were taken into consideration. In particular, the relation was strengthened when children showed an appreciation of two different perspectives based on the concerns for honesty and politeness. It should be noted, however, that this study did not explicitly ask about children's interpretations of the story characters' beliefs and intentions in the moral judgment task nor their interpretations of the politeness situation they themselves encountered (e.g., their own beliefs as a lie- or truth-teller and the experimenter as a lie- or truth-recipient). Future studies need to take a genuine interpretative approach to ask these specific questions, which may reveal an even closer relation between children's moral knowledge and behavior than what has been found in this study.

In summary, this study examined school-aged Chinese children's moral understanding of lie- and truth-telling and their actual lying behaviors in a politeness situation. It revealed that children at all ages categorized untruthful statements as lies and truthful statements as the truth regardless of whether they were told for prosocial or nonprosocial purposes. However, as age increased, children became increasingly less negative and more positive about others' lying in politeness situations, and they were more inclined to tell lies in such situations themselves. Contrary to previous findings (e.g., Talwar et al., 2002), children's moral knowledge about lying was significantly related to their actual behaviors.

Preschoolers' Implicit and Explicit False-Belief Understanding: Relations With Complex Syntactical Mastery

Jason Low
Victoria University of Wellington

Three studies were carried out to investigate sentential complements being the critical device that allows for false-belief understanding in 3- and 4-year-olds ($N = 102$). Participants across studies accurately gazed in anticipation of a character's mistaken belief in a predictive looking task despite erring on verbal responses for direct false-belief questions. Gaze was independent of complement mastery. These patterns held when other low-verbal false-belief tasks were considered and the predictive looking task was presented as a time-controlled film. While implicit (gaze) knowledge predicted explicit (verbal) false-belief understanding, complement mastery and cognitive flexibility also supported explicit reasoning. Overall, explicit false-belief understanding is complexly underpinned by implicit knowledge and input from higher-order systems of language and executive control.

According to de Villiers (2000), children must understand and reproduce complement syntax before achieving an understanding of false beliefs. Complements are statements embedded under propositional attitude verbs within a sentence. In a recent meta-analysis of studies on false-belief understanding, Milligan, Astington, and Dack (2007) uncovered a stronger direction of effect from measures of individual language ability to false-belief comprehension than the reverse. The largest effect size was observed for children's mastery of embedded complement structures, but this finding remains unclear for two reasons. First, the effect size may be overstated as only four studies in the meta-analysis assessed the unique role of sentential complements. Second, the correlation between false-belief reasoning with mastery of sentential complements did not differ significantly from correlations with other measures of language ability (e.g., synonym production; Perner, Stummer, Sprung, & Doherty, 2002). The relation between standard false-belief tasks with a variety of individual language skills may partly reflect implicit–explicit changes in representational format underpinning children's understanding of mental states. As such, we need to clarify the link between complement mastery and false-belief reasoning to better identify the constraints on individual language ability relating to mental state understanding.

Complementation Enables Cognition

de Villiers singled out children's mastery of the grammatical argument structure of mental state and communication verbs taking realis complements (clauses with overt present or past tense) with their associated marking of points of view as prerequisite for representing false beliefs (e.g., de villiers 2004, 2005; de Villiers & de Villiers, 2000, 2003). Consider the sentence: "Homer said *the cat yodeled*." While the complement embedded under the verb is false (the cat yodeled), it is still true that Homer said something. The complement structure also licenses the protagonist's terms of reference even when they are not ours: "Homer said the cat yodeled, but in fact it meowed." de Villiers contends that overt evidence of truth or falsity from the verb *say* is easier to conceptualize and may be a

precursor to understanding sentential complements that include analogic mental state verbs (e.g., *think*).

de Villiers and Pyers (2002) found that memory for the content of complement sentences embedded under communication and mental state verbs at an earlier test point predicted later false-belief comprehension and not the reverse. Training on communication verb sentential complements alone can also improve children's false-belief performance (and not vice versa; Hale & Tager-Flusberg, 2003). Schick, de Villiers, de Villiers, and Hoffmeister (2007) also found predictive correlations linking grasp of communication verb (*told*) complement structure in American Sign Language with false-belief understanding among deaf children. A criticism of the memory for complements task is that even though children are simply asked to restate the false utterance of the protagonist, those utterances may cry out for an explanation in terms of the deceptive motive of the actor. However, Lohmann and Tomasello (2003) found that even training children to talk about objects using complement frames that do not highlight deceptive experiences can facilitate false-belief understanding. These findings fit with the strong view that "sufficient reasoning ability (for false-belief computation, prediction and explanation) is defined by having language of the appropriate degree of complexity" (de Villiers & de Villiers, 2003, p. 338).

Implicit False-Belief Knowledge

One theoretic complication to de Villiers' account of false-belief development remains relatively unexplored: children's implicit knowledge. Clements and Perner (1994) ran a change-in-location false-belief task whereby they videoed children's eye gaze in anticipation of the protagonist reappearing to look for the target object. Children between 2 years 11 months and 3 years 7 months looked more at the correct location despite providing an incorrect verbal false-belief judgment. Older children (by 4 years) matched their verbal response to an overt false-belief question with their visual orienting gesture. It is possible that young children possess an implicit understanding of false beliefs, and implicit knowledge of belief might precede and contribute to explicit understanding. The possibility of a distinction between implicit and explicit false-belief knowledge fits with nondevelopmental research. For example, blindsight patients show no awareness of objects that fall into the affected portion of their visual field and yet are able to accurately intuit features of the objects (Perner & Clements, 2000). On a cautionary note, however, Clements and Perner's (1994) anticipatory eye gaze results might instead index a weaker form of *explicit* knowledge.

One way to disestablish the "implicit" nature of early false-belief knowledge is to argue that young children's visual orienting could reflect less confident (but explicit) expectations. However, Ruffman, Garnham, Import, and Connolly (2001) found that the young children who gave incorrect verbal false-belief predictions did not even want to bet a modest number of counters on the location as indicated by their correct eye gaze. These results suggest that children are not conscious of the knowledge conveyed in their eye gaze.

A second objection is that anticipatory gaze may reflect a seeing = knowing rule (e.g., O'Neill, 1996). Garnham and Ruffman (2001) redesigned the predictive looking false-belief task to comprise three hiding locations wherein the protagonist first explored the middle hiding location before placing the object in the left-hand location. A second character then moved the object to the right-hand location. If predictive gaze is based on a sensitivity to the protagonist not knowing, children should look in anticipation equally often to the left and irrelevant middle locations. However, children looked in anticipation clearly to the left-hand location; anticipatory gaze appears to be based on implicit false-belief understanding.

A third objection stems from studies, involving deaf children, uncovering how performances on low-verbal and traditional verbal measures of false belief are correlated with complement mastery (e.g.,de Villiers & de Villiers, 2003; Schick et al., 2007). However, the critical issue may not be whether tasks are verbal or low verbal per se, but whether a task taps into implicit versus explicit knowledge. In the low-verbal object-hiding theory-of-mind task used by Schick et al., (2007), participants were instructed to point to which of two identical boxes contained a target object upon determining a helper's visual access to the hiding event. When children point, they are explicitly aware of having gestured, and this may not be equivalent to eye glances that are factuality implicit (Goldin-Meadow & Alibali, 1999). The low-verbal and verbal false belief tasks used by Schick et al. may have correlated with complement mastery because both methods tapped explicit knowledge.

Finally, Onishi and Baillargeon (2005) found that 15-month-olds showed increased looking times to an event when the actor's search behavior violated a false belief compared with when it fitted a false belief. These findings have been replicated with 13-month-olds even when similarities to last person-object-location encoding are controlled for (e.g., Surian, Caldi, & Sperber, 2007). In Clements and Perner's (1994) study, however, very young 2-year-olds did not show implicit understanding via anticipatory gaze. In the predictive looking task, the target object is present; 2-year-olds' knowledge of the actual location of the object may interfere with their implicit knowledge of where a protagonist with a false belief might look. This interference could also partly reflect young children's fledgling ability to inhibit or select attention away from a true-belief suggestion (e.g., Leslie, German, & Pollizi, 2005). Of course, this does not mean that the predictive looking task is not appropriate for tapping into implicit false-belief knowledge per se; it may simply mean that the task involves other demands that may swamp the rudimentary nature of 2-year-olds' false-belief sensitivity. Using a simpler version of the predictive looking task where the target object was removed altogether, Southgate, Senju, and Csibra (2007) found that 2-year-olds looked first (and longer) to the location where an actor was expected to search given a false belief. The developmental timeline suggests continuity in implicit false-belief understanding from 2 to 4 years of age and, further, that early knowledge may be formatted "in a rudimentary and implicit form" (Onishi & Baillargeon, 2005, p. 257). A step forward for theory building is to understand how implicit knowledge underpins explicit understanding, and how factors such as language ability make explicit knowledge more accessible.

Rise of Explicit Understanding

One view is that through the endogenous cyclical process of redescription, implicit representations are recoded into explicit ones (with the highest format providing access to declarative verbal reporting; Karmiloff-Smith, 1992). By hypothesis, variation in implicit social-perceptual understanding may reasonably correlate with the extent of explicit verbal false-belief reasoning. Continuity (i.e., a correlation in performance) between implicit and explicit false-belief knowledge is bolstered by certain lines of evidence. First, implicit knowledge is a precondition for receptivity to explicit false-belief training (e.g., Clements, Rustin, & McCallum, 2000). Second, other incipient theory of mind insights such as the duration of infants' correct looking during referential acts are correlated with higher level cognitive outcomes (e.g., Wellman, Phillips, Dunphy-Lelii, & LaLonde, 2004).

To provide a concrete mechanism for how changes in explicit reflection might occur, Zelazo (1994) suggested that redescription could also take place over the course of problem solving when children demonstrate cognitive flexibility or the ability to construct a higher order rule to simultaneously integrate multiple conflicting representations of a single event. Performance on the Dimensional Change Card Sort (DCCS) task is closely correlated to explicit false-belief task performance, independent of age and general intelligence (e.g., Frye, Zelazo, & Palfai, 1995; Müller, Zelazo, & Imrisek, 2005). Zelazo, Gao, and Todd (2007) explain that the two kinds of tasks may be related because both require cognitive flexibility in relating two incompatible perspectives (e.g., in the DCCS—how it is possible to sort the same cards by shape and then by color; in the representational change false-belief task—how it is possible to directly respond with a past or present self-perspective). Preschoolers may become more proficient at reasoning through both types of problems when they flexibly integrate opposing knowledge into an embedded hierarchical "if-if-then" rule. The link between cognitive flexibility and explicit false-belief understanding must, however, be qualified in several ways. First, studies by Carlson and Moses testing other aspects of executive control reveal a strong association between conflict inhibition tasks with standard verbal false-belief performance (e.g., Carlson & Moses, 2001; Carlson, Moses, & Claxton, 2004). Second, Perner and Lang (2000) pointed out that explicit verbal false-belief tasks can be passed without necessarily reformulating two separate rules in a hierarchical three-term fashion (e.g., if I am looking for the marble, then here; if Sally is looking for the marble then there). Third, the evidence on whether explicit mental state understanding or cognitive flexibility over rule switching emerges first is equivocal (e.g., Kloo & Perner, 2003).

Nonetheless, even views concentrating on the cognitive flexibility facet of executive control in relation to advancing mental state awareness maps onto the broader point made here that the grammar of complement constructions cannot be the critical device that allows for false-belief representation. Jacques and Zelazo (2005) have suggested that the relation between individual language ability and explicit false-belief answering can instead be meaningfully recast in terms of language working to service cognitive flexibility in promoting explicit perspective taking. To the extent that cognitive flexibility in rule use refers to linguistically mediated reasoning for promoting explicit control of thought and action (Carlson, 2003), then such a view even fits with research indicating that verbally labeling cards before sorting on the DCCS task can improve inhibitory control to support explicit attentional focus on multiple and conflicting perspectives (e.g., Kirkham, Cruess, & Diamond, 2003). One integrated view may be that, alongside an implicit understanding of false belief, skill sets that include individual language ability (e.g., complement mastery) and cognitive flexibility can help make emergent explicit understandings of false belief.

Only Tantalizing?

Unfortunately, studies emphasizing early implicit sensitivity to false-belief understanding remain tantalizing because they do not include any measure of children's individual language abilities (e.g., Clements & Perner, 1994; Clements et al., 2000; Ruffman et al., 2001). If it turns out that visual orienting does not uniquely tap implicit knowledge but is correlated with complement mastery, it is possible to maintain that certain syntactic structures provide the breakthrough for any false-belief understanding (e.g., de Villiers, 2000, 2004; de Villiers & de Villiers, 2003). If eye gaze is not correlated with mastery of complement structure, it would mean that although certain grammatical platforms may play a role in harnessing explicit levels of false-belief understanding that are more complex and abstract, complementation is unlikely to provide the conceptual foundation for children's metarepresentational ability (Surian et al., 2007). Implicit knowledge is also likely to contribute to explicit false-belief understanding. For the present investigation, two distinct but connected premises were submitted for analysis: (a) explicit false-belief understanding has distinctive roots in implicit knowledge (via anticipatory eye gaze) and (b) cognitive flexibility and complex language ability uniquely contribute to underpinning children's explicit false-belief understanding.

Study 1

The first study examined whether complement mastery was correlated with anticipatory eye gaze and verbal judgments on standard false-belief tasks. Based on studies maintaining that visual orienting and verbal answers can potentially tap into implicit and explicit false-belief understanding, respectively (e.g., Clements & Perner, 1994; Ruffman et al., 2001), two main hypotheses were submitted. First, early false-belief sensitivity was expected to show up on indirect anticipatory eye gaze but not on direct verbal answering. Second, eye gaze was hypothesized to be language independent, but anticipatory gaze and complement mastery were each expected to uniquely contribute to predicting explicit false-belief understanding.

Method

Participants. Data came from 24 participants: twelve 3-year-olds (*M* = 3.8, *SD* = 2.09 months, range = 3.5–3.10; 4 girls and 8 boys) and twelve 4-year-olds (*M* = 4.7, *SD* = 2.62 months, range = 4.1–4.10; 6 girls and 6 boys). A total of 30 children were interviewed but 6 children (four 3-year-olds and two 4-year-olds) were not included in the final analysis as they failed to answer control questions in the various false-belief tasks correctly and did not sit still during the eye gaze task to allow examination of predictive looking. All participants in this study (and also in Studies 2 and 3) were Pakeha (New Zealanders of European descent), spoke English as their first language, and were from middle-class families.

Procedure. All children were individually interviewed in a quiet room at their kindergarten, and each of the 24 data participants took part in four 10- to 15-min fixed-order sessions with an interval of about 1 week between each. In Session 1, the eye-gaze false-belief task was presented. In Session 2, the Peabody Picture Vocabulary Test (PPVT)–III was administered. In Session 3, the Matrices and complement mastery tasks were presented. In Session 4, the unexpected contents, deceptive appearance, and change-in-location false-belief tasks were presented.

Verbal and nonverbal ability. Children's verbal ability was assessed using the PPVT–III (Dunn & Dunn, 1997). Nonverbal ability was measured using Raven's Colored Matrices (Raven, 1993). Raw scores of both measures were used.

Complementation task. The task measuring memory for complements embedded under a communication verb (*say*) was derived from Hale and Tager-Flusberg (2003). Each story involved different characters saying they did one activity when they were doing something else. Stories were worded to avoid any deceptive context or invitations to consider the motives of the false utterance. The order in which the information about what the central character said and what he or she did was counterbalanced across trials. Each trial was accompanied by two drawings, and at the end of each story participants were asked what the central character said. In one trial the experimenter presented a picture of a boy by himself baking cookies and said, "James was baking some cookies for his friend Lucy." The experimenter replaced the first picture with a second one showing the boy and his friend without any action and said, "Lucy came along and asked him what he was doing. James said, "I'm baking some bread." Participants were asked the test question, "What did James say he was baking?" The remaining three trials were about a girl saying she was cutting paper when she was really cutting her hair, a boy saying he kissed his mother when he really kissed Big Bird, and a girl saying she played with a cat when she really played with a dog. Each correct answer received 1 point for a total score of 4.

Eye gaze. Ruffman et al.'s (2001) predictive gaze task was used to measure implicit false-belief understanding. A 3D model (80 cm length × 35 cm width × 50 cm height) of a house was displayed on a table. At the front there was a ladder going to the top and a slide exit on either side (red at left, green at right). Slide exits at the front were separated by a distance of 70 cm and were adjacent to the slide entrances hidden at the back of the model. A red and green box (7 cm × 7 cm × 7 cm) was positioned 2 cm from either side of the respective slide exits. Toy objects were used to enact the event. The child sat on the floor in front of the model, with a camera above it recording eye gaze (see Figure 1). An assistant hidden behind the model house helped the experimenter with the staging of the event.

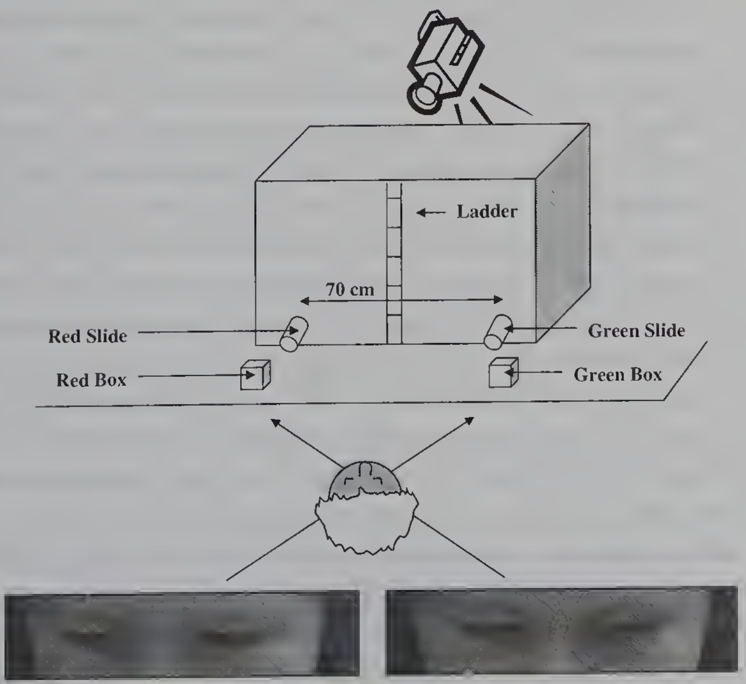

Figure 1. Eye gaze apparatus setup with illustrative frames of gaze direction.

The experimenter first demonstrated to participants that when the central protagonist wanted to look in the red box he would come down the red slide, and when he wanted to look in the green box he would come down the green slide. All children remembered where the protagonist would emerge from to look in the respective boxes. For the false-belief story, the experimenter enacted a narrative whereby the protagonist hid his toy car in the red box and then went to sleep behind the house (the assistant's hand appeared from behind to remove the protagonist upon climbing to the top of the house). Then the experimenter enacted the next episode where another character came along and moved the toy from the red to the green box and left the scene. The experimenter then sat behind the child. The assistant hidden behind the model house then announced that the central character was waking up and wanted to go play with his toy. The experimenter then wondered aloud to elicit anticipatory gaze, "I wonder which slide [protagonist] will come down to look for his car." Four seconds later, children were asked an explicit false-belief question: "Which slide will [protagonist] come down to look for his car?" A true-belief control story with the protagonist (a different character) witnessing the target (a different object) changing locations from the red to green container was also enacted. False- and true-belief trials were counterbalanced. Participants passed the true-belief explicit question and looked longer to the green slide location, providing confidence that gaze on the false-belief trial was not because of participants retracing story events and looking to where the protagonist first put the object. All participants passed control questions asked after the standard explicit false- and true-belief questions: reality (where is the [object] now?), memory (where did [protagonist] put his [object] in the beginning?), and perceptual access (did [protagonist] see [displacer] move the [object]?).

Videotapes of participants' eye gaze for the false-belief trial over a 4-s period following the "I wonder" prompt were analyzed to determine the number of frames during which children looked to a given location when anticipating the character's descent. Miyuki and Chisato (2006) pointed out that the whites of human eyes produce strong contrast with the pupils when looking left or right, and in that sense, detection of gaze direction can be relatively straightforward. Using VideoReDo Plus, one rater coded all tapes in slow motion and scored gaze direction on a frame-by-frame basis (looking times were accurate to 0.04 s; 25 frames/s). Another rater coded 20% of the videotapes, and raters agreed 100% of the time as to whether or not the child was looking more to the correct location. The gaze task captures rich variance in children's implicit false-belief knowledge via latency of visual orienting over 4 s; explicit understanding, however, was only tapped by verbal answers to a single direct false-belief question. To ensure sufficient variance in the measurement of explicit knowledge, three other direct false-belief tasks were included.

Unexpected contents and deceptive appearance tasks. Single trials of the unexpected contents and deceptive appearance tasks were given (Bialystok & Senman, 2004; Gopnik & Astington, 1988). For unexpected contents, participants were shown an M&Ms tube and asked what it contained (all said ''M&Ms''). They were then shown that it contained a spoon instead of M&Ms. Participants were asked about their own false belief (When you first saw this tube, what did you think was inside?) as well as to predict what an out of sight puppet (Ernie) would think was in the tube (When Ernie sees this tube, what will he think is inside?). Participants were then asked the reality control question (What is inside the tube right now?). For deceptive appearance (involving a sponge rock), participants were shown the object placed on a table and asked, ''What is this?'' All children answered correctly (rock or stone). Next the object's hidden property was revealed and two direct false-belief questions of the object's appearance were asked: ''What did you think this was when you first saw it?'' and ''Ernie did not hear or see what we were doing; what will Ernie think this is?'' Participants were then asked the reality control question (What is this really?).

Change-in-location task. The unexpected contents and deceptive appearance tasks contributed a maximum of 2 points each to explicit understanding (two direct false-belief test questions in each context). Verbal answers to the single direct question in Ruffman et al.'s (2001) gaze task contributed 1 point to explicit false-belief understanding as presented in a change-in-location context; thus, a single trial of Baron-Cohen, Leslie, and Frith's (1985) Sally-Ann change-in-location task was also administered. Toy characters were used and the hiding locations employed a basket and a jug with a small plastic fruit serving as the target object. The explicit test question involved children answering where the central protagonist (Sally) would first look for the (displaced) object. Then participants were asked two control questions: ''Where is the fruit now?'' and ''Where did Sally put the fruit?''

Overall, six explicit false-belief questions were asked and their contexts (unexpected contents, deceptive appearance, and change in location) contributed equal subscores to explicit false-belief answering. All participants answered the associated control questions correctly. A composite explicit false-belief score was calculated for each participant by adding the points across all direct test questions yielding a maximum score of 6 ($\alpha = .82$).

Results and Discussion

Preliminary analyses revealed that there were no gender effects in Study 1 (or in Studies 2 and 3), and including gender in the regression models did not affect the results. Consequently, gender was not included in all analyses reported here.

Eye gaze. The location of children's initial look following the anticipatory ''I wonder'' prompt was analyzed first. Significantly more children showed correct first looks ($N = 21/24$; 87%) than expected by chance based on the binomial distribution ($p < .001$). As a second approach to the data, eye gaze was assessed in terms of the total amount of time spent looking at the correct and incorrect locations. There was no significant age group difference for the amount of time spent looking at the correct location or the incorrect location (see Table 1 for mean scores). Nonetheless, collapsed across age groups, children spent a longer total amount of time looking at the correct location ($M = 1.45$ s, $SD = 0.78$) than the incorrect location ($M = 0.83$, $SD = 0.69$), $F(1, 23) = 8.02$, $p < .01$, $\eta_p^2 = .26$. Finally, an analysis of participants' visual orienting preferences relative to their ability to give a correct verbal answer on the single explicit false-belief question for the gaze task was carried out. A conservative metric was used to capture the *degree* of correct preferential looking whereby participants were classified as passing eye gaze only if the looking time *difference* for the false-belief trial ([looking at correct location] − [looking at incorrect location]) was at least +0.15 s. There was a significant link between anticipatory gaze and giving a correct verbal answer for the explicit question, $\chi^2(1, N = 24) = 4.51$, $p < .05$, Cramer's $\phi = .43$. Ten children (42%) passed eye gaze and correctly answered the single explicit false-belief question while 5 children failed both (21%). Critically, 37% ($n = 9$) of

children passed eye gaze while erring on their verbal answers to the explicit false-belief question but no participant showed the reverse relation.

Group differences on explicit false-belief and other measures. Mean scores on each of the other measures are also reported in Table 1. A one-way ANOVA indicated that 4-year-olds had a higher aggregate explicit false-belief score than 3-year-olds. Similar analyses also revealed significant age group differences in PPVT performance and complement mastery. There was no significant age group difference in general nonverbal ability on the Matrices task.

Correlations and hierarchical regressions. For the remaining analyses in Study 1, to examine empirical connections between implicit and explicit false-belief understanding, the difference in looking time variable was used as the candidate metric for reflecting implicit knowledge. The reasoning is as follows. First, a looking time difference metric converges with approaches used in other relevant developmental literature, for instance, gaze following and social attention, where correlations between visual orienting durations and higher cognitive task performance are computed and interpreted (e.g., Brooks & Meltzoff, 2005; Wellman et al., 2004). Other metrics such as the correct first look, while important for determining that children's predictive looking behaviors do not reflect chance responding, do not yield sufficient variation to avoid spuriously low correlations with explicit false-belief understanding (or complement mastery; cf. Bornstein & Sigman, 1986). Finally, looking-time difference provides a clearer index of a state of mind as reflected in the degree of preference in children's visual orienting responses (Ruffman, 2000) and, further, duration of difference in looking time by yielding variation fits with arguments that there is real, though subtle, growth in implicit knowledge (Munakata, McClelland, Johnson, & Siegler, 1997). Full and partial correlations are reported in Table 2 (top row). Full correlations indicated that explicit false-belief understanding (composite score), aside from being related to chronological age, was related to

eye gaze and language ability (both general vocabulary and complementation). There was no significant bivariate correlation between eye gaze and complement mastery.

When the effects of chronological age and general developmental abilities were controlled, explicit false-belief reasoning was related to eye gaze and complement mastery. Partial correlation results supported the hypothesis that spontaneous anticipatory eye gaze marked implicit knowledge that was not significantly related to individual differences in complement mastery. There appear to be dissociations in preschoolers' false-belief knowledge between the behavioral and verbal levels. A hierarchical regression analysis was conducted to determine whether eye gaze and complement mastery each contributed unique variance in predicting explicit understanding (see Table 3).

Age, and PPVT and Raven's scores were entered as the first block of independent variables, and overall, they accounted for 49% of explicit false-belief variance. Analysis of regression coefficients revealed age, $\beta = .48$, $t(20) = 2.67$, $p = .015$, to be a focal predictor of explicit false-belief understanding. Eye gaze performance was entered in the second step, and variation in implicit understanding uniquely accounted for a further 14% of variance in explicit reasoning. Complement mastery was entered at the third step and accounted for further unique variance (11%) in explicit reasoning. Analysis of regression coefficients confirmed that, even at the third step, eye gaze performance continued to exert unique predictive value to explicit false-belief reasoning, $\beta = .41$, $t(18) = 3.34$, $p = .004$. Implicit knowledge and complement mastery appeared to uniquely scaffold preschoolers' explicit false-belief understanding.

Study 2

While the findings of Study 1 were consistent with theoretic predictions, three issues needed to be addressed further. First, the sample size was small, so it is important to replicate the findings. Second, de Villiers (e.g., de Villiers & de Villiers, 2003) argued that extant findings on anticipatory looking are difficult to align with evidence gained from deaf studies involving less verbal measures of false belief. If less or nonverbal tasks do not pattern after verbal ones, then deaf children should demonstrate increased skills on less verbal measures because such participants are more visually oriented, but this does not appear to be the case (e.g., Schick et al., 2007, using the object-hiding task; Woolfe, Want, & Siegal, 2002, using the thought-bubbles task). However, even with such less verbal false-belief tasks, children are still asked to make a direct prediction based on a protagonist's epistemic state, suggesting that those tasks essentially draw on explicit knowledge. In contrast, eye glances are not recorded in response to a direct question; rather, they are implicitly elicited in anticipation of a character's actions (Ruffman, 2000, 2004). To disentangle these ideas, Study 2 provided children a larger battery of false-belief measures that included the object-hiding and thought-bubbles tasks. Following appeals to implicit and explicit false-belief understanding, it was predicted that complement mastery would be correlated with explicit false-belief understanding (including performance on the object-hiding and thought-bubbles tasks) but not with implicit (anticipatory looking) knowledge. While the results of Study 1 supported the first theoretic submission that explicit false-belief decisions have roots in unique implicit knowledge and that grasp of complex language contributes to conscious understanding, I also submitted a second premise that explicit knowledge may be reconfigured at higher levels of disembodiment through cognitive flexibility and natural language. While implicit knowledge via eye gaze was predicted to correlate with explicit verbal false-belief reasoning (as in Study 1), DCCS performance and complement mastery were predicted to each correlate with explicit understanding.

Method

Participants. New data came from 36 participants: eighteen 3-year-olds (M = 3.6, SD = 2.38 months, range = 3.4–3.11; 5 girls and 13 boys) and eighteen 4-year-olds (M = 4.4, SD = 2.94 months, range = 4.1–4.10; 6 girls and 12 boys). A total of 43 children were tested but five 3-year-olds failed to answer control questions in the false-belief tasks correctly and two 3-year-olds did not attend the final testing session, and so those individuals were not included in the final analysis.

Procedure. Participants were individually tested in a room at their kindergarten across six 10- to 15-min sessions with an interval of 1 week between each. Dovetailing with Study 1, tasks were presented in the following order. In Session 1, the eye-gaze task was presented. In Session 2, the PPVT–III was administered. In Session 3, the Matrices and complement mastery tasks were given. In Session 4, the unexpected contents, deceptive appearance, and change-in-location false-belief tasks were presented. In Session 5, the DCCS and thought-bubbles tasks were given. In Session 6, the object-hiding task was presented.

DCCS (full version). Participants were shown two target cards (blue rabbit and red boat) attached to one of two target trays and told of two preswitch rules (e.g., by color) for sorting a series of bivalent cards (red rabbits and blue boats). After successfully completing a practice trial sorting two cards, participants started the preswitch phase (e.g., "If it's blue it goes here, and if it's red it goes there. This is a blue one, where does it go?"). No feedback was given. Participants needed to sort all six preswitch trials correctly in order to receive a score of 1 (Zelazo, 2006).

For the postswitch phase participants were told: "Now we are not going to play the color game anymore. We are going to play a shape game now. In the shape game, all rabbits go here and all boats go there. If it's a rabbit it goes here, and if it's a boat it goes there." The experimenter picked up a card and labeled it by its relevant dimension, and the child had to sort cards independently (e.g., "This is a rabbit, where does it go?"). Participants had to sort at least five of six trials to pass the postswitch phase (Zelazo, 2006).

The full DCCS task comes with a third phase (the border trials) that requires a higher level of cognitive flexibility. Some of the test cards were presented with black borders and the others were normal: "Now we are playing a different game. If there is a black line around the card like this one (red rabbit with a border), we play the color game. In the color game, all red ones go here and all blue ones go there. This card is red, so we put it over here. If there is no black line around the card, like this one (red rabbit without a border), we play the shape game. In the shape game, all rabbits go here and all boats go there. This one is a rabbit, so we put it here.'' This phase comprised 12 trials (three red rabbits and three blue boats without borders, three red rabbits and three blue boats with borders). On each trial, the rule was repeated. Children must sort at least 9 of 12 cards correctly to pass this phase (Zelazo, 2006).

The full DCCS was administered to capture continuous changes on cognitive flexibility over rule use (Hongwanishkul, Happaney, Lee, & Zelazo, 2005). Test cards were presented such that no more than two cards of the same type were presented consecutively. Each child's performance was scored as 0 (failed preswitch phase), 1 (passed pre- but failed postswitch phase), 2 (passed pre- and postswitch, but failed the border phase), or 3 (passed all phases; Zelazo, 2006).

False-belief tasks. With respect to Ruffman et al.'s (2001) eye-gaze task, all participants passed the true-belief control trial. One rater coded all tapes for the false-belief trial in slow motion and scored gaze direction on a frame-by-frame basis (looking times were accurate to 0.04 s). Another rater coded 20% of the videotapes, and raters agreed 100% of the time as to whether or not the child was looking more to the correct location. As in Study 1, single trials of the standard M&Ms, sponge-rock and Sally-Ann false-belief tasks were also administered. Overall, correct answers on the direct false-belief test questions for the task contexts of unexpected contents, deceptive appearance, and change in location each provided a subtotal score of 2, respectively. The new false-belief tasks were thought bubbles (Woolfe et al., 2002) and object hiding (Call & Tomasello, 1999).

False belief: Thought bubbles. A pretest was carried out to check that participants understood what thought bubbles meant. Two pictures were shown: one of boy taking a dog for a walk and the other of a boy thinking about a dog (with a thought bubble over his head containing a dog). The experimenter asked: ''Which boy is thinking about a dog?'' All children correctly pointed to the picture depicting a thought bubble. The task proceeded with two false-belief and two true-belief (control) trials (counterbalanced). An example false-belief trial showed a boy whose hand was reaching inside a partially shut kitchen cupboard. The experimenter said, ''Billy is reaching into the cupboard for a glass of water.'' Then the experimenter placed her palm over the protagonist's face and said, ''Let's cover Billy up so he does not see what is inside the cupboard.'' The cupboard door-flap was opened: ''Look, there is a mouse in the cupboard.'' (The picture shows Billy's hand reaching toward a mouse.) The flap was covered back, and the experimenter removed her palm covering the protagonist. She then presented another picture of Billy with an empty thought bubble over his head. A series of forced-choice picture items were shown underneath: a glass of water (false belief), a mouse (reality), an apple, and a bag (distracters). Children were instructed: ''Point to what Billy thinks is inside the cupboard.'' The other false-belief trial involved a boy who was fishing but whose line snagged a boot hidden behind reeds. True-belief trials involved a girl who sees a tall boy looking at her from behind a fence (the fence was removed to reveal a tall boy), and a boy walking along the beach who sees a fish tail from behind a bush (the bush was removed to reveal a fish). All participants passed the true-belief trials. The maximum correct false-belief score for the thought-bubbles task was 2.

False belief: Object hiding. Participants had to work out and point to which of two identical boxes contained an object. Children were told that the communicator (seated behind the hider) would help them find where an object (a balloon) was hidden by pointing to the correct box. Following Call and Tomasello (1999), three control trials were first administered. In the visible displacement trial, the hider concealed the balloon (carried out behind a raised barrier) and presented the two boxes to the child. The communicator then pointed to the box the balloon was in. Then the communicator turned around to have a drink of water and searched noisily in her bag. This distraction was natural while being obvious enough to ensure that the child knew the communicator was distracted and not paying attention to what would be happening next. In full view of the child, the hider opened up both boxes, transferred the balloon from one to the other, and closed the lids to the boxes. Then the communicator (timing was well practiced) turned around, and the hider asked the child to point to where the balloon was. This control trial confirmed that all participants could successfully keep track of the hider taking the object out from one box and moving it into the other. The next control trial was nearly identical to the first except that the hider simply switched the location of the boxes in full view of the child without taking the balloon out. The hider then asked the child to point to where the sticker was. This second control trial confirmed that all participants were able to successfully keep track of the object when the hider changed the location of the box in which the object was hidden. In the final control trial, after the hider hid the balloon and presented the boxes to the child, the communicator before pointing to the location of the object turned around to drink water and search in her bag. At this point, the hider opened both boxes and switched the balloon from one container to another and closed the lids to the containers, all in full view of the child. Then the communicator turned around and pointed to the (incorrect) container she had seen the balloon hidden. Then the hider asked the child to point to where the balloon was. This last control trial confirmed that all participants were able to successfully ignore the communicator's signal when it was wrong.

In the verbal false-belief trials, children watched the communicator observing the hider conceal the balloon. Then the hider presented the two boxes toward the child. Before the communicator pointed to which box the balloon was in, she turned around to drink and search in her bag. Then, in full view of the child, the hider opened the lid of the loaded box and moved the balloon into the other container and put the lids back on. After the hider switched the balloon, she asked the critical verbal false-belief question, "When [communicator] turns back around, where will she think the balloon is?" After the child pointed, the communicator turned back around and pointed to the box where she thought the balloon was. Two of such trials were administered and the scores were averaged.

In the two nonverbal false-belief trials, the hider hid the balloon in one of the boxes behind the barrier and presented them to the child. The communicator turned around to drink and search in her bag. The hider then swapped the location of the boxes in full view of the child. Then the communicator faced forward to signal which location she had seen the balloon hidden; thus, the box that she pointed to was incorrect, as she did not see the hider swapping the boxes. The child, who had no knowledge of the balloon's whereabouts until that moment was then asked to point to where the balloon was. Call and Tomasello (1999) argued that this trial represented a nonverbal measure of false belief because participants need to interpret the nonverbal information provided by the communicator in an appropriate way: (a) she initially saw the balloon being hidden in one of the boxes, but (b) did not see the boxes swapping locations, and (c) must have marked the particular box upon turning back around based on her outdated false belief, and so (d) the balloon must be in the other box. Two nonverbal trials were given and scores averaged. Presentation of the verbal and nonverbal false-belief blocks was counterbalanced. Average scores on the verbal and nonverbal false-belief blocks were recombined to produce a full object-hiding task score (maximum of 2).

Results and Discussion

Eye gaze and explicit false-belief performance. Replicating Study 1, a majority of the children displayed correct first looks (N = 32/36) than expected by chance ($p < .001$, binomial test). There was no significant age difference for the amount of time spent looking at the correct or the incorrect location (see Table 1 for mean values). However, children still spent a longer total amount of time looking at the correct location (M = 1.46 s) than the incorrect location (M = 0.64), $F(1, 35) = 16.62$, $p < .001$, $\eta_p^2 = .32$. As in Study 1, contingencies between passing/failing visual orienting versus giving a correct/incorrect verbal answer to the single explicit false-belief question found in Ruffman et al.'s (2001) predictive looking task were examined. There was a significant relation between eye gaze and verbal responding on the direct false-belief question, $\chi^2(1, N = 36) = 4.98$, $p < .05$, Cramer's $\phi = .37$. Sixteen children (44%) passed eye gaze and correctly answered the single explicit false-belief question while 7 children failed both (20%). However, many more children passed eye gaze while erring on the verbal answer to the explicit false-belief question (33%, $n = 12$) but only 1 participant (3%) showed the reverse relation.

Ruffman (2004) has argued that the object-hiding task is equivalent to standard false-belief measures tapping into explicit knowledge in that children are directly asked a question about the central protagonist's belief. Fitting with Ruffman's argument, many children passed eye gaze while erring on all of the false-belief test questions on the full object-hiding task (53%; $n = 19$) but only 1 participant (3%) showed the reverse relation of passing the object-hiding task but failing eye gaze. Similarly, more children passed eye gaze while erring on all of the false-belief questions on the thought-bubbles task (31%; $n = 11$) but only 2 participants (6%) showed the reverse relation of passing thought bubbles but failing eye gaze. In short, the dissociation between accurately gazing in anticipation of a character's mistaken belief while erring on verbal responses to the direct false-belief question in the predictive looking task was also found when contingencies between anticipatory gaze and overt pointing responses given for the object-hiding and thought-bubbles tasks were considered. Furthermore, not only were the verbal and nonverbal subparts of object-hiding task correlated ($r = .71$, $p < .001$), but children's scores on the overt false-belief questions asked for unexpected contents, deceptive appearance, change in location, thought bubbles, and verbal and nonverbal parts of the object-hiding task were intercorrelated ($\alpha = .87$).

In relation to bivariate associations with complex language ability, children's scores to overt false-belief questions for the change-in-location, deceptive appearance, and unexpected-contents task contexts were each correlated with complement mastery ($r = .48$, $p < .01$; $r = .54$, $p < .01$; and $r = .36$, $p < .05$, respectively). Children's tallies on the thought-bubbles task alongside scores on the verbal and nonverbal parts of the object-hiding task were also correlated with complement mastery ($r = .49$, $p < .01$; $r = .40$, $p < .05$; $r = .38$. $p < .05$, respectively). These results replicate work with deaf children (e.g., Schick et al., 2007) and could be claimed to fit with the view that complement mastery is important for any false belief reasoning. However, these particular false-belief tasks tap explicit knowledge by posing direct questions to children; as such, it is not surprising that they should all correlate positively with complement mastery (Ruffman, 2000, 2004). Critically, and anticipating the rest of the results, eye gaze remained separate by being *not* correlated with complement mastery. Consequently, a composite *explicit* false-belief understanding score was calculated by averaging subscores on answers to direct questions for unexpected contents, change in location, deceptive appearance, thought bubbles, and the full object-hiding task (hence, average maximum composite total = 2). Four-year-olds obtained significantly higher composite explicit false-belief scores compared to 3-year-olds (see Table 1).

Correlations and hierarchical regressions. Mean scores on the remaining measures of interest are also found in Table 1, and the direction of age group differences replicate those uncovered in Study 1. The analyses then turned to investigate correlations between anticipatory eye gaze (measured by the difference metric, as per Study 1) and composite explicit false-belief understanding with other variables of interest. Bivariate and partial correlations are reported in Table 2 (second row, above diagonal). At the bivariate level, PPVT performance, complement mastery, cognitive flexibility, and explicit false-belief understanding were related to chronological age. PPVT and complementation scores were also interrelated, and explicit false-belief reasoning was correlated with both PPVT and complementation performance. Explicit false-belief reasoning was further correlated with anticipatory eye gaze and cognitive flexibility. General nonverbal ability on the Matrices was also correlated with anticipatory gaze. Complement mastery was also correlated with cognitive flexibility at the bivariate level. Upon partial correlation analysis, only the following results remained: (a) explicit false-belief reasoning was related to anticipatory eye gaze performance, (b) explicit false-belief reasoning was related to cognitive flexibility and complement mastery, and (c) complement mastery was correlated with cognitive flexibility.

Two hierarchical regression analyses were conducted to determine whether implicit knowledge reflected in anticipatory eye gaze, together with cognitive flexibility and complementation, contributed unique variance to the prediction of explicit false-belief understanding. Age, and PPVT and Raven's scores were entered as the first block of independent variables. In the first regression analysis, eye gaze performance and cognitive flexibility were entered in the second and third steps, respectively. The second regression analysis was similar to the first except that complement mastery was entered at the final step. I did not pit cognitive flexibility against complement mastery when considering their unique effects because they were correlated, and it is possible that complex language might service the work of cognitive flexibility in promoting explicit false-belief reasoning (e.g., Müller et al., 2005; a point taken up in the General Discussion). Regressions are summarized in Table 4.

In the first regression analysis, age was the only significant predictor at Step 1, and accounted for 34% of explicit false-belief variance. Implicit (eye gaze) knowledge and cognitive flexibility contributed uniquely to explicit false-belief variance after effects associated with age, PPVT performance, and nonverbal reasoning on the Matrices were jointly removed. They accounted for a further 13% and 10% of the variance, respectively. For the second regression analysis, complement mastery significantly accounted for a further 9% of the variance after the effects of implicit knowledge was removed. Overall, implicit knowledge, cognitive flexibility and complement mastery contributed unique variance to predicting explicit false-belief understanding.

Study 3

The predictive looking task set up in Studies 1 and 2 involved live experimenters fiddling about

with the cardboard house and dolls in front of the child. It is possible that the timing and accentuation of events was not as rigorously controlled as it would be with a fixed video. It is important to re-examine anticipatory gaze while ensuring that all participants witnessed the unfolding of the episodes in the predictive looking task in a time-controlled fashion. Moreover, Study 2 was the only one that included the DCCS measure; it is important to replicate the findings that cognitive flexibility, alongside complement mastery, contributed unique variance to explicit false-belief understanding. A third study was carried out where Ruffman et al.'s (2001) predictive looking task was staged and filmed first and only then played back on a monitor to all participants. This change ensured that the timing and accentuation of events to elicit eye gaze was rigorously controlled for all participants. This study again included standard measures of explicit false-belief understanding together with the complement mastery and DCCS tasks. It was predicted that eye gaze would not be correlated with complex language and that cognitive flexibility and complement mastery would contribute unique variance to the prediction of explicit false-belief reasoning.

Method

Participants. New data came from 42 participants: twenty-one 3-year-olds ($M = 3.4$, SD = 3.78 months, range = 3.0–3.10; 13 girls and 8 boys) and twenty-one 4-year-olds ($M = 4.5$, SD = 2.79 months, range = 4.1–4.10; 9 girls and 12 boys). A total of 46 children were tested but three 3-year-olds and one 4-year old were not included in the final analysis as they failed to answer control questions in the false belief tasks correctly.

Procedure. Participants were individually tested in a quiet room at their kindergarten, and all took part in four 10- to 15-min sessions spaced about 1 week apart from each other. Tasks were in the same order as in Studies 1 and 2. Except for two methodological changes, Study 3 replicated the tasks used in Study 2.

First, with respect to the predictive looking task, the only difference was that the episodes in the gaze task (for false- and true-belief trials) were enacted and filmed, and the digitized film clips with accompanying audio track were then played back to children on a 15.4-in. (diagonal) monitor. The film clips were digitized into mpeg formats such that most of the screen was filled upon playback—this ensured that the correct and incorrect locations in the false- and true-belief stories were mapped toward either ends of the monitor. At least to a certain extent, then, the linear conditions of observing the screen was maximized to ensure that the whites of participants' eyes would produce strong contrast with the pupils upon looking left or right. In this way, steps were taken to ensure that anticipatory eye gaze patterns were, as much as possible, straightforward to interpret and analyze. Each participant sat in front of the computer monitor (on a table) and a camera was placed above it to record eye gaze. One rater coded all recordings of the false-belief trial in slow motion and scored gaze direction on a frame-by-frame basis (all participants passed the true-belief control predictive looking trial). Another rater coded 20% of the videotapes, and raters agreed 100% of the time as to whether or not the child was looking more to the correct location.

Second, for the explicit false-belief battery, the thought-bubbles and object-hiding tasks were not used; Study 2 showed that those tasks mapped onto standard measures of direct false-belief reasoning. Following Study 1, then, only single trials of the standard M&Ms, sponge-rock, and Sally-Ann false-belief tasks were administered. Correct verbal answers on the direct test questions based on the contexts of unexpected contents, deceptive appearance, and change in location each contributed a subtotal of 2 points to explicit false-belief knowledge; this yielded a combined maximum score of 6 for each participant ($\alpha = .70$).

Results and Discussion

Eye gaze. Replicating Study 2, significantly more children showed correct first looks ($N = 37/42$) than expected by chance based on the binomial distribution ($p < .001$). There were no significant age group differences for the amount of time spent looking at the correct or the incorrect location (see Table 1). As in Studies 1 and 2, children still spent a longer total amount of time looking at the correct location ($M = 1.87$ s) than the incorrect location ($M = 0.63$), $F(1, 41) = 60.14$, $p < .001$, $\eta_p^2 = .60$. There was also a significant link between accurately gazing in anticipation of a character's mistaken belief and giving a correct verbal answer for the explicit false-belief question, $\chi^2(1, N = 42) = 4.68$, $p < .05$, Cramer's $\phi = .33$. Nineteen children (45%) passed eye gaze and correctly answered the single explicit false-belief question while 5 children failed both (12%). However, 43% ($n = 18$) of children passed eye gaze while erring on their verbal responses to the explicit false-belief question, but no participant showed the reverse relation. Beyond eye gaze, group differences on the remaining measures of interest also replicated the findings of Study 2 (see Table 1).

Correlations and hierarchical regressions. Full bivariate and partial correlations are reported in Table 2 (second row, below diagonal). As in Study 2, when the effects of chronological age and general developmental abilities were controlled, explicit false-belief reasoning was related to eye gaze, cognitive flexibility, and complement mastery. Anticipatory eye gaze continued to show no significant correlation with complement mastery. Cognitive flexibility and complement mastery remained correlated during full partial correlation analysis. Following analyses in Study 2, two hierarchical regressions were conducted to clarify whether implicit (gaze) knowledge, alongside cognitive flexibility and complex syntactical understanding contributed unique variance to the prediction of explicit false-belief reasoning (see Table 5).

In the first regression analysis, PPVT performance was a significant predictor at Step 1, and accounted for 30% of explicit false-belief variance. Implicit knowledge and cognitive flexibility contributed uniquely to explicit false-belief variance after effects associated with age, PPVT performance, and nonverbal reasoning on the Matrices were jointly removed. They accounted for a further 18% and 7% of the variance, respectively. Interestingly, in Step 3 when all variables were considered in the first regression, PPVT performance no longer contributed unique variance to predicting explicit false-belief scores. General lexical knowledge via the PPVT may have predicted explicit false-belief performance at Step 1 because, on some superficial level, those verbal theory-of-mind tasks require some level of language ability (e.g., Chandler, Fritz, & Hala, 1989). However, the PPVT taps not only into word knowledge but also discourse semantics (e.g., words have a labeling function). Jacques and Zelazo (2005) explained that labeling can also help theory-of-mind performance by facilitating cognitive flexibility, which in turn promotes higher level consciousness in thought and control over explicit false-belief attribution. They also posited that

understanding the arbitrary and symbolic nature of labels themselves could allow for psychologic distancing, which in turn promotes cognitive flexibility. Either way, the effects of semantic ability (lexical and discourse semantics) via the PPVT for explicit false-belief performance may be partly because of effects on cognitive flexibility. This may explain why PPVT scores were no longer significant once cognitive flexibility performance was entered at the final step of the regression. At the final step of the second regression analysis, complement mastery significantly accounted for 12% of the variance after the effects of implicit knowledge was removed. Even when all variables were considered, implicit knowledge continued to uniquely predict explicit false-belief understanding.

General Discussion

According to de Villiers (2000, 2004, 2005), the structural properties of tensed complement syntax provide the critical breakthrough format that allows false-belief understanding. Embedded within this view are the related claims that children's nonverbal and verbal false-belief task performance pattern after each other in their dependency upon complement mastery and that children are not likely to demonstrate any false-belief reasoning that is fugitive from linguistic propositional representation. Fitting with previous research (e.g., Milligan et al., 2007), Studies 1–3 revealed a significant relation between complement mastery and false-belief understanding. However, the current findings go beyond extant research by revealing that the relation is only evident for tasks that directly ask children to make false-belief decisions and not for tasks that indirectly elicit false-belief understanding. These findings elevate theorizing on language and theory of mind by weaving in data on children's implicit and explicit understanding.

Implicit understanding of false belief was confirmed across various analyses of eye gaze: correct first look, longer total looking to the correct location, and in terms of the richer metric of difference in looking time when noise because of fixations at the incorrect location was removed. Despite the relatively course-grain analyses of eye gaze, the findings follow suit with an accumulating number of studies showing that looking behavior can provide important information about distinctions between implicit and explicit knowledge (e.g., Clements & Perner, 1994; Onishi & Baillargeon, 2005; Ruffman et al., 2001; Southgate et al., 2007; Surian et al., 2007). The use of formal automatic eye-tracking technology to measure gaze fixation on well-defined points could expand the scope of analysis on the grade of implicit knowledge being tapped as a function of exact ocular spatiotemporal trajectories. Nonetheless, the present investigation provides important evidence that anticipatory looking is implicit in a new sense: Complement mastery is not correlated with gaze performance, and complex syntactical understanding is only correlated with direct false-belief performance. These results were replicated across three studies with larger sample sizes and when the predictive looking task was presented as a film to remove timing confounds. The dissociation signature whereby grasp of complementation structure relationally impacts on one form of knowledge but not another is evidence for separate implicit and explicit representational systems.

In Study 2 where other less verbal false-belief tasks such as object hiding and thought bubbles were included, the pattern of findings replicated Schick et al.'s (2007) work showing a significant relation between responding on these kinds of tasks with complement mastery. While anticipatory gaze performance was correlated with object-hiding and thought-bubbles false-belief scores, eye gaze on the predictive looking task still did not correlate with complement mastery. Performance on those low-verbal false belief tasks was, however, strongly correlated with verbal answers provided for traditional false-belief tasks (i.e., change in location, unexpected contents, and deceptive appearance). It seems that nonverbal false-belief attribution patterns after direct or verbal answers only insofar as they tap into explicit theory of mind understanding (Ruffman, 2000, 2004).

In the present investigation, there was no significant difference between 3- and 4-year-olds' implicit false-belief knowledge as tapped by the predictive looking task. The issue of whether implicit knowledge, despite its earlier manifestation, should show ontogenetic maturation is a gnawing one. If the present investigation had studied a wider age range (e.g., included 2-year-olds), there may be significant group differences in the extent of implicit knowledge as tapped by the usual predictive looking task, and the difference in looking time variable may even then correlate with chronological age (e.g., Clements & Perner, 1994; Ruffman, 2000). Gradual change in implicit knowledge may also be suggested when we consider children's performance on a variety of indirect false-belief tasks. For example, 15-month-olds show implicit false-belief sensitivity via the violation-of-expectancy methodology (e.g., Onishi & Baillargeon, 2005), and 2-year-olds show implicit false-belief sensitivity when the predictive looking task is simplified by completely removing the target object from the scene (e.g., Southgate et al., 2007). It is possible that children may be building up implicit representations of false belief with a greater number of processing units and stronger connection weights, as embodied in a neural network, and the different types of indirect false-belief tasks may necessitate different grades of implicit network representation.

Mechanismwise, implicit knowledge could develop in part through statistical pattern learning. Children may detect regularities across events where people often successfully locate objects where they last put them. Across most events, these regularities work well, but occasionally children may be confronted by actions where people look for objects in the wrong place. Other inferential systems such as goal or intentional tracking could potentially help parse these actions and contexts so that an implicit false-belief interpretation is discerned over event irregularities where people end up going to look for an object not where it necessarily is. Also, because such events are less common compared to people successfully looking for objects where they currently are, it takes time for implicit false-belief knowledge to be built up with sufficient network complexity (Clements et al., 2000). Consequently, there will be phases in knowledge construction whereby young children show fragile anticipatory gaze, and also phases where young children may show dissociation in false-belief understanding at the levels of spontaneous visual orienting and verbal judgment. Further detections of exceptions to behavioral regularity may result in a state of cognitive disequilibrium that critically pushes systemwide integration of all extant knowledge representations into a higher order format that supports conscious and verbally correct false-belief judgments. Such a theoretic possibility could potentially explain why, as found in Studies 2 and 3, explicit false-belief understanding also correlated significantly with flexibility in handling higher order rules that is partly tapped by the DCCS. Of course, the current data on early implicit false-belief understanding in 3- and 4-year-olds cannot decisively arbitrate on whether the basis of such rudimentary knowledge should be viewed as constructivist and hard-won or nativist in origin. One could instead argue that the high accuracy in first look reflects a modular theory-of-mind mechanism (e.g., Leslie et al., 2005). Leslie et al. (2005) also view the theory-of-mind mechanism to be assisted by its own on-board selection processor that inhibits true-belief suggestions. As young children have limited inhibitory control, they may automatically self-correct in looking between the correct (false belief) and incorrect (true belief) locations, leading to variation over the difference in looking time metric, as was found here. To the extent that an early rudimentary understanding of false belief might be supplied by a modular mechanism, and basic recognition is progressively made explicit through intersections with higher order systems of language and aspects of executive control, there is overlap between constructivist and nativist discussions of the current findings.

Reiterated rounds of internal redescription of implicit knowledge yielding stronger representations of explicit knowledge may come about when children engage in cognitive flexibility over the course of problem solving (Karmiloff-Smith, 1992; Zelazo, 1994). Replicating previous work (e.g., Frye et al., 1995; Müller et al., 2005), Studies 2 and 3 revealed that DCCS performance was positively correlated with composite explicit false-belief performance. This association could have partly come about through cognitive flexibility in constructing an explicit higher order conditional if-if-then rule helping to embed different perspective settings so that conflicting knowledge can be accurately applied. For instance, in the object-hiding direct false-belief task, embedded conditionals might be: if friend turned around (Setting 1), and if she indicated to the object being here, then predict that object is there; but if friend kept observing (Setting 2), and if she indicated to the object being here, then predict that object is here. The result that complement mastery also predicted explicit reasoning could be interpreted to dovetail with Zelazo and colleagues' broader view that complex language may potentially off-load cognitive flexibility for explicit false-belief reasoning (e.g., Jacques & Zelazo, 2005; Müller et al., 2005). It is possible that cognitive flexibility over explicit false-belief reasoning may be more effective if rules are carried out in linguistic formulations; discursive thought may create richer psychologic distance, thereby helping children explicitly understand that perspectives (and rules) are arbitrary or necessarily representational. Rule talking one's way through false-belief problems could also bring out explicit thinking indirectly via the effect of linguistic formulations making psychologic perspectives an object of consideration.

However, we need to carefully consider the implication that mastery of complement syntax per se also predicted children's explicit false-belief reasoning scores. Indeed, in interpreting the correlation between DCCS performance and complement mastery found in Studies 2 and 3, it is difficult to think of how preschoolers could have solved the memory for complements task by necessarily using if-if-then propositional language. Proficiency in hierarchical rule use, as partly tapped by the DCCS task, could provide for accurate conscious false-belief problem solving, but only within limits. Preschoolers could also explicitly compare two representations of a situation through syntactic constructions involving a single verb of belief and an embedded tensed complement (e.g., "Sally thinks *the ball is in the basket*"). In the same way, for the object-hiding task in Study 2, preschoolers could explicitly recognize perspectives and make an accurate judgment when they verbally formulate the communicator's signal as "the friend says (indicates)/thinks *the object is there.*" Understanding richness of minds may also be partly explicated using communication and mental state verb-complement constructions. Nonetheless, there is still the question of how precisely cognitive flexibility and complement mastery might come to developmentally interface or intersect to underpin explicit false-belief understanding. One modest interpretation of the current results may simply be that linguistically mediated thought involving diverse syntactic constructions at different levels of analysis (e.g., from pruned complements to if-if-then rules) is partly responsible for conscious flexibility in shifting from one response perspective to another (e.g., Carlson, 2003; Smith, Apperly, & White, 2003).

The empirical finding that complement mastery was uniquely related to explicit false-belief understanding raises a further thorny issue: Even though participants were not invited to consider the motives of the false utterance, the misstatements in the complements tasks potentially involve misrepresentation of an actual state of affairs. Complement mastery and explicit false-belief reasoning may be correlated because they both involve misrepresentation (as opposed to a more specific role for complex syntax per se). The complements tasks could even be viewed as a simplified (but explicit) measure of false belief. It will be crucial to develop other viable analogs of the complement mastery task to delineate the extent to which it is the implications of certain syntactic constructions that partly lead children to explicitly understand differences in minds. The development of implicit measures (e.g., capitalizing on looking time) could open up investigations as to whether young infants and preschoolers may show nascent sensitivity to how a false proposition can be legally attached to a verb of communication. In doing so, we stand to discover whether an implicit understanding of complement syntax may be related to an implicit understanding of false belief. Finally, we need to test children on multiple measures of indirect theory-of-mind tasks that also include controls for confounds because of associative encoding (e.g., Surian et al., 2007)—higher reliability from composite scores of implicit false belief may uncover whether there are weak, but significant, correlations between rudimentary false-belief knowledge and complement mastery. Overall, it will be important for future research to discover how early implicit understandings that intertwine the beginnings of theory of mind and language acquisition metamorphosize into more explicit knowledge (Astington, 2005).

In conclusion, a richer understanding of children's theory of mind will require collaborative efforts that use multiple methods, theories, and levels of analysis to illuminate how children's conceptual representations may be differentiated and integrated along the implicit–explicit continuum. Explicit false-belief understanding was directly underpinned by unique implicit false-belief knowledge as tapped by anticipatory eye gaze. This finding is important because it means that the causal role of complex language in the development of false-belief reasoning does have to be constrained, to refer not to any reasoning but only to explicit answering. Indeed, aside from preschoolers being able to operate on the basis of automatic implicit knowledge, explicit verbal false-belief responding was also multiply supported by complement mastery and cognitive flexibility. Generally, to the extent that explicit false-belief understanding is open to input from language and higher order systems of executive control, the current findings on distinctions between implicit and explicit false-belief reasoning have significant empirical and theoretic fit with different levels of analysis interested in how growth in reflection makes possible significant cognitive advances. While the answers uncovered in this investigation turned out to be fairly complex, integrative work of the kind attempted here serve as an important start to answering questions on how representational changes in mental state understanding develop as a function of intersections between language, cognitive control, and early core knowledge.

Bridging Theory of Mind and the Personal Domain: Children's Reasoning About Resistance to Parental Control

Kristin Hansen Lagattuta
University of California, Davis

Larry Nucci
University of California, Berkeley

Sandra Leanne Bosacki
Brock University

Four-, 5-, and 7-year-olds ($N = 60$) listened to vignettes featuring characters that wanted to do actions that conflicted with parental rules. Desires included behaviors associated with the personal domain: friend, activity, and clothing choice. Scenarios involving moral rules served as a comparison. Children predicted and explained characters' actions and emotions. Results showed significant increases between 4 and 7 in judgments that characters would comply with rules and feel good, but only for situations involving moral rules. Children frequently predicted that characters would disobey rules that intruded on the personal domain and would feel positive emotions following noncompliance, especially when activities were essential to that character's identity. Findings are discussed in relation to the development of self and personal control.

Young children frequently confront situations where they really want to do something, but their desire conflicts with parental or societal rules. The ability to inhibit personal impulses to abide by rules and norms comprises a major developmental achievement and a central component of moral development (Kochanska & Aksan, 2006; Thompson, Meyer, & McGinley, 2006). Piaget (1962) referred to the affective conflicts that arise between moral duty and desire as the ''problem of will.'' Such acts of willpower pose a difficult challenge for young children, who have less developed inhibitory control (Zelazo & Mueller, 2002) and who generally view positive emotions as resulting from desire fulfillment and negative emotions as caused by not getting what one wants (Harter & Whitesell, 1989; Stein & Levine, 1989; Wellman & Banerjee, 1991). Indeed, studies show that children younger than 7 years of age typically fail to recognize that people can experience positive emotions after inhibiting desires to abide by rules or that people can feel negative emotions after breaking rules to get what they want (Arsenio & Lover, 1995; Keller, Lourenço, Malti, & Saalback, 2003; Lagattuta, 2005; Nunner-Winkler & Sodian, 1988).

This developmental shift from 4 to 7 years in judging that rule breakers feel good to an appreciation that rule breakers can experience negative emotions is considered a significant advance in children's sociomoral reasoning, and it has been widely replicated in the United States and abroad (see Arsenio, Gold, & Adams, 2006). This transition also marks an important coordination between children's understanding of ''mental life'' or ''theory of mind'' and their reasoning about morality and societal norms (Lagattuta, 2005). That is, a core feature of everyday folk psychology is that desire motivates action: Getting what one wants feels good and not getting what one wants elicits negative emotions (see Wellman, 1990). Yet, because humans live in social groups, our actions are not only determined by individual desires, beliefs, or goals but also by the rules and norms that govern these social exchanges (Wellman & Miller, 2008). Between the

ages of 4 and 7 children demonstrate increased ability to integrate theory of mind and sociomoral perspectives by more frequently predicting and explaining emotions not only in relation to people's current desires or goals (a theory of mind perspective) but also in relation to rule obligations and to future outcomes for self and others that may result from making particular decisions (see Lagattuta, 2005, 2008).

Importantly, however, moral development not only involves constructing concepts about rules and norms for what one should not do but also identifying actions that people *can* have personal discretion and control over, choices such as what to wear, what activities to do, and what friends to have (Nucci, 1996; Smetana, 2002). Work conducted by domain theory researchers indicates that children begin to identify a personal domain during early childhood through social messages and choices offered by caregivers (e.g., What shirt do you want to wear?), as well as by children's resistance and negotiation with parents over what constitutes their zone of privacy and prerogative (Killen & Smetana, 1999; Nucci & Smetana, 1996; Nucci & Weber, 1995). Because there may be legitimate grounds for disobedience when rules intrude on the personal domain, children may reason about behavioral and emotional responses to personal domain restrictions differently than other kinds of rules. Previous research reporting an increase between 4 and 7 years in judgments of ''feel good compliance'' and ''feel bad transgression'' have only included moral (harm to others), prudential (personal safety), or social-conventional rules (social norms); rules that children view as obligatory and under the jurisdiction of authority and not in the personal domain (see Smetana, 2005).

The distinction made within social cognitive domain theory among morality, convention, and the personal (Smetana, 2005; Turiel, 2002) begs for a more purposeful linkage with research and theory on children's theory of mind. The current study integrates theory of mind and social domain perspectives by investigating how 4- to 7-year-olds reason about people's behavior choices and emotions in situations where they want to do an activity from the personal domain (clothing, activity, or friendship choice), and a parent tells them they should not engage in that action. If children believe that personal domain restrictions can be disobeyed, then we would expect children to infrequently predict that people will comply with rules that govern the personal domain and infrequently judge that compliance with such rules makes people feel good. In explaining their judgments, children should largely provide goal-oriented explanations, focusing on the character's desires and preferences (desire psychology framework). Suggestive evidence comes from Arsenio (1988), who found that 5- to 11-year-olds attributed negative emotions to characters that had been told by teachers to share private information. On the other hand, if young children do not treat the personal domain uniquely when reasoning about how a person will act and feel, then we should replicate the significant increase between 4 and 7 years in predicting that compliance feels good and transgression feels bad found in previous studies featuring moral, prudential, and social-conventional rules.

Investigation into children's reasoning about behavioral and emotional reactions to personal domain restrictions further provides a new approach for examining children's understanding of the importance of the personal domain for self and identity. The differentiation of the personal domain from matters of morality and convention rests on the assumption that the fulfillment of personal desires is psychologically required for the establishment of ''self.'' According to Nucci (1996), the development of a positive sense of agency, self, and personal identity depends on children's ability to stake a claim to a personal area of actions (see also Erikson, 1968). Indeed, adolescents from diverse cultural and socioeconomic backgrounds explain that control over a personal domain is important for establishing and preserving an identity and for having the freedom ''to be oneself'' (Nucci, 1996, 2006; Smetana, 2005). Here, typical procedures involve interviewing older children (8 years+) and adolescents about which matters they feel are under their personal jurisdiction and why. Because these are obviously difficult concepts for young children to articulate in response to such questioning methods, little is known about whether younger children may recognize the significance of the personal domain for the promotion of self and identity.

To assess 4- to 7-year-olds' knowledge about the relation between identity concerns and the personal domain, we created a new methodology informed by developmental research on children's essentialist thinking. According to Gelman (2003), children (and adults) often believe that people, animals, or things are the way they are because of stable and unobservable properties, or essences. Moreover, children and adults expect essentialized qualities of a person to have strong inductive potential. Thus, for example, when 5- to 7-year-old children were presented with a character who really likes carrots, eats them all of the time, and is named a "carrot eater," they overwhelmingly predicted that she would continue to eat carrots in the future even if no one in her family liked carrots and even if her family tried to stop her (Gelman & Heyman, 1999). Nominalized phrases, such as "carrot eater," were particularly powerful in causing children to treat properties as immutable and central to people's identities. Given that even 7-year-olds most often predicted that "carrot eaters" ("creature believers," "guinea pig lovers," "early wakers") would go against their family to engage in actions essential to self supports our hypothesis that children will likely treat personal domain restrictions, especially those that forbid essentialized activities, as less subject to parental regulation than other rules.

In the current study, then, we varied stories featuring personal domain restrictions so that for some trials the currently desired, but forbidden activity was described as *essential* to the character's sense of identity, and for other trials it was described as *peripheral*. Essential stories described the character as doing the activity every day, feeling very good about him- or herself while doing the activity, and naming him- or herself in relation to the activity using a nominalized phrase (e.g., "Gloria the Painter"). In contrast, peripheral stories described the character as doing the activity only some of the time, feeling just OK about him- or herself while doing the activity, and not naming him- or herself in connection with the activity. If young children are sensitive to connections between the personal domain and identity, then they should predict less compliance and less *feel good compliance* when desired activities are described as essential versus peripheral to the character's sense of self. Children should also frequently explain character's behavior decisions and emotions in these personal-essential situations as motivated by aspects of their self or identity (e.g., "Because she likes to X," "Because he always plays with X").

To rule out the interpretation that children may simply respond to the essential condition in terms of the given action's high desirability for the protagonist, we added an additional story type in which the main character wants to commit a moral transgression to participate in the desired activity (e.g., Gloria wants to steal paints so that she can paint a picture). For these moral rule stories, the activity was also described as essential to the protagonist's identity. We predicted that children would less frequently judge that a person would violate a moral rule (e.g., "You should not steal other people's things") to carry out the highly desired essential goal compared to violating a parental directive that invaded the personal domain (e.g., "You should not paint"). These moral vignettes further serve to ground this study in previous research and to provide a direct comparison between reasoning about moral rules and personal domain restrictions. That is, whereas we expected that predictions of compliance and feel good compliance for the personal domain stories (especially the essential subtype) would remain low over age, these responses would significantly increase for trials featuring moral rules. We further predicted that children would more often cite moral-evaluative concerns (about behaviors being good, bad, right, or wrong) as well as potential future consequences for self or others when explaining character's decisions and emotions in moral rule situations versus scenarios involving personal domain restrictions.

Finally, because some children may never predict that a person would break parental rules, we included personal-essential trials where we explicitly told the participant that the character decided to fulfill his or her desire (e.g., Gloria decides to paint a picture even though her mom said she should not paint). We asked participants to explain why the character made that choice as well as to predict and explain his or her emotions. We added additional questions about whether the child had broken a rule, whether it was OK or not OK to have made that decision, and how the protagonist would feel if he or she never got to participate in that activity ever again. We hypothesized that all age groups would understand that rules had been broken and that the character would feel bad if he or she was forbidden from ever participating in a desired activity. We further predicted that there would be an age-related increase in judging that disobeying personal domain restrictions could be legitimate or "OK" to do. To avoid priming children to consider the legitimacy of rule violations, these explain disobedience trials appeared at the end of the session.

In summary, then, the current study conjoins theory of mind concerns with understanding the development of young children's conceptions of self and others as psychological beings with domain theory distinctions between morality and the personal domain. Children were presented with scenarios featuring a child protagonist who wants to engage in an action that violates a rule stated by a parent. Trials varied by whether the rule governed the personal (clothing, friendship, activity choice) versus moral domain (hitting, stealing), and by whether the desired activity was described as essential versus peripheral to that character's identity. We targeted 4- to 7-year-olds because previous studies have found significant changes in children's knowledge that transgression can feel bad and compliance can feel good during this age period. We hypothesized that children would treat personal domain restrictions differently because these directives violate claims to individual jurisdiction and control. In addition to examining children's predictions, we analyzed their explanations for why characters made certain decisions and experienced particular emotions. Here, attention was focused on children's provision of goal-, rule-, and future-oriented explanations as well as references to identity or moral-evaluative concerns. This multiple-assessment approach (analyzing predictions and explanations) has been found effective for assessing developmental changes in social reasoning during early childhood (see Lagattuta, 2005; Wellman & Lagattuta, 2000; Wellman & Liu, 2004).

Method

Participants

Participants included 60 children from three age groups: twenty 4-year-olds (M = 4.5 years, range = 4.0–4.92 years); twenty 5-year-olds (M = 5.41 years, range = 5.0–5.92 years); and twenty 7-year-olds (M = 7.44 years, range = 7.0–8.0 years), with equal numbers of males and females in each age group. Four- and 5-year-olds were primarily recruited from a preschool operated by an urban Midwestern university. Seven-year-olds were primarily recruited from a public elementary school from the same geographic area serving families with similar demographics. In total, the sample was 65% European American, 17% Asian American, 15% African American, and 3% Other. Although precise data on parental education and income level were not obtained, the majority of the sample came from middle-income families. Two additional children participated but were replaced due to experimenter error (one 4-year-old) and failure to complete the interview (one 5-year-old).

Design and Procedure

Participants listened to eight stories, each featuring a child protagonist who wants to do a particular action, but his or her desire conflicts with a prohibitive rule stated by his or her mother. Action preferences centered on four behaviors commonly associated with the personal domain (see Nucci & Weber, 1995): wanting to play a *sport* (baseball, soccer), wanting to engage in a *creative activity* (play with Legos, paint), wanting to wear a particular *clothing type* (sparkly clothes, superhero clothes), and wanting to play with a particular *friend*. One story in each content type featured a male central character and the other a female central character. The race and ethnic composition of the story characters matched the sample population. To aid in story comprehension, all vignettes were depicted on colorful 5 × 6 in. laminated pictures.

There were three different story types: *personal-essential*, *personal-peripheral*, and *moral-essential*. Here, the first part of the label refers to whether the prohibitive rule applied to the personal (athletic or creative activity, friendship, or clothing choice) or to the moral domain (stealing, causing physical harm). The second part of the label indicates whether the desired activity was described as essential (a fundamental component) versus peripheral (not very important) to that character's sense of self or identity. Table 1 summarizes the dimensions of each story type.

This experimental design is not a complete 2 × 2 factorial design because the moral-peripheral subtype was excluded to reduce the length of the experimental session and because this subtype was the least interesting from a theoretical standpoint. The two central contrasts of interest were between essential and peripheral versions of the personal domain restriction trials (i.e., in cases of rules infringing on the personal domain, does it matter whether the currently desired activity is essential vs. peripheral to one's sense of identity?) and between moral versus personal domain restriction versions of the essential core trials (i.e., when an activity is essential to one's sense of identity, does it matter whether the potential rule violation pertains to the moral vs. personal domain?). Note that for both personal domain restrictions and moral rules, the mother did not provide a reason for forbidding the activity. This allowed measurement of children's baseline judgments about people's behaviors and emotions in situations where parents do not provide explicit justifications for rules.

Personal-essential stories. For personal-essential stories, the desired activity was described as a fundamental core to the character's sense of identity and daily routine. Several approaches were used to convey this essential quality: The characters were

Table 1
Summary of Story Type Dimensions

Story type	Identity relevance: Essential	Identity relevance: Peripheral	Rule domain: Personal	Rule domain: Moral
	• Daily participation • Feels very good about self when engaging in the activity • Names self in relation to the activity	• Occasional participation • Feels OK about self when engaging in the activity • No naming	• You should not wear X clothes • You should not do X (activity) • You should not play with X (friend)	• You should not push or hit • You should not take other people's things
Personal-essential[a]	√		√	
Personal-peripheral		√	√	
Moral-essential	√			√

[a] As described in the Method section, personal-essential was the only story type that had two types of questioning: (a) predict-and-explain and (b) explain disobedience. The other two story types only had predict-and-explain questioning.

described as doing the activity everyday, naming themselves in relation to the activity by using a nominalized phrase (e.g., "Gloria the Painter"), and feeling very good about themselves when engaging in this activity. These components were informed by empirical findings in the essentialism literature (e.g., Gelman, 2003; Gelman & Heyman, 1999) showing that young children interpret this kind of phrasing and lexicalization as indicating immutable, stable, and central aspects of identity.

For example, as shown in Figure 1 (top left), "Gloria likes to paint pictures. She paints pictures almost every day. In fact, Gloria thinks of herself as 'Gloria the Painter.' 'Gloria the Painter' thinks she creates great pictures and that makes her feel happy about herself." The essential labels for the other stories included: "Max the Lego Builder," "Carlos the Baseball Player," "Linda the Soccer Player," "Sarah the Sparkle Princess" (girl who likes to wear sparkly clothes), "John the Superhero" (boy who likes to wear superhero clothes), "Amy the Best Friend," and "Tom the Best Friend."

For this story type, the central character was shown smiling and engaging in the activity in Card 1. Card 2 showed a four-square grid of the character smiling and participating in that activity four different times. For sport stories, Card 2 displayed the character playing that sport on four different occasions; for clothing choice, Card 2 showed the character wearing that type of clothing four different times; and for friendship choice, Card 2 depicted the character playing with the same friend on four different occasions (the friend had a distinctive hat or hair bow).

In the final scene of the personal-essential stories (see Figure 1, bottom row), the character wants to engage in the desired action, the mother states a prohibitive rule, and then the mother leaves the scene and the protagonist thinks about what to do. For example, "Well, the next day, Gloria needs to find something to do. Right now, Gloria wants to paint pictures but her mom says, 'Gloria, you should not paint pictures!' Gloria's mom leaves the room. Gloria decides what to do next." Picture Card 3 showed the main character and the mother-facing profile toward the desired activity (e.g., the easel with paper and paints). For the final scene, the mother cutout was lifted off of Card 3 so the protagonist was featured alone in the scene.

Personal-peripheral stories. Personal-peripheral stories described the character as participating in the particular activity only infrequently and as feeling just "okay" when engaged in that activity. For these stories, the character also did not name him- or herself in relation to the activity (e.g., Gloria is just referred to as "Gloria" not "Gloria the Painter"). Here, the aim was to establish that the character did not typically engage in the activity because it was not a stable, core, aspect of his or her identity.

For example, as shown in Figure 1 (top right), "Gloria likes to paint pictures some of the time. But most of the time she does other things. Gloria thinks she paints okay pictures and that makes her feel okay about herself." For this story version, Card 1 displayed the central character standing and smiling (not engaged in the desired activity) and Card 2 showed the character engaged in the targeted activity one time with a neutral expression and smiling while participating in three other activities (e.g., reading, swinging, walking). Card 2 for sport stories featured three other sport-related activities (swimming, kicking a ball, jump rope),

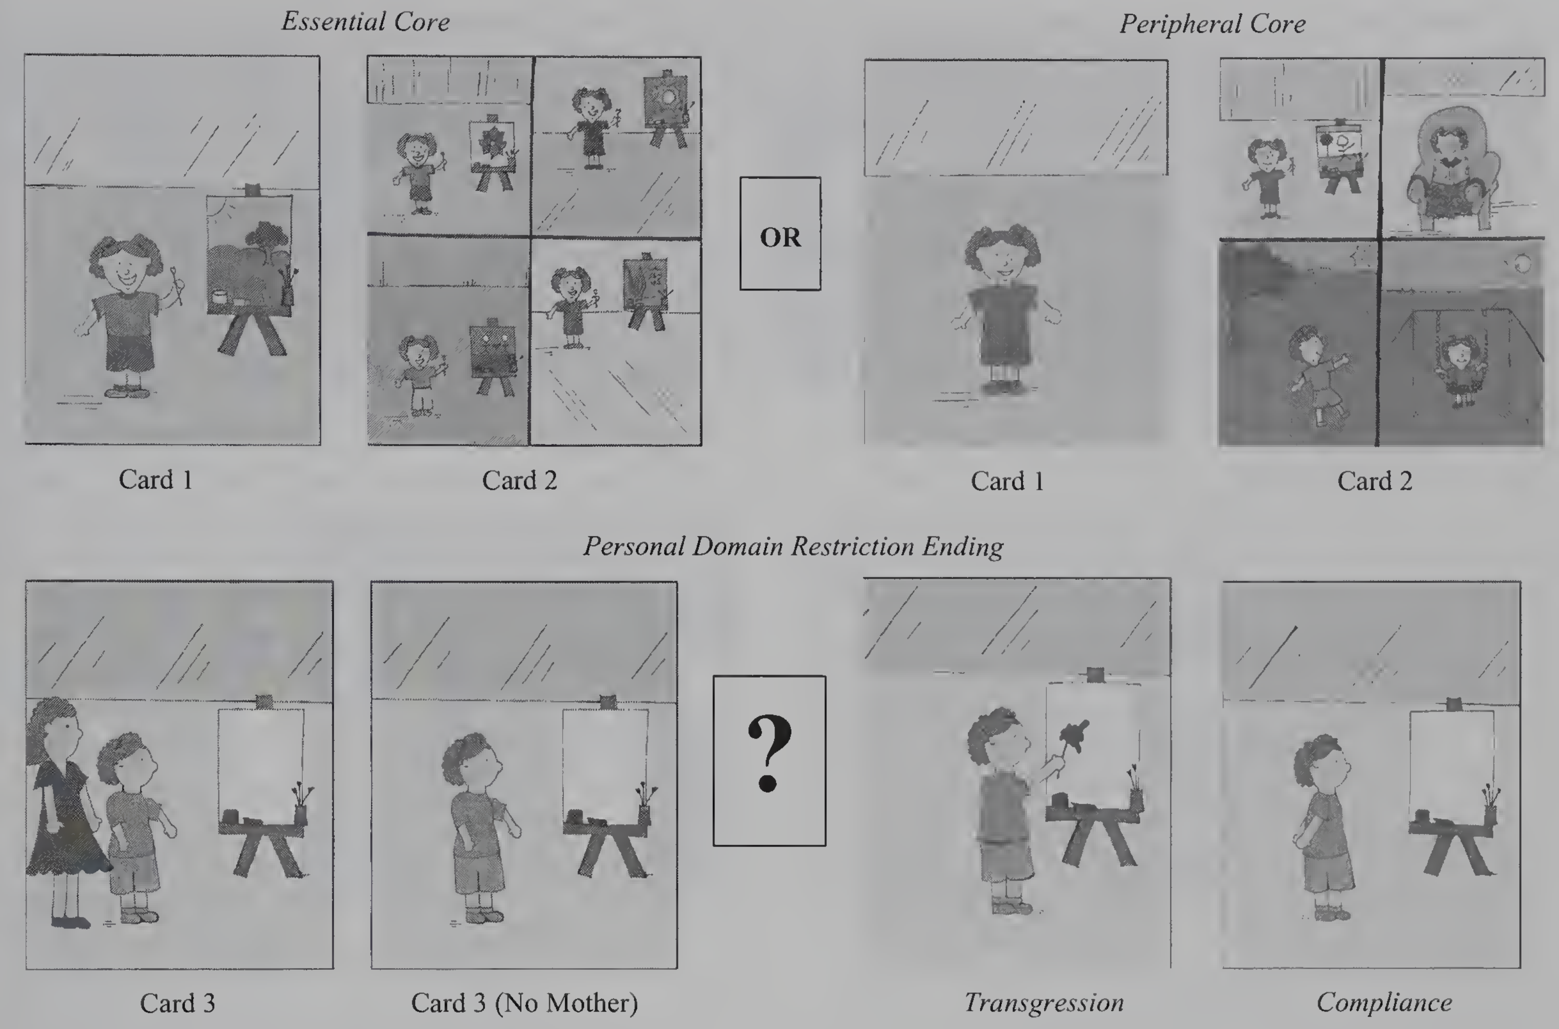

Figure 1. Example illustrations for a personal domain restriction story.

Card 2 for clothing choice stories featured the character wearing three other outfits, and Card 2 for friendship choice stories showed the protagonist playing with three other friends.

The final scene and story cards for the personal-peripheral stories were identical to that of the personal-essential stories (see Figure 1, bottom row).

Moral-essential stories. As described, moral-essential stories were created as a contrast to the personal-essential story versions. Of interest was whether young children would predict that in cases where the character identified very strongly with the activity choice he or she would even break moral rules (victimize other people) to fulfill his or her desire. Thus, moral-essential stories started with the identical essential core of the personal-essential stories. What differed was the rule type in the final scene. In the final scene, the central character wants to break a moral rule (steal or hit) to engage in the desired activity. For example as shown in Figure 2, ''Well, the next day Gloria needs to find something to do. Right now, Gloria wants to grab away her brother's paintbrush and paints so she can use them, but her mom says, 'Gloria, you should not take away your brother's paints!' Gloria's mom leaves the room. Gloria decides what to do next.'' Again, as with the personal domain restriction stories, the central character and the mother are shown in the profile in Card 3 and then the mother card was removed.

For the moral-essential stories featuring stealing as the moral rule (clothing, creative activity), the potential victim was always shown from behind in Card 3 with the desired belongings situated next to or behind him or her. For moral-essential stories featuring the desire to hit (friendship, sports), the potential victim was shown telling the main protagonist that he or she cannot play. In these cases, the protagonist wants to ''push/hit the boy/girl hard so he/she can play [soccer/baseball/with a best friend]'' and the mother states, ''You should not push/hit.'' For example, the Tom story read, ''Well, the next day at the park Tom sees another boy playing with Mark [who was previously described as Tom's best friend]. The boy says, ''Go away, Tom, you can't play!'' Right now, Tom wants to push the boy hard so he can play with Mark, but

Tom's mom says, "You should not push other people."

Questioning

Control questions. Several control questions assessed young children's ability to follow the premises of each story. Three control questions—*preference, self-evaluation*, and *self-relevance*—followed the initial core of each vignette where the experimenter described details about whether the desired activity was essential versus peripheral to that character's identity. More specifically, children were asked, "Does [character] like to [action] all of the time or only sometimes?" (preference) and "Does [character] feel just okay or happy about himself/herself when she is [action]?" (self-evaluation). For these two questions, the order of the response choices (e.g., all of the time vs. sometimes) was counterbalanced across trials.

Children were also asked, "How important do you think [action] is to [character]?" (self-relevance). To answer this question, children were shown a vertical 5-point Likert-type pictorial scale, with a series of yellow stars ranging in graduated size from ½ in. (bottom) to 2 in. in diameter (top). To ensure that each child understood the meaning of the scale points, familiarization with the star scale was done prior to the testing session. Specifically, children were told,

> "During my stories, we will use this star scale. You can use these stars to tell me how important you think things are to the kids in the stories. Let me show you how it works. Please tell me something you really like to do—something that means a whole lot to you. [child responds] Great! You really like X it means a lot to you—it is really important to you. So, let us point to the biggest star. [child points] Great! Now, tell me something you only like to do a tiny, little bit; something you do not care much about. [child responds]. OK! You only like X a tiny bit, it does not mean much to you—it is only a tiny, little bit important. So, let us point to the smallest star. [child points]. Great! Well, I like to go swimming sometimes—I do not care a whole lot about swimming, so it would not be the biggest star (point to the biggest star), but swimming is more than just a tiny, little bit important to me, so it would not be the smallest star (point to the littlest star). I think it is medium important to me, so I am going to point to the middle star (points to middle star)."

Also, each time the experimenter asked the self-relevance control question during testing, she reminded the child of the two scale anchors: "Remember, the biggest star means it is really, really important, and the littlest star means that it is only a tiny, little bit important."

For all story types, children were explicitly told the character's current desire (e.g., "Gloria really wants to paint pictures") and the prohibitive rule (e.g., "Gloria's mom says, 'You should not paint pictures'"). To verify that children followed this key information, the *rule* ("What rule does his/her mom say?") and *desire* control questions ("What does X want to do?") were asked in counterbalanced order across trials prior to the final scene.

Predict-and-explain test questions. At the conclusion of each story for the first six trials (two personal-essential, two personal-peripheral, two moral-essential), children were asked to predict and explain the character's *action decision*. They were provided with two forced-choice options: One action decision fulfilled the character's immediate desire (*transgression*) whereas the other action decision conformed to the parental rule (*compliance*). Picture cards illustrated each response choice. In these picture cards, characters were shown profile so that no emotion expression could be discerned from their face. As with Lagattuta (2005), willpower/compliance actions depicted the protagonist with his or her hands behind his or her back to show clearly that the character had decided not to engage in the prohibited activity.

As shown in Figure 1 (bottom right), for the Gloria personal domain restriction versions, children were asked, "Do you think Gloria will paint a picture or leave the paints alone?" As shown in Figure 2 (bottom row), the action decision test question for the moral rule version of the Gloria story asked, "Do you think Gloria will take her brother's paints or leave them alone?" The response choice options (e.g., paint a picture vs. leave the paints alone) were counterbalanced across story trials. Once the child chose an action decision, that card was placed in the story line to complete the sequence. The other response card was discarded. Next, the experimenter asked the child to explain the reason for the decision, for example, "So, Gloria chooses to X [child's response], why do you think Gloria chose to X? What was she thinking?" Because we were primarily interested in children's reasoning about what was going on inside the characters' minds, we only questioned participants about what the characters *would* do, not what they *should* do in that situation.

Final test questions for the predict-and-explain trials focused on the character's emotional response to the decision to fulfill his or her desire versus comply with a rule. Following Lagattuta (2005), children were asked a *primary emotion question*, for example, "How does Gloria feel right now, when she is [action]? Does she feel good or feel bad?" The order of the response choice was counterbalanced across story trials. The experimenter then asked the child to explain the reason for the emotion, as in, "Why does Gloria feel X?" Finally, children were asked the *secondary emotion probe*, "Could Gloria be feeling anything else right now, or just X? Why?"

Explain disobedience test questions. For the last two trials of the testing session, children were given two additional personal-essential stories. For these trials, instead of asking children to predict the character's action decision, the experimenter *told* participants that the character decided to fulfill his or her desire and then asked participants to explain why (the transgression decision card was added to the end of the story). Children were then asked to predict and explain the character's emotions following the same procedures as the predict-and-explain trials (i.e., the primary and secondary emotion probes). These explain disobedience trials focused on personal-essential stories because of our central interest in children's reasoning about situations where disobedience may indeed be legitimate. That is, the inclusion of these trials ensured that each child had, at minimum, two opportunities to explain acts of rule violation and to predict and explain emotions following noncompliance in situations where rules violated the personal domain and the desired action was essential to identity.

Three additional test probes were also included in the explain disobedience trials to gather additional information about how children reasoned about *rule violations* ("Did X follow his/her mom's rule or not follow it?"), *rule legitimacy* ("Do you think it was okay or not okay for [Gloria to paint a picture]?"), and *emotions* ("How do you think X would feel if he/she never, ever got to [paint] again?"). These probes were not included in the initial six predict-and-explain trials because we did not want to influence children's responses by calling attention to issues of the legitimacy or acceptability of different kinds of rules.

General Procedure

Participants were interviewed individually in a quiet room by a female experimenter after informed consent was provided by the university research ethics board, school authorities, and the child's parents. Before the interview began, the experimenter also asked children to provide verbal assent. Each participant received a total of eight story trials: six predict-and-explain trials (two personal-essential, two personal-peripheral, and two moral-essential) followed by two explain disobedience trials (personal-essential). To maximize children's comprehension of the peripheral versus essential story premise, the experimenter repeated the relevant story element(s) if children made any errors in their responses to the control questions. For example, if the child stated that a character in a peripheral version of a story liked to engage in the activity ''all of the time'' they were reminded both verbally and via pointing to the story pictures that the character did it ''only sometimes.'' The procedure lasted approximately 30 min.

Due to the repeated measures design, several measures were taken to control for potential order effects. Personal-peripheral trials always appeared as the first two trials because these were the only trials where the character had a peripheral interest in the desired activity (all other trials had the essential core). Initial pilot testing revealed that children attended less to the unique premise of the peripheral versions when they appeared after the essential story versions. The presentation of the moral-essential and personal-essential predict-and-explain trials (trial order 3–6) was counterbalanced, with each story type appearing equally in each trial order slot, and with trials of the same story type (e.g., moral-essential) never appearing consecutively. No participant received more than one trial of a story type with the same desire focus (e.g., receiving both the ''sparkly clothes'' and ''superhero clothes'' stories for the two personal-peripheral trials). Finally, all specific stories + ending types (e.g., Gloria moral-essential) appeared equally for each age group. Twenty unique order combinations were created, with one version randomly assigned to each participant in each age group. As stated previously, all forced-choice response options for control questions and test questions were counterbalanced across trials so that children with a response bias to pick the first or second option would respond at chance.

Coding of Explanations for Decisions and Emotions

Trained undergraduate research assistants independently coded the behavior and emotion explanations from verbatim written transcripts of the experimental sessions. Coders were blind to participant-identifying information. Behavior and emotion explanations were categorized into three main categories following criteria by Lagattuta (2005): *goal oriented*, *rule oriented*, and *future oriented*. Cohen's Kappa based on 75% of the transcripts was high, $\kappa = .96$.

Goal-oriented explanations fit within a theory of mind, desire psychology framework. They explained the behavior or emotion as caused by the character's personal goals or desires (e.g., ''Because she wanted to do what she wanted to do,'' ''Because he wanted to wear his superhero clothes''). Rule-oriented explanations followed more of a sociomoral perspective. They explained the behavior or emotion as caused by adherence, failure, or obligation to follow the rules (e.g., ''Because he listened to his mom,'' ''Because she broke the rule''). Finally, future-oriented explanations explained the emotion or behavior as caused by a potential future outcome or consequence (e.g., ''Because his mom will get mad,'' ''Because she could have hurt that girl if she pushed her''). Future-oriented explanations cross-cut theory of mind, social domain theory, and self perspectives in that they provide insight into children's reasoning about how a person's decisions and emotions in the here-and-now are influenced by his or her expectations for how those actions will impact the self or another person in the future (see Atance & O'Neill, 2005; Lagattuta, 2005, 2007, 2008). Future-oriented explanations were further coded as to whether they described consequences to the self, another person, or both the self and another person.

There were two additional coding dimensions unique to this study: *identity-related* and *moral-evaluative* explanations (Cohen's $\kappa = .95$). As described, these categories were of theoretical interest because we wanted to examine whether children would: (a) more often refer to aspects of self or identity when explaining how characters would respond to personal domain restrictions versus moral rules and (b) more frequently explain behavioral or emotional responses to moral rules versus personal domain restrictions in relation to how others or the self would evaluate the behavior (e.g., as right or wrong, good or bad).

Identity-related explanations explained the behavior or emotion as caused by the importance of the activity to the character's identity (''Because that's part of who he is,'' ''Because she always does it''), including references to stable attitudes or preferences (e.g., ''Because he loves to play with that friend,'' ''Because she doesn't care about painting''). To be conservative, identity-related explanations excluded simple mentions of the character's immediate desires. Desires, even though self-relevant, do not clearly indicate enduring attitudes. That is, whereas attitudes such as *like, love,* and *hate* (see Heider, 1946) convey dispositional stability (a lasting positive or negative orientation toward something), "wants" are often transitory or situational, and they provide no clear indication that the preference did or will persist over time (Gelman, 2004). Therefore, the explanation "Because she wanted to paint" would not be considered an identity-related explanation; however, "Because she likes to paint" would be coded as such. Moral-evaluative explanations explained the behavior or emotion as caused by an actual or anticipated emotional reaction or moral evaluation by either another person or by the self (e.g., "'Because he thinks it was a bad thing to do," "Because his mom will be really disappointed," "Because stealing is wrong").

As with Lagattuta (2005) explanations could be coded into one or multiple categories. The coding categories were not mutually exclusive. For example, the explanation, "[Gloria feels bad] because her mom said that she wasn't allowed to paint and she really, really wanted to paint a picture," was coded as both goal oriented and rule oriented.

Results

Results are organized into four sections. Preliminary analyses examine children's answers to the control questions regarding the story premises. We then analyze children's responses to the predict-and-explain trials: first their predictions and then their explanations for story character's decisions and emotions. Finally, we analyze children's responses for the explain disobedience trials. Except when otherwise noted, data were analyzed using repeated measures analysis of variance (ANOVA), with the significance level set at $p < .05$. Significant main effects were followed up with Tukey's honestly significant difference (HSD) tests to evaluate pairwise comparisons, with only significant pairwise comparisons among means reported. Simple effects tests examined significant interactions. Partial eta squares (η_p^2) are provided as a measure of effect size for all significant main effects and interactions.

Control Questions

Repeated measures ANOVAs assessed whether children distinguished the essential core stories from the peripheral core stories. Three story types (personal-essential explain disobedience, personal-essential, moral-essential) had essential cores, whereas one story type (personal-peripheral) had the peripheral core. Scores ranged from 0 to 2 per story type totaling the number of trials children answered each forced-choice question correctly the first time. Correct answers for the essential core stories included: Character liked to do the activity "all of the time" and felt "happy about self" when participating in that activity. Correct answers for the peripheral core stories included: Character liked to do activity "some of the time" and felt "just OK about self" when engaged in that action. For the "how important" question, we averaged ratings for the star scale (from 1 = *tiny, little bit important* to 5 = *very important*) across the two trials of each story type. Preliminary analyses showed that the order of the response options did not affect answer choices. All age groups utilized the 5 points of the star scale, and all participants correctly answered the desire and rule control questions.

In response to whether the character liked to do the activity "all of the time" versus "some of the time," a 3 (age: 4, 5, 7) × 4 (story type: personal-essential explain disobedience, personal-essential, moral-essential, personal-peripheral) repeated measures ANOVA resulted only in a main effect for age, $F(2, 52) = 3.25$, $p < .05$, $\eta_p^2 = .11$. Four-year-olds ($M = 1.69$) gave correct responses significantly less often than 7-year-olds ($M = 1.91$), $p < .05$, Tukey's HSD (M for 5-year-olds = 1.80). Age and story type main effects emerged for correct responses to whether the character "felt happy versus just OK" when doing the activity: $F(2, 54) = 4.95$, $p < .01$, $\eta_p^2 = .16$ for age, and $F(3, 162) = 6.86$, $p < .0001$, $\eta_p^2 = .11$ for story type. Participants more often correctly responded to the three essential stories ($Ms = 1.85$, 1.68, and 1.67, respectively) than to the peripheral stories ($M = 1.57$). Four-year-olds made more errors ($M = 1.50$ correct) than 7-year-olds ($M = 1.90$), $p < .01$ (M for 5-year-olds = 1.68). Still, participants rated the activities in the essential stories ($Ms = 4.80$, 4.79, and 4.79, respectively) as significantly higher in importance to the character than the activities in the peripheral stories ($M = 2.95$), $F(3, 162) = 160.04$, $p < .0001$, $\eta_p^2 = .75$. Overall, then, children responded appropriately to most control questions, with 4-year-olds showing some difficulty with the premise of the personal-peripheral stories. As described, the experimenter corrected control question errors before continuing by repeating back the relevant story elements and providing the correct response.

Predictions for Decisions and Emotions: Predict-and-Explain Trials

For the predict-and-explain trials, four predictions are of central interest: (a) the frequency that children predicted the character would abide by the rule (*predict compliance*), (b) the frequency that children predicted that the character would comply with the rule and feel good as the primary emotion (*feel good compliance primary*), (c) the frequency that children predicted that the character would abide by the rule and feel good as the primary or secondary emotion (*feel good compliance total*), and (d) the frequency that children predicted that the character would comply and feel good (feel good compliance) or transgress and feel bad (*feel bad transgression*) as the primary or secondary emotion: a broader measure of moral-normative responses. Scores ranged from 0 to 2 totaling the number of trials per story type that children provided each type of response. Preliminary analyses showed that children's predictions were not influenced by (a) gender of story character, (b) the order of the desire versus rule control questions, (c) the order of the action decision choices, or (d) the type of activity (clothing, friend, sport activity, or art activity choice). These factors were removed in the analyses that follow.

Predict compliance. As shown in Figure 3, a 3 (age) × 2 (sex) × 3 (story type: personal-essential, personal-peripheral, moral-essential) repeated measures ANOVA for predict compliance scores resulted in a main effect for story type, $F(2, 108) = 3.62$, $p < .03$, $\eta_p^2 = .12$, qualified by a significant Age × Story Type interaction, $F(4, 108) = 3.81$, $p < .03$, $\eta_p^2 = .12$. Children judged that story characters would comply with rules significantly more often for moral-essential trials ($M = 1.07$, $SE = .11$) than for personal-essential trials ($M = .80$, $SE = .11$), $ps < .05$. Simple effects tests, however, revealed that story type was only significant for the 7-year-olds. In addition, age was a significant factor only for moral-essential stories, with 7-year-olds predicting compliance with moral rules ($M = 1.50$, $SE = .19$) significantly more often than 4- ($M = .95$, $SE = .19$) or 5-year-olds ($M = .75$, $SE = .19$), $ps < .05$.

Predict feel good compliance as primary emotion. A 3 (age) × 2 (sex) × 3 (story type) repeated measures ANOVA for predict feel good compliance primary scores resulted in no significant main effects or interactions. All age groups rarely predicted that story characters would comply with the rule and feel good as the primary emotion (4-year-olds: $M = .23$, $SE = .10$; 5-year-olds: $M = .28$, $SE = .10$; 7-year-olds: $M = .40$, $SE = .10$).

Predict feel good compliance as primary or secondary emotion. Figure 4 shows data for children's decision-emotion predictions in response to the primary or secondary emotion probe. Of interest was whether children ever predicted that the person would comply and feel positive emotions. A 3 (age) × 2 (sex) × 3 (story type) ANOVA resulted in a main effect for story type, $F(2, 108) = 6.14$, $p < .01$, $\eta_p^2 = .19$, qualified by an Age × Story Type interaction, $F(4, 108) = 3.42$, $p < .04$, $\eta_p^2 = .11$. Simple effects tests showed that 7-year-olds predicted feel good compliance significantly less often for personal-essential stories ($M = .30$, $SE = .13$) than for personal-peripheral ($M = .60$, $SE = .15$) or moral-essential ($M = .85$, $SE = .17$) stories, $ps < .05$. Younger children did not differentiate by story type. Age differences only emerged in predictions for the moral-essential situations, with 7-year-olds predicting feel good compliance ($M = .85$, $SE = .17$) significantly more often than 4- ($M = .30$, $SE = .17$) or 5-year-olds ($M = .45$, $SE = .17$), $ps < .05$.

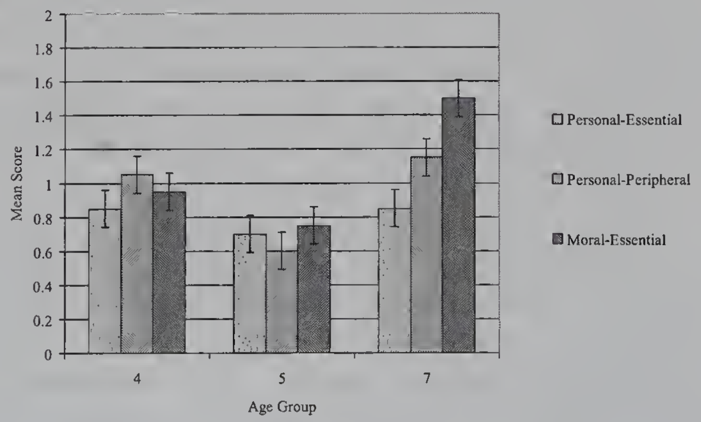

Figure 3. Mean scores (+*SE*) for predicting compliance.

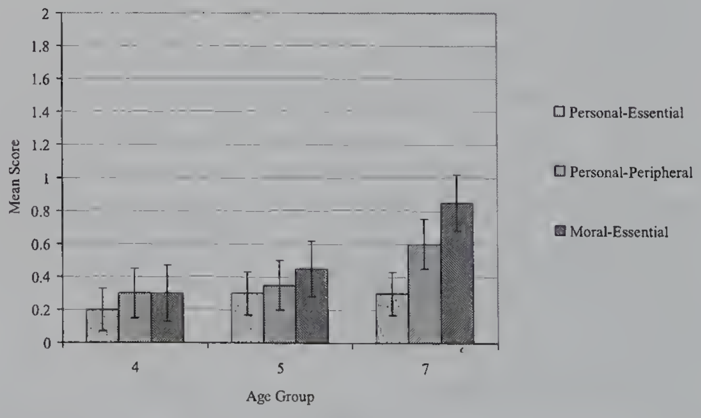

Figure 4. Mean scores (+*SE*) for predicting compliance + feel good as the primary or secondary emotion.

Predict feel good compliance or feel bad transgression. Final prediction analyses examined children's more global provision of moral-normative responses: predicting feel good compliance or feel bad transgression as either the primary or secondary emotion. As shown in Figure 5, a 3 (age) × 2 (sex) × 3 (story type) repeated measures ANOVA resulted in significant main effects for age, $F(2, 54) = 3.91$, $p < .02$, $\eta_p^2 = .13$, and for story type, $F(4, 108) = 5.32$, $p < .01$, $\eta_p^2 = .17$. Five- ($M = 1.08$, $SE = .14$) and 7-year-olds ($M = .95$, $SE = .14$) made these moral-normative predictions significantly more often than 4-year-olds ($M = .57$, $SE = .14$), $p < .05$. Moral-essential stories provoked a significantly higher frequency of feel good compliance or feel bad transgression predictions ($M = 1.08$, $SE = .11$) compared to either the personal-essential stories ($M = .70$, $SE = .10$) or personal-peripheral stories ($M = .82$, $SE = .11$), $ps < .05$.

Interim summary. Seven-year-olds exhibited greater attention to rule type and identity relevance than 4- and 5-year-olds when making predictions about people's decisions and emotions. Analyses examining children's predictions of "compliance" as well as "feel good compliance" (total) showed that only 7-year-olds differentiated by story type: They more frequently provided these responses to moral-essential versus personal-essential trials. In contrast, 4- and 5-year-olds predicted low rates of compliance and feel good compliance across trials. Additional prediction analyses encompassing a broader range of moral-normative responses (predictions of feel good compliance *or* feel bad transgression) revealed sensitivity to rule type and identity relevance even in younger children. That is, all age groups most often judged that characters would abide by rules and feel positive emotions or transgress and experience negative emotions in situations involving moral rules, and they least often made such predictions in situations involving personal domain restrictions that forbade activities essential to the character's identity.

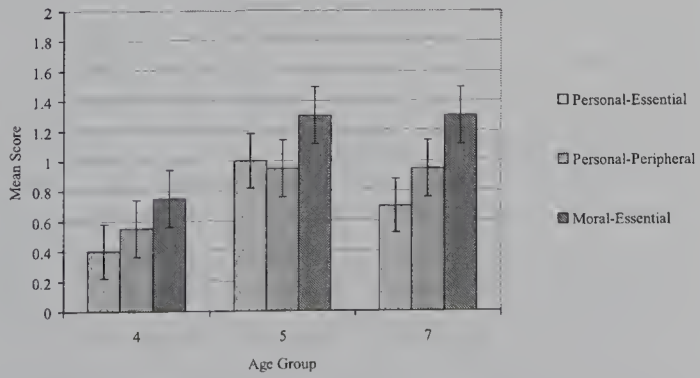

Figure 5. Mean scores (+*SE*) for predicting feel good compliance or feel bad transgression.

Explaining Action Decisions and Emotions: Predict-and-Explain Trials

Explanation analyses examine children's provision of goal-, rule-, and future-oriented explanations for story characters' decisions and emotions, as well as the frequency that children explained behaviors or emotions by making references to the character's identity or to moral-evaluative concerns (see the Method section for coding criteria). Scores ranged from 0 to 2, totaling the number of trials per *each story type* that children provided that type of explanation to justify *either* the character's action decision *or* emotion (regardless of what they predicted the character would do or feel). This scoring procedure reduces reporting redundancy because preliminary analyses on the behavior and emotion explanations separately yielded the same results. Because children did not predict the character's action decision in the explain disobedience trials (they were told the character disobeyed), these data are presented separately in a subsequent section.

Goal-oriented explanations As shown at the top of Table 2, a 3 (age) × 2 (sex) × 3 (story type) repeated measures ANOVA for goal-oriented explanations resulted in no main effects or interactions. Children frequently explained behavior choices and emotions in relation to character's desires, intentions, or goals regardless of story type ($Ms = 1.38$ for 4-year-olds, 1.62 for 5-year-olds, and 1.65 for 7-year-olds).

Rule-oriented explanations As shown in the middle of Table 2, a 3 (age) × 2 (sex) × 3 (story type) repeated measures ANOVA for rule-oriented explanations resulted in a main effect for age, $F(2, 54) = 5.57$, $p < .01$, $\eta_p^2 = .17$, and a near-significant main effect for sex, $F(1, 54) = 3.56$, $p = .065$, $\eta_p^2 = .06$. Seven-year-olds provided rule-oriented explanations for characters' decisions and emotions ($M = 1.62$, $SE = .14$) significantly more often than 4- ($M = .98$, $SE = .14$) and 5-year-olds ($M = 1.10$, $SE = .14$), $ps < .05$ (Tukey's HSD). There was a trend for females to explain actions and feelings in relation to rules more often than males ($Ms = 1.39$ vs. 1.08).

Future-oriented explanations The bottom of Table 2 displays data for future-oriented explanations. A 3 (age) × 2 (sex) × 3 (story type) repeated measures ANOVA revealed significant main effects for story type, $F(2, 108) = 7.06$, $p < .001$, $\eta_p^2 = .12$, and for age, $F(2, 54) = 4.68$, $p < .01$, $\eta_p^2 = .15$. Children explained behaviors and emotions in relation to potential future consequences significantly more

Table 2

Emotion Explanations Scores by Age and Story Type for Predict-and-Explain Story Trials[a]

	Age group		
Emotion explanation type	4	5	7
Goal-oriented explanations (total)	1.38	1.62	1.65
Personal-essential	1.50 (.69)	1.70 (.66)	1.70 (.57)
Personal-peripheral	1.30 (.80)	1.55 (.76)	1.65 (.59)
Moral-essential	1.35 (.75)	1.60 (.68)	1.60 (.75)
Rule-oriented explanations (total)	0.98	1.10	1.62
Personal-essential	0.95 (.95)	1.10 (.85)	1.55 (.76)
Personal-peripheral	1.10 (.79)	0.95 (.89)	1.75 (.64)
Moral-essential	0.90 (.85)	1.25 (.79)	1.55 (.76)
Future-oriented explanations (total)	0.08	0.30	0.53
Personal-essential	0.00 (0)	0.25 (.64)	0.30 (.57)
Personal-peripheral	0.05 (.22)	0.30 (.66)	0.45 (.69)
Moral-essential	0.20 (.52)	0.35 (.67)	0.85 (.75)

[a]Mean scores out of two trials per participant. Data represent the number of trials each type of explanation was provided for either the character's behavior decision and/or emotion. Standard deviations are shown in parentheses.

often for moral-essential stories ($M = .47$, $SE = .09$) than for all other story types, and significantly less often for personal-essential stories ($M = .18$, $SE = .07$) than for all other story types, $ps < .05$. Seven-year-olds explained characters' reactions in relation to potential future outcomes ($M = .53$, $SE = .10$) significantly more often than 4-year-olds ($M = .08$, $SE = .10$), $p < .05$ (Tukey's HSD). Descriptively, 44% of future-oriented explanations focused just on outcomes for the self, 16% focused just on potential consequences for another person, with the remaining 40% referring to possible outcomes for both self and other.

Identity-related and moral-evaluative explanations Final analyses on the predict-and-explain trials focused on the number of trials per story type that children explained characters' action decisions and resulting emotions in relation to the characters' sense of identity (e.g., what he or she likes to do, what is important to the character) or by citing moral-evaluative concerns (e.g., what other people might think of him or her; whether it was a good or bad thing to do). As shown in Figure 6, a 3 (age) × 2 (sex) × 3 (story type) repeated measures ANOVA for identity-related explanations resulted in a significant main effect for story type, $F(2, 108) = 9.65$, $p < .0001$, $\eta_p^2 = .15$. All age groups used identity-related explanations significantly more often to justify characters' decisions and emotions in situations involving personal domain restrictions—both personal-essential ($M = .92$, $SE = .11$) and personal-peripheral ($M = .72$, $SE = .12$)—as opposed to moral rules ($M = .43$, $SE = .09$), $ps < .05$.

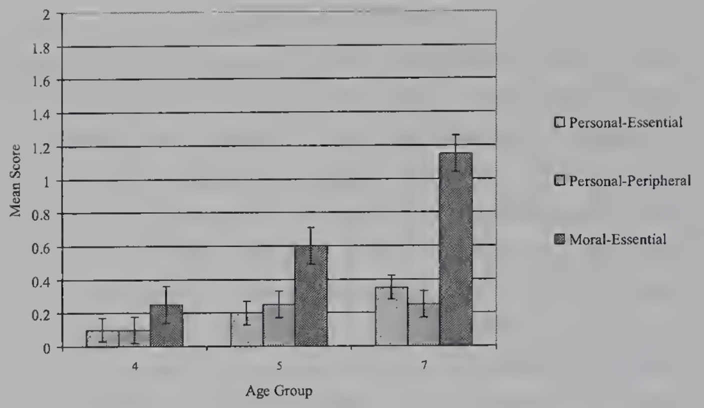

Figure 6. Identity-related explanations (+*SE*) by story type.

The opposite pattern arose for moral-evaluative explanations. As shown in Figure 7, a 3 (age) × 2 (sex) × 3 (story type) repeated measures ANOVA for moral-evaluative explanations resulted in main effects for story type, $F(2, 108) = 20.40$, $p < .001$, $\eta_p^2 = .27$, and for age, $F(2, 54) = 5.99$, $p < .004$, $\eta_p^2 = .18$; both qualified by a Age × Story Type interaction, $F(4, 108) = 4.27$, $p < .003$, $\eta_p^2 = .14$. All age groups explained characters' reactions in relation to moral-evaluative concerns significantly more often for the moral-essential stories ($M = .67$, $SE = .08$) than for either type of personal domain restriction story ($Ms < .22$, $SEs < .07$), $ps < .05$. Age differences only emerged for the moral-essential stories, with 7-year-olds providing moral-evaluative explanations ($M = .58$, $SE = .09$) significantly more often than 5-year-olds ($M = .35$, $SE = .09$), and 5-year-olds doing so more often than 4-year-olds ($Ms = .15$, $SE = .09$), $ps < .05$.

Explain Disobedience Trials

Analyses for the two explain disobedience trials focus on the following responses: (a) predicting positive emotions for transgression as either the primary or secondary emotion, (b) provision of identity-related and moral-evaluative explanations, (c) stating that the character did not obey the rule, (d) judging that disobeying the rule was "not OK," and (e) predicting that the character would feel bad if he or she could never engage in that action. Scores ranged from 0 to 2 summing the number of trials per story type that children provided each type of response.

First, consider children's predictions that the character would "feel bad" after disobeying a rule

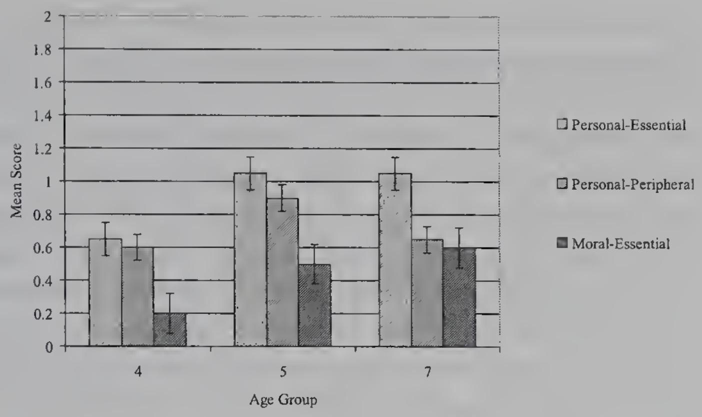

Figure 7. Moral-evaluative explanations (+*SE*) by story type.

that forbade participation in a personal domain activity essential to the character's sense of identity. A 3 (age) × 2 (sex) ANOVA for primary emotion predictions resulted in no main effects or interactions. A parallel ANOVA for predicting negative emotions as either the primary or secondary emotion also resulted in no main effects or interactions. All age groups infrequently predicted that transgressing against rules in the personal domain would lead to negative emotions as the primary emotion (*M*s = .15, .45, .30 for 4-, 5-, and 7-year-olds, respectively) or as either the primary or secondary emotion (*M*s = .25, .65, and .70).

Children's explanation patterns for the personal-essential explain disobedience trials paralleled the findings from the personal-essential predict-and-explain trials: Identity-related explanations were provided frequently by participants as a justification for the characters' decisions or emotions (*M*s = 1.20 trials for 4-year-olds, 1.35 for 5-year-olds, and 1.30 for 7-year-olds), whereas moral-evaluative explanations were nearly nonexistent (*M*s = .35, .25, and .20). Univariate ANOVAs confirmed there were no age differences, *p*s > .05.

We then examined children's beliefs that a rule had, in fact, been broken. A 3 (age) × 2 (sex) ANOVA for disobedience scores resulted in a main effect for age, $F(2, 54) = 4.38$, $p < .017$, $\eta_p^2 = .14$. Whereas 5- and 7-year-olds judged that a rule had been broken 100% of the time, 4-year-olds did so only 85% of the time. Moreover, most children judged that breaking the rule was "not OK" to do (*M*s = 1.65, 1.60, and 1.75 for 4-, 5-, and 7-year-olds, respectively). A 3 (age) × 2 (sex) ANOVA for "not OK" scores resulted in no main effects or interactions.

Finally, children predicted nearly 100% of the time (*M*s = 1.95 for 4-year-olds, 2.0 for 5- and 7-year-olds) that the characters would feel bad if they never could participate again in the desired activity that was essential to their identity.

Discussion

At the same time that children are learning to comply with societal and parental rules, they begin to carve out a personal domain of actions where they can actively stake claims to autonomy, control, and choice (Nucci & Turiel, 2000). Put simply, children learn to identify situations where there may be legitimate grounds for *disobeying*. Although previous research has established that older children and adolescents acknowledge that these claims to the personal domain are important for autonomy and individual identity (Nucci & Turiel, 2000), little is known about the emergence of these intuitions during early childhood. The current study provides a new approach by bridging methodology from social domain theory (Smetana, 2006), essentialism (Gelman, 2003), and theory of mind (Lagattuta, 2005). Findings reveal that when young children reason about people's decisions and emotions, they attend to rule domain (personal vs. moral) and identity relevance (essential vs. peripheral). Data are most robust for 7-year-olds, with evidence for initial insights in children as young as 4 years.

When Will a Person Decide to Comply?

When making predictions about what people will do in situations where their desires conflict with rules, does desire trump rule or rule trump desire? As predicted, there were no significant age differences between 4 and 7 years in predicting that people would comply with rules that intruded on the personal domain: Participants predicted that characters would disobey parents and fulfill their desires the majority of the time (e.g., Carlos will play baseball, Tom will play with his best friend, Sarah will wear her sparkly clothes). In contrast, when situations involved moral rules, predictions of compliance significantly increased with age (nearly double the rate), even though the desired activity was described as essential to that person's identity (e.g., "Max the LegoBuilder" will not steal to build with highly desired Legos). Sensitivity to rule type and identity relevance was clearest for the 7-year-olds: They judged that characters would comply with rules significantly more often for moral-essential than for personal-essential trials (personal-peripheral trials did not differ from either type). In contrast, 4- and 5-year-olds did not differentiate by story type and typically predicted that desires would drive people's behaviors. Future research using open-ended (What do you think Gloria will do?) versus forced-choice (Do you think Gloria will X or Y?) prompts would also be revealing because it would allow children the opportunity to suggest compromise solutions (e.g., comply now and paint later). Analyses of such compromise suggestions could provide further insight into how young children learn to establish the boundaries of a personal domain via negotiating and making concessions with authority figures.

Previous research has shown that children as young as 3 years view moral rules as more obligatory than rules governing the personal domain and treat moral rule infractions as more severe than breaking rules that intrude on the personal domain (Killen & Smetana, 1999; Nucci, 1981; Tisak, 1993). Thus, it is puzzling why 4- and 5-year-olds did not predict higher rates of compliance with moral rules versus personal domain restrictions in the current study. Still, past researchers have not asked children to judge whether people will act to fulfill desires essential to their identity versus abide by moral rules. Rather, studies have focused on children's reasoning about whether children versus parents (or teachers) have the right to make certain rules, whether certain rules can be changed, how severely a person should be punished for breaking certain rules, or whether a parent versus child should make decisions (e.g., Nucci & Weber, 1995). These are different questions than whether they believe highly intense desires versus rules more strongly motivate behavior. Given that children develop early knowledge (age < 2 years) that desires drive actions (see Wellman & Lagattuta, 2000), they likely have difficulty factoring other aspects of the situation—in this case, the importance of rules or possible harm to others—that may alter this relation (see Lagattuta, 2005, 2008). Potentially, moral-peripheral situations, a story type not tested in the current study, may be a situation where 4- and 5-year-olds may predict higher compliance because in these cases the desired activity is less important.

Does Abiding by Rules Feel Good and Transgressing Feel Bad?

Research on young children's reasoning about emotions and rules has focused on children's understanding that harming others for personal gain can make the victimizer feel bad. Results have consistently found that whereas children 7–8 years and older acknowledge that victimizers can experience negative emotions, younger children typically judge that victimizers just feel happy (see Arsenio et al., 2006). Recently, Lagattuta (2005) identified the same age shift for children's judgments about social-conventional and prudential rules: With age, children increasingly predict that compliance can feel good (despite desire inhibition) and transgression can feel bad (despite desire fulfillment). The current research takes a different approach. Importantly, predictions of feel good compliance and feel bad transgression should not always be considered the optimal, or most developmentally advanced response. In some situations, notably when authority figures restrict actions essential to sense of self or identity, judgments of "feel bad compliance" and "feel good transgression" may be more appropriate.

Although all age groups understood that characters would feel bad being forbidden from activities essential to self, 7-year-olds showed the strongest ability to differentiate situations by rule domain and identity relevance. Seven-year-olds predicted feel good compliance at significantly lower rates for the personal-essential scenarios than for all other story types, and they predicted significantly higher rates of feel good compliance for the moral-essential trials than all other story types. Age differences only emerged for the moral-essential scenarios: Seven-year-olds judged that compliance with moral rules can make a person feel good significantly more often than did 4- and 5-year-olds. Story type did not affect 4- and 5-year-olds' predictions of feel good compliance: Young children infrequently predicted these action–emotion sequences. Importantly, however, when analyses broadened to include both predictions of feel good compliance and feel bad transgression, all age groups treated moral rules differently than personal domain restrictions. Thus, although there is some early awareness about different action–emotion sequences depending on rule domain and identity relevance, between the ages of 4 and 7 children demonstrate increasing ability to differentiate by situation when reasoning about people's decisions and emotions.

These developmental findings correspond with data by Shaw and Wainryb (2006) showing that 7-year-olds (as with older, but not younger children) judge that not all compliance is good: Going along with unfair peer demands can cause negative emotions, lower self-worth, and increased risk of further victimization. More broadly, children's responses resonate with Werner and Kaplan's (1963) theory of increased differentiation and integration of concepts over development. That is, 4- and 5-year-olds (compared to 7-year-olds) had more difficulty differentiating and integrating information about rule domain and identity relevance to reason about how the character would act and feel (see also Helwig, Zelazo, & Wilson, 2001).

Clues from Children's Explanations

Children's explanations for why characters made certain decisions and experienced particular emotions clarify and extend the prediction data. Foremost, they reveal that children as young as 4 years do attend to rule domain and identity relevance when reasoning about people's actions and emotions. Unlike most analyses on the prediction data, significant main effects for story type in the explanation data were not qualified by significant interactions with age. Across age, children provided future-oriented (e.g., "She maybe felt bad for the girl she hit because maybe she was crying") and moral-evaluative (e.g., "It wouldn't be very nice to take somebody else's clothes and just leave, because they're the other person's") explanations significantly more often for moral-essential scenarios than for situations featuring personal domain restrictions. These data support previous research showing that young children make distinctions between the moral and personal domains in relation to whether the action could have harmful consequences for others (Killen & Smetana, 1999; Nucci, 1981). Developmental patterns also converge with prior studies. Seven-year-olds provided future-oriented and moral-evaluative explanations significantly more often than 4- and 5-year-olds, fitting with previous research showing increased attention to and understanding of future possibilities (Atance & O'Neill, 2005; Lagattuta, 2005, 2007), as well as rising concern about being valued, accepted, and approved by others during this age period (Higgins, 1991; Ruble & Frey, 1991).

In contrast, personal-essential situations elicited significantly more justifications focusing on aspects of the character's sense of self and identity (e.g., "Because she loves playing soccer so much . . . that's part of who she is") compared to personal-peripheral and moral-essential story types. Thus, children showed awareness of connections between identity and the need to stake claims to a personal domain of action and choice. Here is one particularly revealing example from a 7-year-old: "'Cause she thinks that Sue is such a nice person that she wouldn't, she wouldn't be herself if she didn't get to play with her anymore, cause she likes to play with her so much that if she didn't do it, then she would be so sad all the time, because she wants to play with Sue so bad." Here again, it is important to stress that for both the personal-essential and the moral-essential scenarios, the desire to participate in the action was very high. Thus, although children provided identity-related explanations based on the intensity of the desire (personal-peripheral < personal-essential), they also attended to rule domain (moral-essential < personal-peripheral < personal-essential).

Two types of explanations did not vary by story type: goal oriented and rule oriented. This is understandable given that these explanations could sensibly be applied to compliance (e.g., "Because she didn't get what she wanted" [goal oriented], "Because she followed the rule" [rule oriented]) or transgression decisions (e.g., "Because he wanted to wear those clothes and he did it," "Because she didn't listen to what her mom said"). Nevertheless, as with previous research (Lagattuta, 2005), rule-oriented explanations did significantly increase with age, showing increased ability to integrate theory of mind and social-normative perspectives: People's emotions and decisions are not just motivated by desires and goals but also by attention to rules.

Issues and Unanswered Questions

Did children understand that a rule had been broken? As even 7-year-olds most often predicted that characters would disobey personal domain restrictions, perhaps children did not treat these restrictions as "rules." Methods and data argue against this interpretation. All story trials explicitly stated the rule (X's Mom says, "You should not . . .") and included a rule control question ("What *rule* did his/her mom say?"). For the explain disobedience trials (featuring personal-essential situations), children were directly asked whether the story character broke the mother's rule and whether it was OK to do so. All age groups correctly answered the rule control question for 100% trials. Contrary to our predictions, there was not an age-related decline in judgments that disobeying personal domain restrictions was "not OK": All age groups, even 7-year-olds, stated that these acts of noncompliance were "not OK" (*Ms* = 83%–88% trials).

This intriguing disconnect between children's judgments—yes, the character will break the rule and feel good, but no, it is not OK to make this decision—has been found in previous studies. For example, Lourenço (1997) reported that although the majority of 4- and 6-year-olds predicted a person who broke a moral rule would feel happy, they acknowledged that the victimizer was "bad." Moreover, Kalish and Shiverick (2004) found that whereas 30% of children said that the character would actually obey a rule, 75%–95% said he or she should follow the rule (see also Nucci & Weber, 1995). Thus, children as young as 4 years understand that people knowingly—not naively—decide to disobey rules. Given that children make even stronger demands for personal jurisdiction during adolescence (Nucci, 2006), future research may find that this disconnect changes over time to *convergence*: Yes, he will break the rule, yes, he will feel happy, and yes, it is OK to make that decision (e.g., because the mother did not have the right to make that rule in the first place).

Did young children understand the essential versus peripheral distinction? In our procedures, 7-year-olds demonstrated greater knowledge than 4- and 5-year-olds about the impact of identity relevance on people's decisions and emotions. One interpretation is that because older children more highly attend to people's characteristics, attributes, and personality traits (Harter, 1998; Ruble & Frey, 1991), they have more advanced knowledge about the role identity plays in people's decisions and emotions. Another possibility, however, is that developmental differences emerged because 4- and 5-year-olds failed to understand the initial premise of the peripheral stories—that the activity, although desired at this moment, was not a central part of that character's sense of self. Although all age groups rated the activities higher in importance to characters when actions were described as essential versus peripheral to their identity, young children made more mistakes than 7-year-olds in answering the control questions for the peripheral core stories. Thus, because young children did not demonstrate equal initial understanding of the peripheral versus essential premise, it may have affected their ability to differentiate by identity relevance when reasoning about people's actions and emotions.

A challenge for future research, then, is to make the essential versus peripheral distinction more salient to young children. For the current study, we purposely featured actions within the personal domain (e.g., playing soccer, building with Legos) that are popular with children of this age group. As a result, children may have had difficulty imagining that another person would not enjoy these activities. One potential solution is to use novel-label predicates instead of known actions (e.g., "X likes to flimmer" and the rule is "not to flimmer"; see Kalish & Shiverick, 2004). A substantial drawback to this approach, however, is that when a novel label is used, the child has no information from which to judge whether the action is in the personal, moral, or social-conventional domain. For example, the child cannot ascertain whether by choosing "to flimmer" he or she could harm others. The current data reveal that this distinction—between moral rules versus personal domain restrictions—has an even higher impact on children's reasoning about people's decisions and emotions than identity relevance. Thus, if future studies use novel labels for actions, it would be critical to provide clues to rule domain: "X wants to flimmer. If X flimmers, someone else could get hurt" (moral rule) or, "X wants to flimmer. If X flimmers, X could get hurt" (prudential rule).

Do these findings apply more broadly to other social classes or cultures? Results of the current study are based on the reasoning of middle-class American children. Because these children typically have relative freedom to choose what to wear, who to play with, and what to do (see Kusserow, 2004), they may develop earlier knowledge about the emotional costs of complying with personal domain restrictions. Research has shown that children and adolescents in other cultures have different ideas about rights to autonomy and democracy in decision-making processes (see Helwig, 2006; Helwig, Arnold, Tan, & Boyd, 2007), and this could shape their reasoning about decisions and emotions in rule situations. Still, although the particulars of what gets defined as the personal domain can vary across cultural settings (e.g., Muslim women cannot choose what to wear), the establishment of a zone of personal choice and privacy appears to be culturally universal. Claims to personal jurisdiction have been documented in diverse cultures and social classes in North America, South America, the Middle East, and Asia (see Nucci, 2001; Smetana, 2002, 2006). These cross-cultural findings strongly suggest that our core data would likely generalize beyond the sample tested given cultural sensitivity to which particular activities are defined as personal.

Adult–Child Interactions and Socialization

Young children's judgment that people frequently disobey parental rules that intrude on the personal domain—and feel good about breaking these rules—has implications for adult–child interactions and socialization practices. Foremost, they argue for balance in promoting morality in young children: not only restricting actions that they should not do but also helping them to identify situations where they *can* assert personal control (see Nucci, 2006). Such an approach does not advocate telling children to blatantly disobey authority but rather promotes helping children respectfully negotiate socially and culturally acceptable areas of personal choice. Negotiation of claims to a personal domain has been found across very diverse cultures and social classes, with adults granting some space, and children seeking control to safeguard their developing identity and autonomy (Grusec & Goodnow, 1994; Nucci, 1994; Nucci, Camino, & Sapiro, 1996; Smetana, 2002). The current findings show that by 4 years of age children have some appreciation about these connections between identity development, and personal control. Thus, overregulation of the child's personal domain may be psychologically harmful in that the adult not only restricts the child the ability to express his or her self but also evaluates that aspect of the child's identity as immoral or unworthy (e.g., "You shouldn't act that . . . dress like that . . . be friends with them!"). Recent evidence supports these mental health implications. Adolescents whose parents severely restrict control over a personal domain report elevated rates of anxiety and depression, a finding documented in the United States and Japan (Hasebe, Nucci, & Nucci, 2004) as well as in urban and rural China (Helwig, Yang, Nucci, Yun, & To, 2009).

Conclusions

Results of the current research show that between the ages of 4 and 7 years children develop emerging knowledge about acts of legitimate disobedience: There are certain situations where people will resist authority and feel good about making that decision. All age groups infrequently predicted feel good compliance for situations featuring personal domain restrictions, with 7-year-olds least often doing so when rules forbade actions essential versus peripheral to the characters' identities. Moreover, all age groups more often justified characters' actions and emotions by referencing aspects of their identity in the personal-essential condition compared to all other story types. Still, between the ages of 4 and 7, children demonstrated increasing awareness of the limits to legitimate disobedience. That is, there was a significant age-related increase in predicting feel good compliance with moral rules that required the character to inhibit desires essential to his or her sense of self. By building bridges between theory of mind, social domain theory, and essentialism, this study reveals that it is not only possible to examine young children's knowledge about the importance of personal jurisdiction for self and identity but also that it is a rich area for continued exploration.

Developmental Patterns in Decision-Making Autonomy Across Middle Childhood and Adolescence: European American Parents' Perspectives

Laura Wray-Lake, Ann C. Crouter, and Susan M. McHale
The Pennsylvania State University

Longitudinal patterns in parents' reports of youth decision-making autonomy from ages 9 to 20 were examined in a study of 201 European American families with 2 offspring. Multilevel modeling analyses revealed that decision-making autonomy increased gradually across middle childhood and adolescence before rising sharply in late adolescence. Social domain theory was supported by analyses of 8 decision types spanning prudential, conventional, personal, and multifaceted domains. Decision making was higher for girls, youth whom parents perceived as easier to supervise, and youth with better educated parents. Firstborns and secondborns had different age-related trajectories of decision-making autonomy. Findings shed light on the developmental trajectories and family processes associated with adolescents' fundamental task of gaining autonomy.

Developmental scholars have placed a high priority on understanding autonomy in youth (Baumrind, 1991; Collins, Gleason, & Sesma, 1997; Eccles et al., 1991; Holmbeck, Paikoff, & Brooks-Gunn, 1995; Smetana, Campione-Barr, & Daddis, 2004; Steinberg, 2001). Although autonomy can be defined in terms of behaviors, cognitions, or emotions, behavioral autonomy has been of particular interest (Collins et al., 1997; Hill & Holmbeck, 1987). Because it has long been acknowledged that becoming more autonomous is a central developmental task for adolescents (Erikson, 1968), most research and theorizing on autonomy has focused on adolescence. There is a paucity of longitudinal studies on autonomy across middle childhood and adolescence, however, and little is known about the nature of growth and change in behavioral autonomy as children become adolescents and move toward young adulthood.

The first goal of this study was to chart the trajectory of decision making—an indicator of behavioral autonomy—from middle childhood through adolescence using longitudinal data spanning ages 9–20 based on European American parents' reports. Everyday decisions about youth activities cut across a variety of social domains, and social domain theory predicts that autonomy levels will differ depending on the domain in question (Smetana, 1995; Turiel, 1998). Thus, a second goal was to examine the trajectories of eight decision-making items representing four domains: personal, social-conventional, prudential, and multifaceted. Based on an ecological perspective, the third goal was to examine correlates of decision-making trajectories including child characteristics (e.g., birth order, gender, openness to supervision) and family socioeconomic background.

Development of Decision-Making Autonomy

Behavioral autonomy refers to youth's freedom to regulate their own behavior as part of the process of developing independence and self-guided action (Collins et al., 1997; Feldman & Wood, 1994). Family decision making, a type of behavioral autonomy, refers to the everyday practices of making choices about youth activities, a process within which youth assert and parents negotiate control

(Collins et al., 1997). Youth autonomy is minimal when parents make unilateral decisions for youth, moderate when parents and youth make joint decisions, and complete when youth make decisions unilaterally (Dornbusch et al., 1985; Lamborn, Dornbusch, & Steinberg, 1996). The development of behavioral autonomy has important implications: Both parent-unilateral and adolescent-unilateral decision making in adolescence have been linked to negative adjustment, whereas joint decision making is often seen as optimal for developmental and family functioning (e.g., Lamborn et al., 1996; Steinberg, Elmen, & Mounts, 1989). The level of decision making considered optimal, however, likely depends on what is normative for youth's age and developmental stage, as well as child and context characteristics.

Cross-sectional and longitudinal studies of adolescents have documented that family decision making becomes more adolescent driven and less parent unilateral with age (Dornbusch, Ritter, Mont-Reynaud, & Chen, 1990; Dornbusch et al., 1985; Eccles et al., 1991; Gutman & Eccles, 2007; Smetana et al., 2004). Using cross-sectional data, Dornbusch et al. (1985; Dornbusch et al., 1990) found that age was associated with more youth-unilateral and less parent-unilateral decision making. Joint decision making was highest during middle adolescence and lower in early and late adolescence (Dornbusch et al., 1985), suggesting that joint decision making is a transition between low and high decision-making autonomy. In other words, these studies suggest that the development of decision-making autonomy sequentially progresses through parent-unilateral, joint, and adolescent-unilateral decision making across adolescence.

Taking a more comprehensive longitudinal approach than previous studies, Gutman and Eccles (2007) examined decision-making autonomy using four waves of data spanning 8 years from the seventh grade to the year after high school. They found a quadratic pattern: Decision making increased across ages 13–19 and rose sharply between ages 15 and 17. These findings shed light on decision-making trajectories and suggest that steep increases occur in late adolescence, but the trajectory was estimated using only a single item reported by adolescents. Research into *autonomy expectations*, which are moderately correlated with behavioral autonomy, also provides insight into the timing of increase in autonomy across adolescence: Daddis and Smetana (2005) found that, on average, mothers expected adolescents to have autonomy for personal issues (i.e., decisions of individual preference) at ages 14–15 and to have autonomy for prudential issues (i.e., decisions with more negative consequences) at ages 16–17. In other longitudinal work, Smetana et al. (2004) studied an African American adolescent sample at three occasions over 5 years between ages 13 and 17 and reported a linear increase in decision-making autonomy. This finding was qualified by the social domain in which decisions were made, an issue discussed below. With only three occasions of measurement, however, complex longitudinal patterns could not be uncovered.

Longitudinal work on decision making has focused on adolescence, and little is known about the nature of autonomy in middle childhood. Decision-making processes do not always follow a simple linear progression across childhood and adolescence (Jacobs & Klaczynski, 2002). Charting how and when decision-making autonomy increases from middle childhood through adolescence, as our study does for a sample of European American families, fills a lacuna in the documentation of longitudinal developmental processes. Based on previous work (Daddis & Smetana, 2005; Gutman & Eccles, 2007), and using parents' reports, we expected a gradual increase in decision-making autonomy across ages 9–15, followed by a steep rise starting between ages 15 and 17.

Domain-Specific Decision Making

Social domain theory (Nucci, 2001; Smetana, 1995; Smetana, Crean, & Campione-Barr, 2005; Turiel, 1998) suggests that youth may achieve different levels of decision-making autonomy depending on the domain under which the decision falls. Autonomy is expected earliest in *personal domains* such as appearance (e.g., hairstyle, clothing) where decisions only impact the individual and pertain to private aspects of life (Daddis & Smetana, 2005; Feldman & Wood, 1994; Nucci, 2001; Smetana et al., 2004). Decisions falling under the *social-conventional domain* are those for which cultural norms within the family, community, or society serve as guidelines (e.g., manners, responsibility for household chores). Due to the possible negative consequences of violating such norms, lower autonomy is expected in the conventional as compared to the personal domain. *Prudential issues* are those that have potential negative consequences for health and safety, and thus the lowest levels of autonomy are expected in this domain (Smetana et al., 2004).

Multifaceted decisions reflect overlapping domains and typically traverse the personal and conventional or prudential domains (Smetana, 2000). For example, an adolescent's choice of friends is often seen as a personal issue by the adolescent but as a prudential issue by parents. Thus, multifaceted decisions may be a source of conflict for parents and adolescents (Smetana et al., 2005). Predictions about multifaceted decisions are least clear as there is little theorizing regarding the expected level of autonomy in relation to other domains (Baumrind, 2005). However, Smetana et al. (2004) predicted and found that adolescents had higher autonomy for multifaceted decisions than for those in conventional or prudential domains, as multifaceted decisions tend to be made jointly by parents and adolescents.

In the current study, youth's decision-making autonomy was measured by asking parents to report on youth decisions in eight areas: appearance, choosing activities, money, social life, bedtime/curfew, chores, homework/schoolwork, and health. Appearance lies in the personal domain, chores in the conventional, and health in the prudential domain; the remaining decision types are multifaceted. Even though these items are more generally worded than in previous research in social domain theory, longitudinal trajectories by domain represent a contribution to this literature. Based on theory and previous findings, we expected that parents' reports of youth autonomy levels would be highest for decisions about appearance, followed by the multifaceted decisions of choosing activities, homework/schoolwork, money, social life, and curfew. Autonomy levels should be lower for conventional decisions about chores than for personal or multifaceted decisions. Lowest autonomy levels were expected for (prudential) health decisions.

Along with testing predictions regarding level of differences across decision domains, we also examined differences in developmental trajectories by decision type. Smetana et al. (2004) found that both adolescents' and mothers' reports of autonomy in decisions across personal, conventional, prudential, and multifaceted domains increased gradually across ages 13–17, with one exception: Mothers' reports of adolescent autonomy in conventional decisions did not change. Our study examined decision-making autonomy over a longer time frame, and thus increases were expected across all domains. Based on Daddis and Smetana's (2005) finding that parents had expectations for earlier youth autonomy in personal decisions than in prudential ones, it is plausible that autonomy in conventional and prudential decisions may increase at a slower rate across adolescence. An alternative hypothesis, however, is that domains with lower autonomy levels in middle childhood and early adolescence would show steeper increases because they begin at a lower baseline and thus have farther to go before reaching full autonomy. Given the lack of previous research and theorizing, our examination of trajectory differences by domain was exploratory.

Correlates of Decision-Making Trajectories

From an ecological perspective, individual characteristics and family context help to shape youth development. As we elaborate, certain individual characteristics, such as gender and openness to supervision, may elicit more autonomy than others. In addition, two children within the same family may have different opportunities for decision-making autonomy based on their position in the family. Socioeconomic status (SES) may foster or hinder children's autonomy.

Gender. Findings on the role of gender in adolescent decision making are mixed. Some literature documents more autonomous decision making for boys (Dornbusch et al., 1990; Dowdy & Kliewer, 1998), and parents' autonomy expectations have also been found to be earlier for boys than for girls (Daddis & Smetana, 2005). In contrast, other literature suggests that girls experience greater decision-making autonomy than boys (Bumpus et al., 2001; Flanagan, 1990), and still other work finds no gender differences (Fuligni & Eccles, 1993; Peterson, Bush, & Supple, 1999; Smetana, 2000; Smetana et al., 2004). Gutman and Eccles (2007) found no main effects for gender but reported that girls and boys had different trajectories in decision-making autonomy: Girls' autonomy increased from ages 13 to 19, rising steeply between ages 15 and 17, whereas boys' autonomy increased linearly from ages 13 to 17 and afterward were stable. We examined gender differences in autonomy and tested for an interaction between gender and age, but proposed no hypotheses, given prior mixed findings and lack of theory.

Openness to supervision. Openness to supervision is defined as a youth's willingness to disclose information to parents and cooperate in the monitoring process (Kerns, Aspelmeier, Gentzler, & Grabill, 2001), and has been linked to greater parental knowledge of youth's activities and more positive parent–child relationships (Crouter, Bumpus, Davis, & McHale, 2005; Kerns et al., 2001). We measured parents' reports of children's openness to supervision in middle childhood, giving us the opportunity to examine how parents' perceptions of their children predict their reports of youth's autonomy development through adolescence. Children are active agents in their own development, and children's personal characteristics can influence family dynamics (Crouter & Booth, 2003). Children's openness to supervision should afford them greater involvement in decision making within the family, as cooperation engenders trust (Maccoby & Martin, 1983). We expected that parents' perceptions of children's openness to supervision would predict reports of higher levels and faster increases in youth decision-making autonomy from middle childhood through adolescence.

Birth order. Family theories imply birth order differences in decision-making autonomy. First, a growing body of literature based in a family systems perspective (Cox & Paley, 1997) suggests that parents with two children tend to learn from experience with their firstborn and adjust their parenting practices toward, expectations for, and relationships with their secondborn child (Shanahan, McHale, Crouter, & Osgood, 2007; Whiteman, McHale, & Crouter, 2003, 2007). These studies have shown that when siblings are compared at the same age, parents have less conflict with, more warmth toward, and more knowledge about secondborn compared to firstborn children. Regarding autonomy, the learning from experience model suggests that parents may relax expectations and allow autonomy earlier for secondborns compared to firstborns. Second, differentiation theory predicts that siblings endeavor to establish unique niches within the family in order to minimize their competition and maximize parental investment of resources (Ansbacher & Ansbacher, 1956; McHale et al., 2006; Sulloway, 1996). Building on Adler's theory of individual psychology, Sulloway (1996) argued that later born children seek autonomy in order to set themselves apart from more conforming and adult-oriented firstborns.

Both the learning from experience hypothesis and sibling differentiation theory imply greater autonomy for secondborns than for firstborns. Yet two cross-sectional studies found higher autonomy for firstborns than for secondborns (Bumpus et al., 2001; Small, Eastman, & Cornelius, 1988). In the majority of cross-sectional designs, birth order and age are confounded, in that later born siblings are also chronologically younger than earlier born siblings. Only in cross-sectional studies with substantial variability in the ages of sibling pairs can birth order and age be disentangled, and this concern has not been a focus of prior research. In contrast, a longitudinal design comparing siblings from the same family at the same age eliminates the confounding of age and birth order that characterizes most cross-sectional studies of siblings. Our data include 201 firstborn and secondborn sibling pairs that entered the study at roughly ages 11 and 9, respectively; our longitudinal design allowed us to make within-family comparisons to understand birth-order differences and study developmental changes for individuals. To fully illustrate the advantages of within-family comparisons related to birth order, we tested birth order differences in decision making by siblings' chronological age *and* by occasion of measurement, comparing firstborn and secondborn siblings' decision-making autonomy at the same age (using data from different measurement occasions) and at the same points in time (when the siblings differed in age). Using these two approaches, our goal was to reconcile differences between theoretical perspectives predicting greater autonomy for secondborns with cross-sectional findings showing greater autonomy for firstborns.

Parents' education. We treated parents' education as a proxy for social class, testing competing hypotheses regarding social class and youth decision making. According to Lareau (2003), parents from lower SES backgrounds value "accomplishment of natural growth" and leave children to create their own stimulation, thus granting them more autonomy. In contrast, parents of higher SES backgrounds value "concerted cultivation" and structure children's social lives and activities, resulting in lower autonomy for these youth. Consistent with this model, Flanagan (1990) found that mothers with long-term unemployment and less education reported greater decision-making autonomy for youth (particularly daughters).

Other studies, in contrast, suggest that higher SES predicts greater adolescent autonomy (e.g., Dornbusch et al., 1990; Nucci, Camino, & Sapiro, 1996). These studies are grounded in a broad literature suggesting SES differences in parenting styles. Lower SES parents tend to rely on more imperatives and restrictions, lowering youth autonomy, compared to higher SES parents (cf. Parke & Buriel, 2006). Thus, two bodies of literature suggest that parents' education may be related to youth decision-making autonomy in different ways. We examined the association between parents' education and youth decision making to test these competing hypotheses.

Study Goals

In sum, this study addressed three goals. First, we examined the trajectory of global decision making from middle childhood through late adolescence using reports from European American parents. Second, we charted trajectories of eight decision-making items in four domains to test hypotheses derived from the social domain literature. Third, we tested gender, youth's openness to supervision, birth order, and parents' education as potential correlates of the development of decision-making autonomy from middle childhood through adolescence.

Method

Sample and Procedure

Data were drawn from seven waves (Waves 2, 3, and 6 through 10) of a 10-year longitudinal study exploring family relationships and gender development across middle childhood and adolescence. Waves 1, 4, and 5 could not be included because the decision-making measure was not available at these waves. Waves 2, 3, and 6 through 10 are referred to here as Occasions 1 through 7. Families were recruited through letters sent home with fourth- and fifth-grade students in 16 school districts. Interested families returned self-addressed stamped postcards if they met three criteria: (a) a mother and father (either biological or adoptive) present in the household, (b) a firstborn child in the fourth or fifth grade, and (c) at least one sibling 1–4 years younger. Of the eligible families who returned postcards, over 90% agreed to participate in the study. Comparisons of participating families with U.S. Census data suggested that parents in the sample were slightly older and better educated than dual-earner families from the same counties.

Of the 203 families that originally agreed to participate, 2 families dropped out after the first wave and were excluded here. Thus, current analyses used 201 families. A team of interviewers conducted separate 2- to 3-hr home interviews with fathers, mothers, and the two target siblings in each family. Families received a $100 honorarium in Waves 1, 2, and 3 and $200 thereafter. The last point of data collection for each family was the year after the firstborn sibling graduated from high school, which varied across families, and meant that the sample size dropped beginning at Occasion 4. Attrition was low: At Occasion 4, the last wave in which all youth participated, 95% of the original sample remained. Across the study, 9 families experienced divorce, 3 sets of parents separated, a parent's death affected 6 families (5 were fathers), and 2 adolescents had children of their own. Of the 177 individuals who reached the ages of 19 or 20 by the end of the study (mostly firstborns), the majority were attending a 4-year college (66%). In addition, 18% were employed full- or part-time, 12% attended a 2-year or vocational school, and 4% had joined the military. Finally, 24% lived at home with their parents.

The sample was composed of White, working- and middle-class families residing in small cities and rural areas. With the exception of 2 adopted Asian American children, all families were European American, which was representative of the region. At Occasion 1, average family income was $63,355 (*SD* = 31,472), slightly wealthier than other families in the area. Mothers and fathers averaged 14.63 (*SD* = 2.11) and 14.72 (*SD* = 2.40) years of education, respectively, representing vocational training/some college. Firstborn children (103 girls and 98 boys) were 11.83 years of age on average (*SD* = 0.55), and secondborns (100 girls and 101 boys) averaged 9.22 years of age (*SD* = 0.93).

Measures

Decision making. The adolescent decision-making questionnaire was adapted from Dornbusch et al. (1985), and domains were taken from Smetana (1988). Only parent reports were collected across the entire study period. The decision-making measure consisted of eight items. Mothers and fathers were asked to "think about how decisions have been made during the past year in different areas of your child's life." They circled the number corresponding to the family member(s) who usually made decisions in eight areas: chores, appearance, homework/schoolwork, social life, bedtime/curfew, health, choosing activities, and money. Appearance was classified under the personal domain, chores under the conventional domain, and health under the prudential domain; all other decision types were classified as multifaceted. Original response options ranged from 1 to 9, representing the following: (1) child alone, (2) mother, (3) father, (4) both parents, (5) father and child, (6) mother and child, (7) parents and child, (8) other person(s), and (9) nobody. Items were recoded to a 3-point scale to indicate decisions made by: (1) one or both parents, (2) child and one

or both parents, and (3) child alone. The 3-point scale captures the dimensions of parent-unilateral, joint, and adolescent-unilateral decision making used in the previous literature (Dornbusch et al., 1985). Autonomy is conceived of as a continuum from parent unilateral to adolescent unilateral with joint decision making as the midpoint. A continuous scale was considered most appropriate for illustrating developmental patterns. Responses of "nobody" or "other person(s)" were rare (.01% and .001% of all responses across waves) and were coded as missing.

Collapsed across occasions and reports for each child, mother and father reports were moderately correlated ($r = .50$, $p < .001$). Thus, mother and father reports of decision-making autonomy were averaged. In cases where one parent's report was missing, data from the available parent were used. The decision to average parents' reports was supported by additional analyses (available upon request) showing the same longitudinal pattern for mothers and fathers as well as high percent agreement on reports for each child and each item. Across occasions, mothers ($M = 1.94$) reported higher decision-making autonomy for secondborns than did fathers ($M = 1.77$), $t(200) = 9.75$, $p < .001$; the difference between mother ($M = 2.05$) and father ($M = 2.02$) reports of decision making for firstborns was marginal, $t(200) = 1.80$, $p < .10$.

A global decision-making index was created by averaging all items. In addition, each item was examined separately. Creation of the global decision-making index was supported by satisfactory Cronbach's alpha coefficients for each offspring at each wave (α range = .74–.83, $M = 0.79$). Higher item and index means on decision-making items reflected greater autonomy in decision making. Means for the decision-making index appear in Table 1.

Openness to supervision. At Occasion 2, mothers and fathers rated offspring's openness to supervision using 12 items adapted from the Child Check-In Scale (Kerns et al., 2001), for example, "My child returns periodically throughout the day to check in." Response options ranged from *not at all* (1) to *very often* (5). Mother and father reports were moderately correlated for firstborns ($r = .36$, $p < .001$) and secondborns ($r = .40$, $p < .001$), and were averaged. Higher scores reflected greater openness to supervision. Cronbach's alphas were satisfactory (αs = .89 and .92 for firstborn and secondborn offspring, respectively). Firstborns were perceived as easier to supervise ($M = 4.23$), on average, than secondborns ($M = 4.16$), $t(199) = -2.31$, $p < .05$. Firstborn girls were perceived as easier to supervise ($M = 4.30$) than firstborn boys ($M = 4.15$), $t(199)=2.26$, $p < .05$, but there were no differences in openness to supervision for secondborn girls ($M = 4.21$) versus boys ($M = 4.10$), $t(198) = 1.53$, *ns*.

Parents' education. We treated parents' education in years as a correlate of decision making. Both mothers' and fathers' levels of education were highly stable over time. The average correlation across all occasions was .96 for mothers and .84 for fathers. Mothers' and fathers' education was moderately correlated ($r = .45$, on average, across waves). Thus, we used the average of both parents' education at Occasion 1 ($M = 14.67$, $SD = 2.00$).

Table 1 shows correlations between the global decision-making index and continuous predictors. Parents' reports of decision-making autonomy were highly correlated across waves; Occasion 7 correlations were less strong, probably due to the smaller sample size that was an artifact of the study's design (i.e., following families until the year after the firstborn's high school graduation). Parents' education was more highly correlated with decision-making autonomy in earlier waves. Correlations between openness to supervision and decision-making autonomy were low.

Results

Analytic Plan

Multilevel modeling analyses were conducted using SAS PROC MIXED 9.1. Unconditional polynomial growth models were estimated for the global decision-making index and for each of the eight decision-making items. Correlates of gender, children's openness to supervision, birth order, and parents' education were examined in each model.

Our nested data design called for three levels. The *Level 1*, or within-person, model captured predictors of intraindividual change in decision making over time, and time (defined as age of the child) was the unit of analysis. Time was centered at age 10, the earliest age at which both siblings were surveyed. *Level 2* captured the between-sibling (or within-family) effect, and thus the unit of analysis was individual siblings (i.e., firstborns, secondborns). Effects estimated at Level 2 were gender (girl = 0, boy = 1), birth order (firstborn = 0, secondborn = 1), openness to supervision (mean centered), and interaction terms involving those variables. *Level 3* included parents' education (mean centered) as a between-family effect (shared by both offspring).

We estimated a series of models, beginning with unconditional growth models, to describe change in global decision making and decision-making types. Prior to adding predictors to the global decision-making index model, intraclass correlation coefficients revealed substantial variance at each level: Seventy-four percent of the variance at Level 1 (within person) was unshared, and 48% of variance at Level 2 (between siblings) was unshared. Restricted maximum likelihood estimates were used for reporting model parameters and assessing the significance of random effects. As each correlate was added to the models, interactions were tested with fixed effects of time, birth order, and gender. Nonsignificant interactions were pruned before testing additional effects.

Pattern of Change for Global Decision-Making Index

The overall pattern of change for the global decision-making index was a positive cubic effect of age (see Table 2 and Figure 1). The best fitting unconditional growth curve called for a random linear term at Level 3 and a random intercept at Level 2; in other words, a linear slope was estimated for each family and an intercept was estimated for each child.

As Figure 1 illustrates, parents' reports of youth input into decision making increased gradually in middle childhood (age 9–11), remained relatively flat across early adolescence (age 11–13), and increased more steadily across middle adolescence (age 13–15). After age 15, the curve rose steeply, indicating that adolescents began to experience greater autonomy in decision making. Thus, the overall pattern was a gradual yet steady increase in decision making across middle childhood through middle adolescence, followed by a rapid increase in

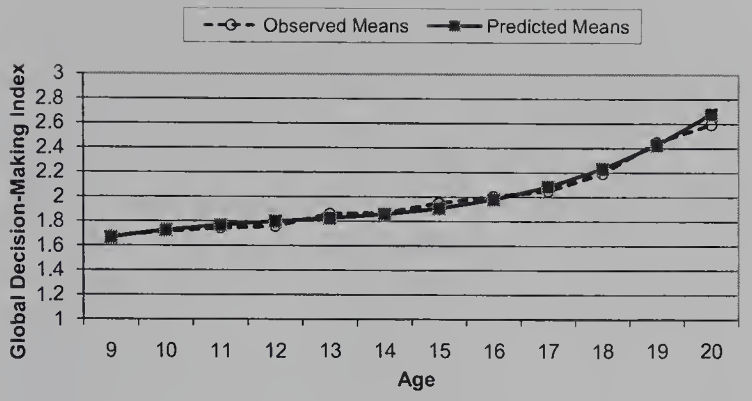

Figure 1. Average trajectory and observed means for global decision-making index by age.

decision-making autonomy in middle to late adolescence. The decision-making scale ranged from 1 to 3, with a score of 2 indicating joint parent–offspring decision making. At age 18 and after, mean levels of decision making approached but did not reach full autonomy, suggesting that joint decision making between parents and adolescents remained normative in most domains.

Mean Differences for Decision-Making Items

After specifying the growth curve for the decision-making index, we turned to item-level analyses. As described above, social domain theory posits different levels of decision-making autonomy depending on the domain. To test for overall level differences, we averaged each item across all occasions, and conducted repeated measures analyses of variance (ANOVAs) separately on parents' reports for firstborns and secondborns, repeating on the eight decision-making domains (means shown in Figure 2). Using contrast statements, means for each domain were contrasted with every other domain. Given the 28 comparisons for each child, we used a stringent error rate of $p < .001$ to evaluate significant differences.

For firstborns, all means were significantly different from the others with a few exceptions: Decision-making means for schoolwork ($M = 2.21$), activities ($M = 2.20$), and money ($M = 2.14$) were not significantly different, and means for money and social life ($M = 2.13$) were not different (see Figure 2). A similar pattern emerged for secondborns, yet fewer differences were found: Decision making for money ($M = 2.06$) was not significantly different from means for appearance ($M = 2.07$); schoolwork ($M = 1.96$), activities ($M = 1.98$), and social life ($M = 1.97$) were not different; and health ($M = 1.64$) was not different from curfew ($M = 1.68$).

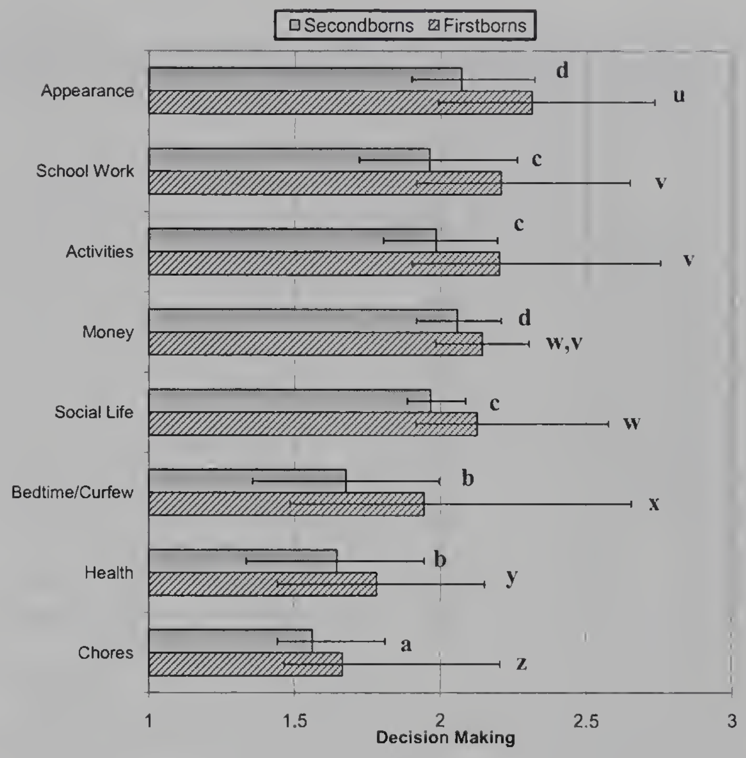

Figure 2. Across-time decision-making item means for firstborn and secondborns.

Note. Means represent averages pooled across seven occasions. Bars represent range of change over time for each item. Secondborn differences (shaded bars) of $p < .05$ are denoted by a, b, c, and d. Firstborn differences (striped bars) of $p < .001$ are denoted by u, v, w, x, y, and z.

In accordance with the predictions of social domain theory (Smetana, 1995; Smetana et al., 2004), the personal domain of appearance had the highest mean level of autonomy compared to all other domains for firstborns ($M = 2.31$). As expected, low levels of autonomy were found for the prudential domain of health for both children (see Figure 2). Unexpectedly, however, autonomy was lower for chores than for health for both firstborns and secondborns. As hypothesized, means for multifaceted decisions generally fell in between highest means of the personal domain and lowest means of the conventional and prudential domains. For secondborns, however, decision-making autonomy for money was as high as the personal domain of appearance, and autonomy for curfew was as low as the prudential domain of health.

Growth Curves by Decision-Making Type

We then examined growth curves by decision type to determine whether developmental trajectories differed by decision-making domain. Fixed and random effects for final models are shown in Table 3. Figure 3 depicts patterns in predicted means for parents' reports of decision-making

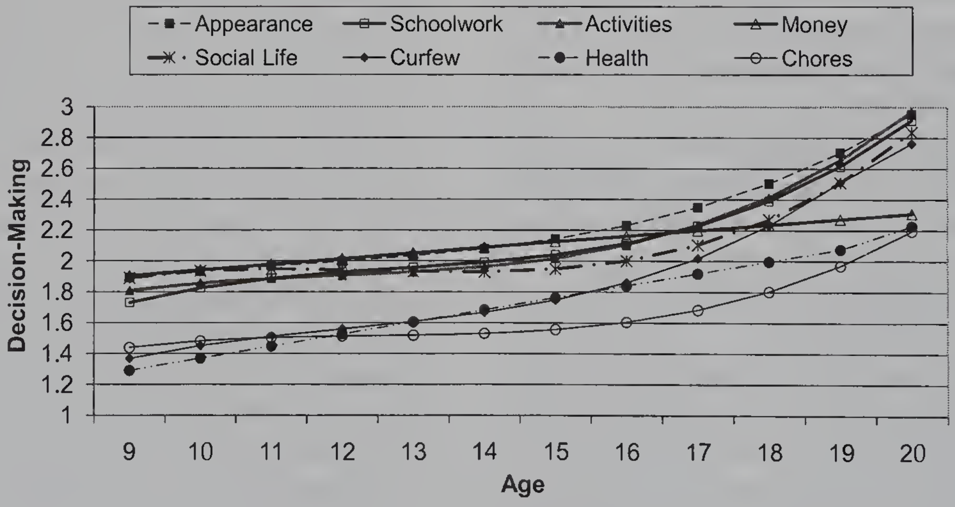

Figure 3. Developmental trajectories of decision making by item. *Note*. Predicted means from growth curve models are displayed.

items by age. Unconditional growth curves revealed that six of eight decision-making items followed a cubic pattern, as shown by significant fixed effects of age up to the cubic polynomial. Consistent with the global decision-making index, these curves were relatively stable in middle childhood, increased gradually during early and middle adolescence, and increased sharply during late adolescence. Only decisions made about money and health followed a different, linear pattern, with parents' reports of autonomy in decisions of these types increasing gradually and steadily from ages 9 to 20.

Item-level trajectories elaborated on the findings of average level differences reported above. Items seemed to form two groups reflecting higher and lower autonomy in middle childhood and again in late adolescence (see Figure 3); these observations were supported by repeated measures ANOVAs of mean differences by item at the beginning (ages 9–11) and end (ages 17–20) of the trajectories. In middle childhood, means for chores, health, and curfew fell close to parent-unilateral decision making ($M = 1.43$, $SD = 0.29$), reflecting low autonomy. The remaining items reflected high autonomy in middle childhood, approaching joint decision making ($M = 1.87$, $SD = 0.27$). Decision types that started high tended to remain higher in autonomy across time, and types that started low tended to remain lower in autonomy across time, with two exceptions. In late adolescence, decisions about money were still made jointly. Thus, in late adolescence, chores, money, and health reflected joint decision making on average ($M = 2.01$, $SD = 0.28$). Decisions about curfew started low in autonomy ($M = 1.37$ at age 9) but showed high autonomy in late adolescence ($M = 2.70$ at age 20), exhibiting substantial change over time. Overall, decisions regarding curfew, social life, activities, schoolwork, and appearance, when averaged in late adolescence, fell between joint decision making and adolescent-unilateral decision making ($M = 2.36$, $SD = 0.38$).

Correlates of Decision Making

To address our third goal, we examined youth characteristics and parents' education as correlates of parents' reports of global decision making. The final global decision-making model (see Table 4) explained 31% of within-person (Level 1) variance and 33% of between-sibling (Level 2) variance.

There was a significant main effect of gender on global decision making: Parents reported more decision-making autonomy for girls than for boys, and girls were higher, on average, by a factor of .04 units. Openness to supervision was positively associated with parent reports of global decision-making autonomy: For each ease of supervision unit above average, decision-making autonomy was higher on average by .06 units. Parents' education was significantly and positively related to global decision-making autonomy. For each year of parents' education over the sample average, decision making was higher on average by .01 units. The effects of gender, openness to supervision, and parents' education were consistent over time and did not interact with other predictors.

Turning to birth order, a significant main effect of birth order indicated that parents reported greater autonomy for secondborns than firstborns at age 10 ($\beta = .16$, $p < .001$). This birth order effect was qualified by interactions with linear, quadratic and cubic age effects (see Table 4). These effects indicated a significant statistical test of different age-related trajectories for firstborn and secondborn siblings: Firstborns showed a clear cubic pattern, like the average decision-making trajectory described above. In contrast, secondborns increased gradually and linearly in decision-making autonomy with age. Although secondborns had higher decision-making autonomy than firstborns at age 10, this birth order difference lessened with age (see Figure 4a). Reestimating the model with the intercept at ages 13 ($\beta = .01$, *ns*), 15 ($\beta = .04$, $p < .01$), and 18 ($\beta = -.02$, *ns*) confirmed the attenuated effect of birth order on decision-making autonomy with age.

To reconcile our findings with the extant literature, we contrasted the effect of birth order when siblings were *the same age* with the effect of birth order when parents were asked at *the same occasion* about each offspring's decision-making autonomy. To conduct this analysis, we treated occasion as the metric of time instead of age. After first fitting an unconditional growth model to decision-making

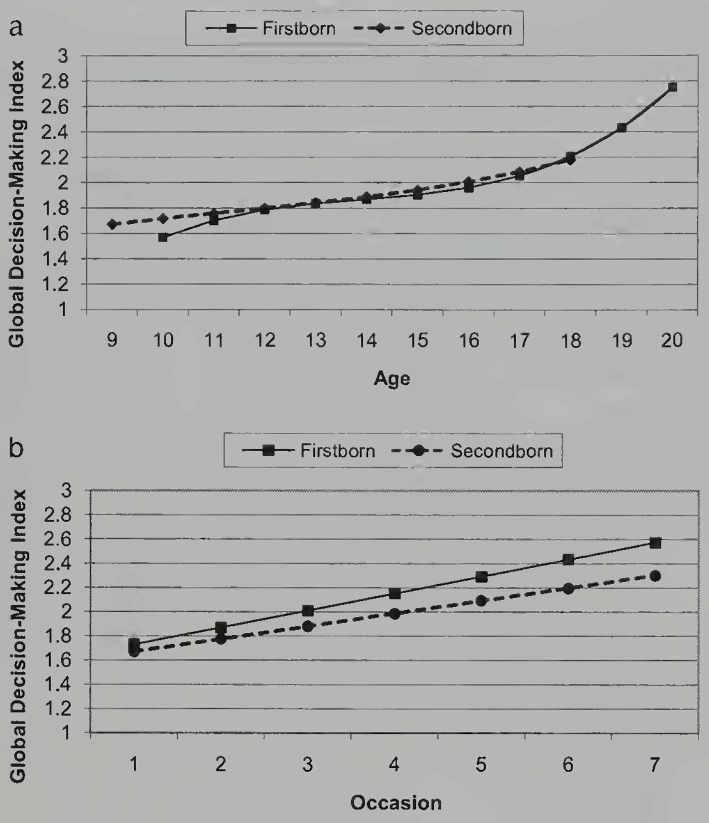

Figure 4. Birth Order × Age (a) and Birth Order × Occasion (b) interaction for global decision-making index.

autonomy by occasion, we entered birth order and the birth order by occasion interaction. Occasion was centered at the first occasion, which was most comparable to centering (age 10) in the age-based model. The best-fitting unconditional growth curve was a fixed linear effect, with a random Level 2 intercept and random linear slope at Level 3.

In the occasion-based model, parents reported significantly higher decision-making autonomy for firstborns at Occasion 1 than for secondborns at the same occasion by a factor of .06 units. This birth order effect was qualified by an interaction with occasion (see Figure 4b). The interaction indicated that the difference between siblings, favoring firstborns, increased across measurement occasions. Thus, although secondborns had higher decision making than firstborns when measured at age 10 and this effect became smaller with time, firstborns had higher decision making than secondborns at the first occasion, and this effect became larger with time. Firstborns reached the oldest ages in the study (19 and 20; the year after high school graduation) and showed steep increases in autonomy at these ages (see Figure 4a), whereas secondborns were not surveyed at these ages. This difference helps to explain why firstborns had greater decision-making autonomy on average across the study compared to secondborns (Figures 2 and 4b) and why the overall pattern looks more similar to the firstborn trajectory (Figure 1). Yet during middle childhood, parents reported more autonomy for secondborns than firstborns.

Discussion

This study provides a comprehensive longitudinal examination of youth decision-making autonomy in European American families from the perspective of parents. Developing autonomy is a fundamental task of middle childhood and adolescence (Erikson, 1968), and part of the developmental process involves mothers and fathers exercising authority and negotiating control with children (e.g., Smetana, 1995). Thus, mother and father reports of youth decision-making autonomy are important sources for information about family processes. Rather than finding one normative developmental pattern, our study charted variability in the development of decision-making autonomy that depended on decision domain as well as birth order. The findings from parents' reports of global and specific types of decision making enhance our understanding of the development of behavioral autonomy across middle childhood and adolescence and its correlates. In concluding, we summarize the developmental patterns, couch our findings in social domain theory, review the correlates of decision making, discuss limitations, and point to directions for future research.

Overall Developmental Patterns

Global decision-making autonomy increased gradually from middle childhood through adolescence, and showed a steep increase in late adolescence after age 15. This pattern adds specification to the past literature documenting increases in behavioral autonomy in adolescence (Dornbusch et al., 1985; Dornbusch et al., 1990; Gutman & Eccles, 2007; Smetana et al., 2004). For both older and younger siblings, the period spanning middle and late adolescence, from age 15 to 20, was characterized by higher autonomy compared to middle childhood and earlier adolescence.

Analyses of both global and domain-specific decision-making trajectories revealed that joint decision making was normative in our sample across middle childhood and adolescence. Five of the eight decision-making items showed joint decision making starting in middle childhood, and means remained at or below joint decision making for money, health, and chores between ages 17 and 20. The latter findings confirm that parents still have input into some offspring decisions in late adolescence. In middle childhood, joint decision making is not always a given, as our findings revealed that children, before adolescence, had little input in decisions about chores, curfew, and health. Many studies have suggested that joint decision making between parents and offspring has positive implications for adolescents' adjustment (e.g., Lamborn et al., 1996; Peterson et al., 1999; Steinberg et al., 1989). Moreover, behavioral autonomy is defined by independent decision making tempered with support from family and others (Collins et al., 1997; Hill & Holmbeck, 1987). Based on a person–environment fit perspective (Eccles et al., 1991), an ideal family context should provide levels of control and autonomy that entail not giving too much autonomy in middle childhood and not giving too little in late adolescence; though needing replication in other samples, the overall developmental trajectory found for parents' reports in our sample reflects such a pattern.

Social Domain Theory

The tenets of social domain theory were generally supported by our analyses of level differences as a function of decision domain. For both firstborn and secondborn siblings, decisions in the personal domain garnered the most autonomy, decisions in the prudential and conventional domains garnered the least, and multifaceted domains typically fell in the middle. Youth had lower autonomy in decisions about chores than about health, and developmental trajectories also showed that autonomy for decisions about chores was lower than for decisions about health across adolescence. These findings deviated from social domain theory's prediction of lowest autonomy levels for prudential decisions, yet autonomy for health decisions was lower than other domains, as predicted. Findings for the conventional domain of chores were consistent with the findings of Smetana et al. (2004) that autonomy levels were similar for prudential and conventional decisions, that mothers and adolescents tended to view conventional domains as parent decisions, and that mothers' reports of youth autonomy in conventional decisions (i.e., chores, how to talk to parents, language, and manners) remained low over time. Mean differences in decision types for secondborns were not as strong or as consistent with social domain theory as were findings for firstborns, likely because decision-making autonomy was lower, on average, across domains for secondborns.

Item-level developmental trajectories of decision-making autonomy showed variability in terms of growth patterns. Unlike the majority of decision types that followed a cubic pattern of change with age, autonomy for decisions about health and money increased gradually in a linear fashion. Health decisions fit with the conceptual argument that when families negotiate lower levels of adolescent autonomy on prudential decisions, autonomy in these types of decisions also increases at a slower rate across adolescence. The linear increase in autonomy for decisions about money—with means hovering around joint decision making across the study—represents a novel finding to be considered in future studies of social domain theory. Previous work has measured aspects of decisions about money more specifically and categorized them in the personal domain (e.g., Smetana et al., 2004), yet this distinct linear pattern was not consistent with patterns for either the multifaceted or personal domains. It is unclear whether our findings regarding money warrant a substantive conclusion or represent a measurement issue, as the general nature of our question may be responsible for this finding. Future research should consider differentiating the sources of adolescents' money (e.g., job earnings, allowance, gifts), as these sources may relate to families' decisions about autonomy with money.

Overall, similar developmental trajectories emerged for the majority of decision-making types, supporting the use of a global decision-making index. However, decisions about money and health followed linear trajectories, which diverged from the general pattern and thus represent novel findings. Indeed, this study provides the first findings of trajectory differences in decision domains across middle childhood and adolescence and informs future theorizing about domain-specific developmental changes in decision-making autonomy. Level differences in item means and trajectories were prominent, yet necessarily obscured, when decision making was examined as a global index. In short, the global and specific approaches convey important but distinct information about decision-making autonomy.

Correlates of Offspring Decision Making

Parents reported greater decision making for daughters, for youth initially viewed as easier to supervise, and for youth with better educated parents. Furthermore, different age-related trajectories in decision-making autonomy emerged for firstborn and secondborn siblings. Each of these findings is a novel addition to the literature.

Our results converged with those of several prior studies (Bumpus et al., 2001; Flanagan, 1990) in documenting that girls have more autonomy in decisions than do boys. Girls may have greater decision-making autonomy as a function of their relative maturity (Bumpus et al., 2001; Flanagan, 1990). Our results are inconsistent with studies that found no gender differences (e.g., Fuligni & Eccles, 1993; Smetana et al., 2004) or differences favoring boys (e.g., Dornbusch et al., 1990). Differences across studies may reflect sample variation in terms of families' gender role traditionality, and autonomy in global or domain-specific decisions may depend on gender socialization (e.g., Bumpus et al., 2001; Crouter, Whiteman, McHale, & Osgood, 2007).

As expected, openness to supervision in middle childhood predicted greater decision-making autonomy. Being perceived as easy to supervise may indicate to parents that youth can be trusted and are ready to handle more autonomy (Fuligni & Eccles, 1993; Kerns et al., 2001). This effect was moderate in effect size (Cohen's $d = .4$), and as openness to supervision was only measured once in middle childhood, its predictive power suggests that this characteristic matters for autonomy development.

Our finding of a positive association between parents' education and youth decision-making autonomy is consistent with some prior work (Dornbusch et al., 1990; Nucci et al., 1996) and with the link between social class and autonomy found in the broader parenting literature (cf. Parke & Buriel, 2006). Our findings did not support Lareau's (2003) perspective that parents of lower social status offer more autonomy to encourage ''natural growth'' in their children. Instead, our findings suggest that parents with less formal education may emphasize parental authority, perhaps to create a safer environment (Parke & Buriel, 2006), whereas more educated parents emphasize self-direction (Kohn, 1977; Nucci et al., 1996). Further research is needed to identify the mechanisms underlying this association.

Our longitudinal within-family design enabled us to reconcile discrepancies between theory and empirical findings regarding birth order and autonomy. The learning from experience perspective (e.g., Whiteman et al., 2003) and sibling differentiation theory (e.g., Sulloway, 1996) posits greater autonomy for secondborn compared to firstborn children. Empirical findings that older siblings have more decision-making autonomy than younger siblings have been cross-sectional (Bumpus et al., 2001; Small et al., 1988). Consistent with these results, when we used occasion of measurement as the time metric, firstborns had higher decision-making autonomy than secondborns. In contrast, by treating *age* as the time metric, that is, when siblings were compared at the same age, we found that secondborns had greater autonomy in decisions than firstborns, primarily in middle childhood. The latter finding provides some support for the idea that parents relax expectations for secondborns and that younger offspring seek autonomy in an effort to set themselves apart from older siblings. These birth order effects were particularly prominent in middle childhood and early adolescence, as all youth increased in decision-making autonomy over time. Firstborns tended to increase in decision-making autonomy in a cubic fashion much like the overall pattern whereas secondborns' autonomy increased gradually and linearly. Overall, these findings suggest that developmental patterns of decision-making autonomy may be dependent on the family context. The different trajectories may be in part explained by the later ages that firstborns, in contrast to secondborns, reached in our study. Further investigations in other samples are needed to replicate these within-family patterns.

Limitations and Directions for Future Research

This study highlights the merits of longitudinal, within-family designs for understanding how developmental patterns of autonomy unfold over time. An important next step for future research is extending the examination of autonomy further into young adulthood. Arnett (2000) reported that a key criterion for being considered an adult is making independent decisions, yet today's young adults are only ''semi-autonomous.'' Data are needed to examine the circumstances under which joint decision making versus complete autonomy becomes the norm in young adulthood. More data could also demonstrate whether the trajectory for secondborns conforms to firstborns' pattern in late adolescence or whether it remains distinct. Future research into decision-making autonomy may benefit from using measures with a larger range than our 3-point scale in order to capture developmental shifts with greater sensitivity.

Our findings supported and extended the tenets of social domain theory, yet several questions remain unaddressed. Unexpectedly, based on previous work (Smetana et al., 2004), the conventional domain of chores showed a steep rise in late adolescence rather than increasing gradually. Perhaps parents are more restrictive of autonomy in conventional domains like chores in middle childhood and earlier in adolescence, an idea needing further investigation. Though, as predicted, multifaceted decisions showed autonomy levels lower than those in the personal domain and higher than those in conventional and prudential domains, multifaceted decisions represent an ambiguous category that deserves further discussion among social domain theorists. For example, Baumrind (2005) suggests that multifaceted decisions should be classified based on the domain (e.g., conventional, prudential) that is mixed with the personal domain to avoid ambiguity. Our domain-specific findings are noteworthy given their compatibility with social domain theory despite the general nature of our decision-making items, yet replication of these longitudinal findings with other measures would increase confidence in the results.

Other studies have pointed to variation in autonomy reports depending on which family member's perspective is examined (Smetana, 1995; Smetana et al., 2004), and this is an area also in need of further investigation. Although a strength of our study is the combined use of both mother and father reports, as clearly both mothers and fathers are instrumental in negotiating youth decision-making autonomy and related family processes (cf. Parke & Buriel, 2006), the combined index of mothers and fathers may obscure important variability between parents in their perspectives on youth decision-making autonomy. Much of the previous research on decision-making autonomy has used adolescents' reports (e.g., Dornbusch et al., 1990; Fuligni & Eccles, 1993; Lamborn et al., 1996), yet further investigation of the congruence between mother, father, and adolescent reports could shed light on the family processes associated with negotiations of decision-making autonomy (see Smetana et al., 2004; Smetana et al., 2005).

Youth decision-making autonomy is likely to be best understood when studied from an ecological perspective and in cultural context. Thus, future research should implement longitudinal within-family designs to study a more diverse array of families than we were able to study here. Findings from our middle- and working-class European American sample may not generalize to other racial, ethnic, social class, regional, or cultural groups or to dynamics in single-parent or multi-generational families. A burgeoning body of research has begun to consider adolescent autonomy in a wide range of cultural contexts (e.g., Huiberts, Oosterwegel, VanderValk, Vollebergh, & Meeus, 2006; Love & Buriel, 2007; Phinney, Kim-Jo, Osorio, & Vilhjalmsdottir, 2005). Longitudinal work is now needed to examine the developmental patterns of decision-making autonomy in these various family and cultural contexts, taking advantage of designs that permit between- as well as within-family comparisons.

Children's Sensitivity to the Conventionality of Sources

Gil Diesendruck and Nurit Carmel
Bar-Ilan University

Lori Markson
Washington University

Four studies examined preschoolers' sensitivity to agents' knowledge of conventional forms. Three- to 4-year-olds heard a speaker apply either conventional or wrong labels to familiar objects (Studies 1 and 2, *N* = 57) or peculiar but correct labels (Study 3, *N* = 19). When then asked by the speaker for the referent of a novel label, children exposed to an accurate labeler were more likely to choose an unfamiliar object than children exposed to an inaccurate labeler. Study 4 (*N* = 36) replicated these findings using object functions instead of labels. Children hold an assumption of conventionality with regard to both object labels and functions, but they are selective in their application of this assumption toward agents who are knowledgeable of conventions in these domains.

An implicit assumption adults make when communicating is that their partners in a conversation share with them the knowledge that there are certain preferred linguistic forms to express certain meanings. In fact, adults expect their partners to use these forms when intending to express certain meanings and consequently draw inferences about their partners' communicative intents based on their choice of forms. Clark (1988, 1990) defined this basic assumption as the principle of conventionality, and an ensuing inference based on the use of nonconventional forms as the principle of contrast—namely, that if a speaker uses a linguistic form that is different from the conventional one expected, it is probably because the speaker has a contrastive intent in mind.

A number of recent studies show that from a young age, children too seem to rely on an assumption of conventionality when interpreting people's utterances. In fact, studies indicate that already by 3 years of age, children manifest a nuanced assumption of conventionality, such that they are capable of modulating when and when not to apply this assumption (see Kalish & Sabbagh, 2007, for a review).

Most studies of children's assumption of conventionality regarding words have investigated it in the context of its contrastive implication. A widely studied situation in which this implication is manifest is when children are presented with two objects, one familiar and one unfamiliar, and are simply asked to point to the referent of an unfamiliar noun. Based on a principle of conventionality, children in such a situation should assume that the speaker knows the conventional name of the familiar object, and they should thus expect speakers to use that name if he or she intends to refer to that object. According to a principle of contrast, children should reason that if a speaker uses a different unfamiliar name, it is probably because she has a different object in mind. That is, children should select the unfamiliar object as the referent of the unfamiliar name. And indeed, that is what a number of studies with preschool children have found (Markman & Wachtel, 1988; Merriman & Bowman, 1989).

In itself, however, this type of response is also consistent with proposals arguing that children have a number of constraints that guide their word learning. In particular, the response is consistent with a mutual exclusivity bias (Markman & Wachtel, 1988) and a novel-name nameless-category principle (Golinkoff, Mervis, & Hirsh-Pasek, 1994). Two unique predictions of the pragmatic reasoning process exposed above are that children's inferences of contrast should be contingent on:

This research was partly funded by an internal grant from Bar-Ilan University's Rector's Office. We would like to thank the teachers, parents, and children for their participation in the studies. We are also grateful to the following research assistants for their help with data collection and coding: Itai Cohen, Anat Grosz, Elisheva Hecht, Avital Rozensweig, Yael Tadmor, and Amiad Tauber.

(a) whether or not the *form* used is thought to be conventional and (b) whether or not the *speaker* or *user* is believed to know the form.

Regarding the forms about which children assume conventionality, studies have found that children believe that common nouns are known by other speakers of their language, but arbitrary facts about objects, proper nouns, or people's preferences and goals are not. For instance, in Diesendruck and Markson (2001), an experimenter showed 3- to 4-year-old children two novel objects and taught them either a novel label or a novel fact for one of the objects. A puppet, who was either present or absent during this introduction, then asked children to select the object associated with a different novel label or fact, accordingly. Diesendruck and Markson found that children avoided assigning two facts for an object only when the puppet was present during the experimenter's introduction of the fact but not when he was absent. In contrast, children avoided assigning two labels for an object both when the puppet was present and when he was absent. In fact, when directly asked whether or not the puppet knew the labels given by the experimenter, most children replied that the absent puppet did. These findings suggest that children presuppose that speakers of a language know the names of objects in their language but hold no such presupposition about arbitrary facts associated with objects. Children assumed the puppet knew the conventional names of objects and inferred that if he asked them for the referent of a different name it was because he had a different object in mind. Using a similar methodology, Diesendruck (2005) found that preschoolers assume that speakers know the common nouns associated with objects but not the proper nouns (see also Birch & Bloom, 2002). In other words, only certain words are believed to be conventional, thus warranting an inference of contrastive intents. Finally, Henderson and Graham (2005) found that 2-year-olds assume absent adults share with an experimenter knowledge of the novel names of objects but not the experimenter's preferences toward the objects (see also Buresh & Woodward, 2007; Graham, Stock, & Henderson, 2006, for similar findings with younger children).

Regarding the second pragmatic prediction mentioned above, there are a number of studies indicating that already by 2 years of age, children are sensitive to speakers' knowledge state when interpreting their utterances (Akhtar, Carpenter, & Tomasello, 1996; Diesendruck, Markson, Akhtar, & Reudor, 2004; Sabbagh & Baldwin, 2001). Only one study, however, has attempted to address whether children's inference of contrast is modulated by speakers' presumed knowledge of language. Diesendruck (2005) presented pairs of novel objects to Hebrew-English bilingual 3- to 4-year-olds. An experimenter labeled one of the objects with a novel English label, and then a puppet—who was present during the labeling event—asked children for the referent of a novel Hebrew label. The crucial manipulation was that for half of the children, the puppet was introduced—and behaved—as a monolingual Hebrew speaker, and for the other half the puppet was introduced as being a Hebrew-English bilingual. Diesendruck found that children selected the yet unlabeled object when the puppet was bilingual but selected randomly between the two objects when the puppet was monolingual. In other words, children seem to have reasoned that if a monolingual speaker of Hebrew hears an experimenter teach them an English novel word, then the monolingual speaker does not necessarily know that foreign word. Consequently, if that speaker asks children for the referent of a novel Hebrew word, they infer that the speaker might be referring to either object—not necessarily the object that did not have an English label applied to it. In turn, if a bilingual speaker who has heard the experimenter use an English label chooses to use a different label—even if in a different language—then children assume that he knows that English label and thus take the speaker's use of a different label to imply a contrastive intent.

Whereas the findings from this latter study are consistent with the prediction that children assume conventionality only with respect to people who are knowledgeable about the conventions of a language, children in the above study did not get any *direct* evidence for the speakers' knowledge of the relevant conventions. In fact, the above study did not manipulate whether or not the speakers were knowledgeable about *conventional* linguistic forms but rather whether or not the speakers were knowledgeable about the *language* in general. In other words, we cannot determine unambiguously from that study that children's responses derived specifically from the fact that the monolingual speaker violated conventionality per se. The rationale behind Diesendruck's (2005) study was that children might have presumed that a monolingual Hebrew speaker would not have understood the English interaction between the experimenter and the child, and thus would not have learned the *novel label* the experimenter taught the child to one of the objects. The study did not assess, however, whether children believed either speaker knew the *familiar labels* of objects. A primary goal of the present studies was to provide children with specific evidence that certain speakers of their language do not know the conventional names of objects and that, consequently, children should withhold from applying an assumption of conventionality toward such speakers. Thus, different from the Diesendruck (2005) study, the present studies attempted to manipulate only the most relevant aspect of knowledge presupposed by the conventionality account of the disambiguation response.

The second major goal of the studies was to extend the examination of the scope of an assumption of conventionality. As reviewed above, originally, studies on children's assumption of conventionality targeted primarily the domain of language. In fact, there are some suggestions that such an assumption derives from the manner in which parents talk to children (Callanan & Sabbagh, 2004). Like linguistic forms, however, certain cultural forms are also conventionalized. For instance, the functions we attribute to objects (e.g., what forks are for) and the manner in which we use objects (e.g., how we hold forks) are different types of culture-specific knowledge that members of a community need to know and expect peers to know. In recent years, a number of researchers have suggested that, in addition to the domain of language, an assumption of conventionality seems to hold in domains such as games (Rakoczy, 2007) and object functions (German, Truxaw, & Defeyter, 2007; Siegel & Callanan, 2007). For instance, Casler and Kelemen (2005, 2007) showed that 2½-year-olds assume that objects have unique functions. In particular, upon seeing an object being used intentionally for a specific function, even 2-year-olds readily picked that object over other equally affording objects to perform that function. These studies, however, have been conducted with a variety of methodologies and age groups (see Kalish & Sabbagh, 2007, for a review) and thus do not allow for direct comparisons between domains. The present studies used almost identical methods to evaluate whether children hold an assumption of conventionality about both object labels and object functions, and whether they draw similar inferences—namely, about contrast—based on people's manifest knowledge of conventional labels and functions.

In order to address both goals described above, we adopted a methodology originally developed by Koenig and Harris (2005; Koenig, Clement, & Harris, 2004; see also, Birch, Vauthier, & Bloom, 2008; Jaswal & Neely, 2006). In Koenig et al. (2004), for instance, children were either exposed to speakers who manifested knowledge of the conventional names of objects—so-called reliable speakers—or to speakers who manifested ignorance of conventional names—so-called unreliable speakers. Koenig et al. found that 3- to 4-year-olds were more likely to subsequently learn a novel name from a knowledgeable speaker than from an ignorant one (see also Sabbagh & Baldwin, 2001). Different from all these previous studies, in the present studies, rather than assessing whether the knowledge states of speakers differentially influence children's *willingness to learn* labels from such speakers, we asked whether children within this same age range would *draw different inferences* about such speakers' communicative intents in an ambiguous context. That is, we asked whether variations in speakers' manifest knowledge of conventional forms influence the extent to which 3- to 4-year-olds respond to speakers in the manner stipulated by an assumption of conventionality.

To address the first goal, in Study 1 we familiarized 3- to 4-year-old children with two different kinds of speakers: a speaker who showed evidence of being knowledgeable about the conventional labels used to refer to familiar objects and a speaker who showed evidence of being ignorant of the conventional labels used to refer to familiar objects. Children then participated in a standard disambiguation task, in which they were presented with pairs of objects consisting of one familiar and one unfamiliar object, and the same speaker to which they had been previously exposed asked them for the referent of a novel label. The rationale is that if children's inference of contrast is contingent on them assuming that the speaker knows the conventional forms of the language, then children who had been exposed to a knowledgeable speaker should be more likely than those exposed to an ignorant speaker to select the unfamiliar object as the referent of the novel label. Study 2 replicates Study 1 with a different operationalization of speakers' knowledge. Study 3 examines a further implication of this hypothesized reasoning process.

In order to address the second goal, in Study 4 the same method described above was employed, but instead of exposing children to speakers and object labels, we exposed children to users and object functions. A recent study using a similar methodology found that just as with labels, children are more willing to learn a new function from a knowledgeable labeler of object functions than from an ignorant one (Birch et al., 2008). Here, we ask whether users' knowledge affects children's inferences about the conventionality of users. As in the first three studies, we first familiarized children with two kinds of users: a user who showed evidence of being knowledgeable about the conventional functions of familiar objects and a user who showed evidence of being ignorant about the conventional functions of familiar objects. Children then participated in a function disambiguation task, in which they were presented with pairs of objects consisting of one familiar and one unfamiliar object, and the same user to which they had been previously exposed asked them for the object to be used for a new function. The rationale is that if children infer the functions of objects via the same reasoning process deployed for object labels, then in the function disambiguation task, they should show the same differential responding to a knowledgeable and an ignorant user as that hypothesized for knowledgeable and ignorant speakers.

Study 1

Method

Participants

Participants were 33 monolingual Hebrew-speaking Israeli preschoolers, 19 boys and 14 girls (M = 3 years 10 months, SD = 4 months, range = 3 years 3 months to 4 years 5 months). Children were primarily from middle- and upper-middle-class socioeconomic backgrounds. Most children were recruited from and tested in preschools around the university. A few others were recruited from the local community and were tested at their homes. Parental consent was obtained for each child prior to participation.

Materials

In the familiarization phase, four objects highly familiar to children this age were used. The objects were: a plastic banana, a stuffed dog, a doll-size shirt, and a plastic cookie. In the disambiguation phase, eight objects were used: four familiar and four novel. The objects were arranged into pairs of familiar–novel, in such a way that the objects in each pair were similar in their color salience and size. The familiar–novel pairs were: (a) shoe–funnel, (b) car–door-stopper, (c) cup–cylinder, and (d) pen–original object created in the lab. A hand-puppet was also used to provide the labels. The experimenter manipulated the puppet, using a distinctive adult voice whenever speaking for him.

Design

Children were randomly assigned to one of two conditions, *knowledgeable* (n = 16, 7 girls and 9 boys, M_{age} = 3 years 10 months) or *ignorant* (n = 17, 7 girls and 10 boys, M_{age} = 3 years 9 months). There was neither a significant age difference nor a significant difference in the gender distribution between the two conditions. Children participated in four familiarization trials followed by four disambiguation trials.

Procedure

Prior to testing children, the experimenter came to the preschool and played with children for at least 1 hr, so that children would become comfortable with the experimenter. Once rapport had been established, the experimenter invited each child to come sit with her in a quiet area set up ahead of time in the preschool. The entire interaction—in this and all the other studies—was conducted in Hebrew (verbatim translations of what children were told are provided). The child and the experimenter sat at a table, and the experimenter introduced children to her "friend"—a hand-puppet named "Yossi." The experimenter exchanged a few greeting words with the puppet, speaking with a lower toned voice when speaking for the puppet. This introduction was meant to establish that the puppet could speak and was separate from the experimenter. After this brief introduction—which was identical for children in both conditions—the experimenter moved on to the familiarization phase.

Familiarization phase. The familiarization phase was the only phase that differed between the two conditions. In this phase, the experimenter invited the child and the puppet to play with some objects she had brought. The experimenter pulled out one object at a time from her bag and laid it on the table. The puppet looked at the object and named it three times while asserting his knowledge of what the object is (i.e., saying, "I know what this is!"). The main manipulation had to do with whether or not the labels provided by the puppet were correct. In the knowledgeable condition, the puppet labeled the objects correctly with their conventional basic-level names (e.g., upon seeing a banana, he said, "That's a banana, it's a banana; look at the banana!"). In the ignorant condition, the puppet labeled the objects incorrectly (e.g., called the banana an "apple"). After a few seconds during which the child and the puppet could play with an object, the experimenter returned the object to her bag and brought out another familiar object. Again the puppet reacted according to the child's condition. This procedure was repeated for four trials, in order to allow the child to build an assessment of the puppet's knowledge—or ignorance—of the familiar objects' names. The correct labels used for the items banana, dog, shirt, and cookie, were *banana*, *dog*, *shirt*, and *cookie*, respectively. The incorrect labels used were: *apple*, *cow*, *pants*, and *egg*, respectively. Objects were presented in four different orders, such that each object appeared in each position the same number of times across children.

Disambiguation phase. This phase was identical in both conditions. The experimenter placed the first pair of familiar–novel objects in front of the child. The puppet then looked at the child, and asked for one of the objects by using a Hebrew-sounding made-up novel label (e.g., "Can you give me the *beega*?" the other three novel labels were: *bakakhat*, *shafek*, and *geet*). Both the puppet and the experimenter refrained from looking at either one of the objects and instead maintained their gaze on the child. Once the child responded by pointing to, picking up, or handing to the puppet one of the objects, the experimenter removed the two objects, and replaced them with the next pair of familiar–novel objects. The experimenter did not provide any feedback to children about their performance, and instead commented on the game and the toys (e.g., "It's fun to play with these things, right?"). The experimenter recorded children's choices and any other verbal comments children made throughout the entire procedure. Upon completion of the four disambiguation trials, children were thanked, given a sticker in appreciation for their participation, and returned to their class.

The order of presentation of the object pairs was counterbalanced across children, such that each object pair appeared an equal number of times as the first, second, third, and fourth. The left–right placement of each object within a pair was counterbalanced within children, so that on half of the pairs, the familiar object was placed on the right side of the child, and on the other half of the pairs, the novel object was placed on the right side of the child.

Results

The main prediction was that children would be more likely to choose the novel object in response to a request made by a knowledgeable speaker than to one made by an ignorant speaker. The dependent measure used to address this prediction was the number of times (0–4) children selected the novel object as the referent of the novel label used by the puppet in the disambiguation phase.

An analysis of variance (ANOVA) with condition (knowledgeable vs. ignorant) and gender as between-subjects variables, and the participants' age in months as a covariate, on the above dependent measure revealed a main effect of condition, $F(1, 28) = 5.17$, $p < .05$, $\eta_p^2 = .16$; no effect of gender, $p > .8$; no effect of age, $p > .5$; and no interaction between gender and condition, $p > .7$. As illustrated in Figure 1, children in the knowledgeable condition ($M = 3.75$, $SD = 0.45$) were more likely than children in the ignorant condition ($M = 3.00$, $SD = 1.17$) to pick the novel object in response to the puppet's request for a novel label. Interestingly, analyses against chance (chance = 2 selections of a novel object) revealed that children in both conditions were more likely to pick the novel object than would be expected by chance: in the knowledgeable condition, $t(15) = 15.65$, $p < .001$, and in the ignorant condition, $t(16) = 3.52$, $p < .005$.

In order to evaluate children's individual pattern of responses, we classified children into two groups based on how consistently they selected the novel object. Children who selected the novel object on three or four of the four trials were considered *disambiguators*, and those who selected the novel object on two or fewer of the four trials were considered *overlap accepters*. As shown in Table 1, all of the children in the knowledgeable condition were disambiguators, whereas only 10 of the 17 children in the ignorant condition were so, $\chi^2(1, N = 33) = 8.36$, $p < .005$.

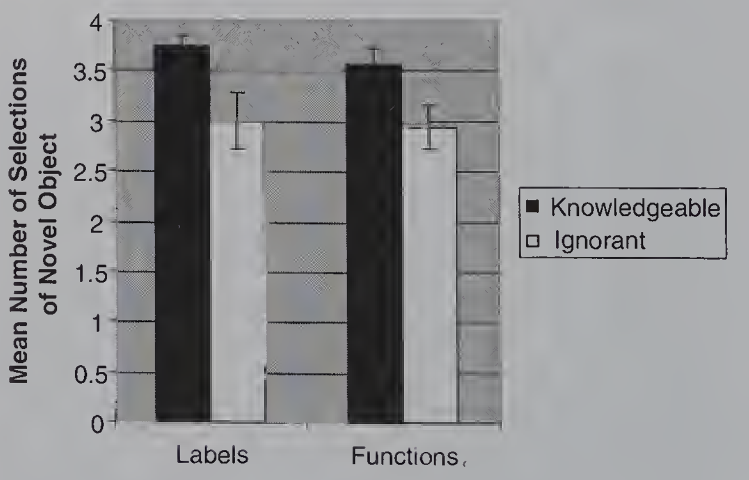

Figure 1. Mean number of selections of novel object in response to novel labels (Study 1) or new functions (Study 4).
Note. Error bars represent standard errors.

Table 1
Distribution of Children in Terms of Response Patterns Across Conditions, in Studies 1, 2, and 4

	Study 1		Study 2		Study 4	
Pattern/condition	Know	Ignor	Know	Ignor	Know	Ignor
Disambiguators	16	10	8	3	16	12
Overlap accepters	0	7	4	9	2	6
N	16	17	12	12	18	18

Note. Know = knowledgeable; Ignor = ignorant.

Finally, in order to directly address a potential interaction between age and condition, we broke down the participants into two age groups according to the median age. This new "age group" variable was then entered into an ANOVA on children's selection of the novel object, with condition as the other between-subjects variable. The interaction between these variables was not significant, $p > .7$.

Discussion

The goal of Study 1 was to investigate whether children would rely on a speaker's preestablished knowledge or ignorance of conventional object names when later interpreting his request for the referent of a novel label. We hypothesized that children exposed to a speaker who had manifested knowledge of conventional object names, compared to those exposed to a speaker who had manifested ignorance of conventional object names, would be more likely to uphold conventionality regarding such a speaker and thus expect him to use conventional labels to refer to familiar objects. Such a knowledgeable speaker's use of a nonconventional (novel) label would thus be more likely to be inferred as manifesting a contrastive referential intent than when an ignorant speaker does so. Namely, a knowledgeable speaker's, but not an ignorant speaker's, use of a novel label would likely indicate his intent to refer to an unfamiliar object.

The results of Study 1 were consistent with this hypothesis. Children were more likely to select a novel object as the referent of a novel label when the speaker asking for the novel label had previously manifested knowledge of the conventional names of objects than when the speaker manifested ignorance of conventional names. These results show that by 3 years of age, children monitor speakers' knowledge of the conventional forms existent in their language and use this information to draw inferences about speakers' referential intents. This adds to Diesendruck's (2005) findings on children's responses to bilingual versus monolingual speakers and reveals that not only can children monitor whether or not a speaker knows the language in general but they in fact react differently to a speaker of the language depending on how knowledgeable or ignorant of conventional object labels the speaker has proven to be.

A possible alternative interpretation of these findings is that children's responses did not derive from assessments of the speakers' knowledge. Rather, children might have simply noticed that one speaker uses the labels that are expected, and the other does not. Consequently, when in the disambiguation phase the ignorant speaker used an unusual label, children might have simply inferred that it is plausible that here too he was referring to the familiar object. According to this interpretation, children might have conceived of the ignorant speaker not so much as lacking knowledge of familiar object names but rather as being silly or joking. Such an interpretation might have been especially exacerbated if children thought it unlikely that a "mature" speaker of a language—as the puppet in Study 1 was portrayed to be—would not know the names of familiar objects.

In order to address this alternative interpretation, in Study 2 we attempted to create scenarios in which a speaker's ignorance would: (a) seem more ecologically plausible and, consequently, (b) less likely to be interpreted as manifesting playfulness.

Study 2

Study 2 followed nearly the identical design and procedure as Study 1 except for two modifications. First, instead of introducing the puppet as a friend of the experimenter, the experimenter described the puppets as children. Crucially, in the ignorant condition, the puppet was described as a young child who had just started learning Hebrew. In the knowledgeable condition, the puppet was described as a school-aged child who already knows a lot of Hebrew. It was expected that this modification would make the behavior of the speaker in the ignorant condition more plausible to the participants. Second, in order to directly assess children's appraisal of the speakers' behaviors, at the end of the experimental trials, the experimenter asked children explicitly about whether they thought the speaker knew the names of the familiar objects in the disambiguation phase and whether they thought the speaker was joking when he labeled the familiar objects in the familiarization phase. These questions served as manipulation checks to verify that children's answers in the two different conditions derived primarily from their assessments of speakers' knowledge states rather than differences in speakers' playfulness.

Method

Participants

Participants were 24 monolingual Hebrew-speaking Israeli preschoolers, 13 boys and 11 girls (M = 3 years 10 months, SD = 5.5 months, range = 3 years 0 months to 4 years 7 months). Children were primarily from middle- and upper-middle-class socioeconomic backgrounds. Children were recruited from, and tested in, their preschools. Parental consent was obtained for each child prior to participation.

Materials

The same materials used in Study 1 were used in Study 2.

Design

Children were randomly assigned to one of two conditions: *knowledgeable–older child* (n = 12, 6 girls and 6 boys, M_{age} = 3 years 9 months) or *ignorant–younger child* (n = 12, 5 girls and 7 boys, M_{age} = 3 years 11 months). There was neither a significant age difference nor a significant difference in the gender distribution between the two conditions. As in Study 1, children participated in four familiarization trials followed by four disambiguation trials.

Procedure

The procedure in Study 2 was almost identical to that of Study 1 except for two modifications: one having to do with the presentation of the puppets and the second having to do with the addition of two questions at the end of the procedure.

Children in the knowledgeable condition in Study 2 were introduced to a puppet described as being an older child. Children were prompted about their acquaintance with children who already attend school, and thus know a lot of Hebrew, and were told that Yossi, the puppet, is like these children. In contrast, children in the ignorant condition were told that the puppet is a young child and that he has just started learning Hebrew. After the introduction of the puppet, the procedure continued exactly as in Study 1. That is, the puppet named, either correctly (knowledgeable condition) or incorrectly (ignorant condition) the four familiar objects in the *familiarization phase* and then asked children for the referents of novel labels in the four trials of the *disambiguation phase*. The same counterbalancing precautions taken in Study 1 were undertaken in Study 2.

After children completed the disambiguation phase, the experimenter pointed to the familiar object in the last trial of that phase (e.g., a pen) and asked children whether they thought the puppet knew the name of the object (e.g., "Do you think that Yossi knows that this is called a 'pen'?"). Children's yes–no answers were recorded. The experimenter then brought out one of the familiar objects from the familiarization phase (e.g., the dog), reminded children what the puppet had called it (e.g., "cow" in the ignorant condition), and asked children if they thought the puppet was joking when he said that. Again, children's yes–no responses were recorded.

Results

The main prediction was that children would be more likely to choose the novel object in response to a request made by a knowledgeable speaker than to one made by an ignorant speaker. The dependent measure used to address this prediction was the number of times (0–4) children selected the novel object as the referent of the novel label used by the puppet in the disambiguation phase.

An ANOVA with condition (knowledgeable vs. ignorant) and gender as between-subjects variables, and the participants' age in months as a covariate, on the above dependent measure revealed a main effect of condition, $F(1, 19) = 14.90$, $p < .005$, $\eta_p^2 = .44$; an effect of gender, $F(1, 19) = 6.97$, $p < .05$, $\eta_p^2 = .27$; but no effect of age, $p > .3$, and no interaction between gender and condition, $p > .2$. The effect of gender resulted from boys ($M = 2.69$, $SD = 1.32$) being more likely than girls ($M = 1.64$, $SD = 1.36$) to choose the novel object. In terms of the condition effect, children in the knowledgeable condition ($M = 3.00$, $SD = 1.05$) were more likely than children in the ignorant condition ($M = 1.42$, $SD = 1.31$) to pick the novel object in response to the puppet's request for a novel label. Analyses against chance (chance = 2 selections of a novel object) revealed that children in the knowledgeable condition, $t(11) = 3.32$, $p < .01$, but not in the ignorant condition, $p > .1$, selected novel objects more often than expected by chance. Finally, as in Study 1, we looked at a possible interaction between age and condition by breaking down the participants into two age groups according to the median age. Here, too, we found no interaction between these factors, $p > .1$.

Analogous to Study 1, in order to evaluate children's individual pattern of responses, we classified children into two groups based on how consistently they selected the novel object. Children who selected the novel object on three or four of the four trials were considered *disambiguators*, while those who selected the novel object on two or fewer of the four trials were considered *overlap accepters*. As shown in Table 1, there were more disambiguators in the knowledgeable than in the ignorant condition, and the opposite was the case in terms of overlap accepters, $\chi^2(1, N = 24) = 4.20$, $p < .05$.

Our last set of analyses looked at children's responses to the two questions at the end of the procedure. We found that all children in the knowledgeable condition responded affirmatively to the question whether or not the puppet knew the name of the last familiar object; however, all but 1 child in the Ignorant condition, responded negatively, $\chi^2(1, N = 24) = 20.31$, $p < .001$. In turn, all children in both conditions, except for 1 in the ignorant condition, responded that the puppet was not joking when he named the familiar object in the familiarization phase.

Discussion

The results of Study 2 are consistent with our interpretation that children's responses to the requests of speakers' who had correctly versus wrongly labeled familiar objects, indeed derived from their assessments of these speakers' knowledge of conventional object names, rather than estimations of their seriousness. This finding is consistent with Koenig and Harris (2005), who found that children infrequently explained an unreliable speaker's incorrect labeling of familiar objects in terms of "pretense" or "silliness." This interpretation is also consistent with previous findings showing that children are more willing to learn new information from sources who had previously been accurate than from those who had been inaccurate (e.g., Birch et al., 2008; Koenig & Harris, 2005). Moreover, the finding that children were capable of differentiating explicitly between a knowledgeable and an ignorant puppet indicates that their responses indeed reflected their appraisal of the puppets, not of the experimenter manipulating the puppets.

An unexpected finding from Study 2 is that boys were more likely than girls to select the novel object. We do not have a clear account of this gender effect. In fact, given that this effect occurred only in this study, it might have been due to some peculiarity in the sample. Moreover, the fact that gender did not interact with condition, that is, both boys and girls were more likely to select the novel object in response to a request made by a knowledgeable than by an ignorant speaker, suggests that any difference there might exist between the genders, it does not seem to involve their capacity to assess speakers' knowledge.

One difference between the findings in Study 2 and those in Study 1 is that whereas children in the ignorant condition of Study 2 selected the novel objects at rates no different from chance, children in the ignorant condition of Study 1 selected the novel objects at rates significantly above chance. Interestingly in this regard, children in Diesendruck's (2005) study, who were exposed to a monolingual speaker who did not know anything about the language used previously to label an object, also responded at chance levels. A possible reconciliation of these findings has to do with the inferences children might have made about the different kinds of speakers. Namely, it is possible that an encounter with a mature speaker who knows the language but nonetheless commits errors in naming familiar objects (i.e., the ignorant speaker in Study 1), was quite puzzling to children. Such a speaker may have prompted children to doubt his knowledge of other familiar words, and the subsequent reasoning process children needed to engage in so as to fix this skepticism may have led to decrement in disambiguation responses. In this light, the encounter with an *immature* speaker who committed errors in naming familiar objects (i.e., the ignorant speaker in Study 2) might have been less puzzling and thus easier to process. Specifically, children might have felt more comfortable simply attributing ignorance to such a speaker, thus not disambiguating at above-chance levels.

A second possible reconciliation has to do with the identity of the speakers. Namely, children may assume that young children or speakers of a different language indeed know very little, if anything, about their language, but presumably mature speakers, even if they have been temporarily inaccurate, may nonetheless know more about the language. In other words, children may be relatively tolerant in their upholding of an assumption of conventionality, and it is only when a speaker is immature or does not understand the language at all that they more readily abandon this assumption (see also Lampinen & Smith, 1995, for consistent findings).

One implication of this latter interpretation is that if a mature speaker manifests knowledge of the language—even if the manner in which he or she refers to objects is unusual—then children should nonetheless uphold an assumption of conventionality about him or her. Study 3 addresses this implication.

Study 3

In order to assess how tolerant children's assumption of conventionality is, in Study 3 we exposed children to a speaker (a puppet friend of the experimenter, as in Study 1) who employed unusual but correct labels to refer to familiar objects. In other words, this type of speaker gave evidence that he was knowledgeable about the language in general, even if his choice of labels to refer to the objects in the familiarization phase was peculiar. To ascertain that children were familiar with these unusual labels and could assess their accuracy, the superordinate labels for each of the familiar objects was used as the unusual label. While familiar to children of this age, superordinate labels are much less frequent in the linguistic input to which children are typically exposed, and are used less frequently by children (Callanan, 1985; Hall, 1994).

The alternative predictions were that if children hold a rigid assumption of conventionality (i.e., that each object has *only one* correct label—typically its basic-level label), then they should infer that an unusual labeler does not know the names of familiar objects, and they should thus respond like children in the Ignorant condition of Study 1 did. In turn, if children hold a more tolerant assumption of conventionality—as hinted by the fact that even children in the ignorant condition of Study 1 selected the novel object at above chance levels—then they should infer that speakers who are knowledgeable about the language might know the conventional labels of familiar objects. In this case, children should respond to Study 3's unusual but knowledgeable labeler like children in the knowledgeable condition of Study 1 did.

Method

Participants

Participants were 19 monolingual Hebrew-speaking Israeli preschoolers, 12 boys and 7 girls (M = 3 years 10 months, SD = 4.7 months, range = 3 years 4 months to 4 years 9 months). Children were primarily from middle- and upper-middle-class socioeconomic backgrounds. Most children were recruited from and tested in preschools around the university. A few others were recruited from the local community and were tested at home. Parental consent was obtained for each child prior to participation.

Materials

The same materials used in Studies 1 and 2 were used in Study 3.

Design

All 19 children participated in the *unusual* condition, in which they were introduced to a puppet in the same way as they had been in Study 1 (i.e., the puppet was introduced as a friend of the experimenter, not as a child). As in Studies 1 and 2, the procedure consisted of four familiarization trials followed by four disambiguation trials.

Procedure

The procedure in Study 3 was nearly identical to the one used in Study 1 with only one exception. In the *familiarization phase,* children were exposed to a puppet who consistently used unusual but correct labels to name the four familiar objects (the same objects used in Study 1). In particular, the puppet used superordinate labels and thus called the banana *fruit*, the dog *animal*, the shirt *clothes* (in Hebrew, there is a singular form for clothes), and the cookie *food*. The rest of the procedure, including the *disambiguation phase* and the counterbalancing precautions, was identical to the procedure in Study 1.

Results

As in Study 1, the dependent measure used to assess children's responses was the number of times (0–4) children selected the novel object as the referent of the novel label used by the puppet in the disambiguation phase. In general, children in Study 3 selected the novel object an average of 3.79

times ($SD = 0.42$), which was significantly more than would be expected by chance (chance = 2), $t(18) = 18.62$, $p < .001$.

In order to address the alternative predictions described above, two planned comparisons were conducted. First, we compared children's performance in Study 3 with the performance of children in Study 1's knowledgeable condition. This comparison revealed no significant difference, $p > .7$. Next, we compared children's performance in Study 3 with the performance of children in Study 1's ignorant condition. This comparison revealed that indeed, children in the unusual condition of Study 3 were more likely to select the unfamiliar object in response to the novel label than were children in the ignorant condition of Study 1, $t(34) = 2.75$, $p < .01$.

As in Study 1, we also conducted a nonparametric test in order to evaluate differences in individual children's response patterns. Using the same classificatory criterion described in Studies 1 and 2, we divided children in the unusual condition into *disambiguators* and *overlap accepters*. All 19 children in the unusual condition were disambiguators. This distribution was similar to the one found among children in the knowledgeable condition of Study 1 and was significantly different from the distribution found in the ignorant condition of Study 1, $\chi^2(1, N = 36) = 9.71$, $p < .005$.

Taken together, the findings from Study 3 reveal that children responded to an unusual but knowledgeable speaker in the same way that they responded to a knowledgeable speaker who used typical basic-level labels to name familiar objects.

Discussion

The goal of Study 3 was to examine whether children would uphold an assumption of conventionality toward a speaker who—while manifesting knowledge of the language—had used unusual names to refer to familiar objects. The results of Study 3 indicate that children did just that. Children seemed to have assumed that if a speaker knows that a banana is called *fruit*, then he likely also knows what a car and a shoe are called. Consequently, when he asked children for the referent of a completely novel word, children inferred that he must be referring to a novel object rather than to one for which children knew the name. This finding also undermines an associationist account of the findings in Study 1: Children did not think that an unusual labeler would always refer to familiar objects with unusual names.

These findings also point to a further implication of conventionality, namely, that while there are *typical* ways of referring to objects, there is not necessarily *only one correct way*. As Clark (1997) discusses, adults and children are aware of the multiple perspectives one can take to refer to objects. We will return to this point in the General Discussion.

Study 4

The previous three studies revealed that children rely on a speaker's manifested knowledge or ignorance of the conventional names of objects when subsequently inferring the speaker's referential intent. In other words, when children have sufficient evidence to uphold an assumption of conventionality toward a speaker, they feel licensed to draw contrastive inferences. This conclusion adds to a growing number of studies revealing children's reliance on an assumption of conventionality regarding words (Buresh & Woodward, 2007; Callanan & Sabbagh, 2004; Diesendruck & Markson, 2001; Henderson & Graham, 2005).

As noted in the Introduction, an assumption of conventionality is useful not only in the realm of language but also with regard to other cultural forms that although somewhat arbitrary and symbolic, are also conventionalized within cultural groups (Kalish & Sabbagh, 2007). The goal of Study 4 was to examine the scope of an assumption of conventionality by investigating whether young children hold such an assumption with regard to object functions. There is evidence that children believe that objects have unique functions (Casler & Kelemen, 2005, 2007) and that these functions are the ones shared by multiple people (Siegel & Callanan, 2007). A recent study also demonstrated that just as with labels, 3- and 4-year-olds prefer learning about the function of a novel object from a user who had been previously accurate in describing the uses of objects than from a user who had been faulty (Birch et al., 2008). In Study 4, we wanted to directly compare children's assumptions and subsequent inferences about names and functions. Study 4 adopts the same methods used in Study 1 to assess children's reasoning process in the domain of names in order to assess their reasoning in the domain of object functions.

Method

Participants

Participants were 36 monolingual Hebrew-speaking Israeli preschoolers, 14 boys and 22 girls (*M* = 3 years 11 months, *SD* = 6.2 months, range = 3 years 3 months to 4 years 8 months). Children were primarily from middle- and upper-middle-class socioeconomic backgrounds. Most children were recruited from and tested in preschools around the university. A few others were recruited from the local community and were tested at home. Parental consent was obtained for each child prior to participation.

Materials

In the familiarization phase, we used four objects highly familiar to children this age and whose function children were assumed to know. The objects were: a toy chair, a plastic spoon, a wooden hammer, and a plastic comb. In the disambiguation phase, eight objects were used: four familiar and four novel. The objects in the disambiguation phase were arranged into pairs of familiar–novel, in such a way that the objects in each pair were similar in their color salience and size, and both objects could fulfill the new functions mentioned in this phase. The familiar–novel pairs are described in Table 2. The pairs were the same for all children but were presented in different orders across children. A hand-puppet was also used to provide the functions. The experimenter manipulated the puppet, using a distinctive voice whenever speaking for him (as in Study 1).

Design

Children were randomly assigned to one of two conditions, *knowledgeable* ($n = 18$, 12 girls and 6 boys, M_{age} = 3 years 11 months) or *ignorant* ($n = 18$, 10 girls and 8 boys, M_{age} = 4 years 0 months). There was neither a significant age difference nor a significant difference in the gender distribution between the two conditions. Children participated in four familiarization trials followed by four disambiguation trials.

Table 2
Pairs of Familiar–Novel Objects Used in Study 4, and the New Functions Requested in the Disambiguation Phase

Familiar object	Novel object	New function
Food plate	Round wooden block	Make noise
Toy hat	Oddly shaped sponge	Wipe off sand
Plastic bottle	Ceramic cone	Smoosh dough
Color marker	Dumpling maker	Make holes

Procedure

The procedure in Study 4 was nearly identical to the procedure in Study 1. The only difference was that in Study 4 children were familiarized with a user who was either knowledgeable or ignorant of objects' functions, and who later asked children for the object needed to perform a new function.

Familiarization phase. The familiarization phase was the only phase that differed between the two conditions. In this phase, the experimenter invited the child and the puppet to play, and presented familiar objects one at a time. The puppet looked at the object and stated what the object was used for three times while asserting his knowledge of what the object is (i.e., saying, "I know what this is!"). The main manipulation had to do with whether or not the functions mentioned by the puppet were the conventional functions associated with the objects. In the knowledgeable condition, the puppet mentioned the conventional functions of the objects (e.g., upon seeing a spoon, he said repeatedly, "That's for eating!"). In the ignorant condition; the puppet mentioned incorrect functions for the objects (e.g., about the spoon, "That's for cutting paper!"). After a few seconds in which the child and the puppet were allowed to play with an object, the experimenter returned the object to her bag and brought out another familiar object. Again the puppet reacted according to the child's condition. This procedure was repeated for four trials in order to allow the child to build an assessment of the puppet's knowledge—or ignorance—of familiar objects' functions. The conventional functions used for the items, chair, spoon, hammer, and comb, were "for sitting," "for eating," "for pounding," and "for combing hair," respectively. The incorrect functions used were "for sweeping floors," "for cutting paper," "for singing," and "for picking flowers," respectively. Order of presentation of the objects was randomized across children, as in Study 1.

Disambiguation phase. This phase was identical in both conditions. The experimenter laid down in front of the child the first pair of familiar–novel objects. The puppet then looked at the child, and asked for one of the objects by using a new function that could be performed with either object (e.g., "Can you give me the one *for making noise*?"). The functions associated with each object pair were the same for all children. This was done because the functions were created so as to be affordable by both objects in each pair. The new functions applied to each pair are listed in Table 2. Both the puppet and the experimenter refrained from looking at either one of the objects and instead maintained their gaze on the child. Once the child responded by pointing to, picking up, or handing to the puppet one of the objects, the experimenter removed the two objects and replaced them with the next pair of familiar–novel objects. The experimenter did not provide any feedback to children about their performance and instead made comments about the game and the toys. The experimenter wrote down children's choices and any other verbal comments children made throughout the entire procedure. Upon completion of the four disambiguation trials, children were thanked, given a sticker in appreciation for their participation, and returned to their class.

The order of presentation of the pairs was counterbalanced across children, as in Study 1. The left–right placement of each object within a pair was counterbalanced within children, so that on half of the pairs, the familiar object was placed on the right side of the child, and on the other half of the pairs, the novel object was placed on the right side of the child.

Results

Our main prediction was that children would be more likely to choose the novel object in response to a request made by a knowledgeable user than one made by an ignorant user. The dependent measure used to address this prediction was the number of times (0–4) children selected the novel object as the referent of the new function requested by the puppet in the disambiguation phase.

An ANOVA with condition (knowledgeable vs. ignorant) and gender as between-subjects variables, and participants' age in months as a covariate, on the above dependent measure revealed a main effect of condition, $F(1, 31) = 4.53$, $p < .05$, $\eta_p^2 = .13$; no effect of gender, $p > .6$; no effect of age, $p > .7$; and no interaction between gender and condition, $p > .9$. As illustrated in Figure 1, children in the knowledgeable condition ($M = 3.56$, $SD = 0.70$) were more likely than children in the ignorant condition ($M = 2.94$, $SD = 0.94$) to pick the novel object in response to the puppet's request for a new function. As in Study 1, analyses against chance (chance = 2) revealed that children in both conditions were more likely to pick the novel object than would be expected by chance: in the knowledgeable condition, $t(17) = 9.36$, $p < .001$, in the ignorant condition, $t(17) = 4.27$, $p < .005$. Finally, the interaction between age as a dichotomous variable based on a median split of the sample, and condition, was not significant, $p > .8$.

In order to evaluate children's individual pattern of responses, we conducted the same nonparametric test run in Study 1, evaluating the distribution of children in terms of response consistency. As shown in Table 1, while the distribution pattern in Study 4 was similar to that found in Study 1, the difference between conditions in Study 4 did not reach significance, $\chi^2(1, N = 36) = 2.57$, $p = .11$.

Taken together, the results of Study 4 were consistent with our hypothesis. Children were more likely to select a novel object as the referent of a new function when the user asking for the function had previously manifested knowledge of the conventional functions of objects than when the user manifested ignorance of conventional functions.

Comparisons Between Studies 1 and 4

Given that Studies 1 and 4 had the same design and procedure, a comparison between them allowed us to directly assess potential differences between children's responses to labels (Study 1) and functions (Study 4). We conducted an ANOVA using Study (1 vs. 4) and condition (knowledgeable vs. ignorant) as between-subjects variables on the mean number of times children selected the novel object in response to the puppet's request (for either a novel label, in Study 1, or a new function, in Study 4). The ANOVA revealed a significant effect of condition, $F(1, 65) = 10.71$, $p < .005$, $\eta_p^2 = .14$; no effect of study, $p > .5$; and no interaction, $p > .7$. These findings were confirmed when looking at the distribution of children in terms of disambiguators or overlap accepters across these two studies. In the knowledgeable conditions across the two studies, 32 of the 34 children were disambiguators, whereas in the ignorant conditions, only 22 of the 35 were so, $\chi^2(1, N = 69) = 9.91$, $p < .005$. In terms of studies, 26 of the 33 children in Study 1 were disambiguators, compared to 28 of the 36 in Study 4, evidently a nonsignificant difference, $p > .9$.

Altogether, the knowledge state of the requester affected children's responses in the same way, whether he was asking for the referents of labels or for the functions of objects. Moreover, children did not show a stronger tendency to avoid overlap between two labels than between two functions.

Discussion

The goal of Study 4 was to assess whether children's inferences about the referents of functions would be similar to their inferences about the referents of object names. The findings indicate that they were. Children in Study 4 were more likely to infer a contrastive intent when a user seemed knowledgeable about the conventional functions of objects than when a user seemed ignorant of such conventions. In fact, the direct comparison of children's responses to object functions and their responses to object labels revealed no significant differences. Given the similarity in the methodologies used to assess children's responses in these two domains, the above findings intimate that the same inferential process underlies children's responses in both domains.

General Discussion

A fundamental assumption for successful communication to take place is that partners in a conversation share knowledge about the expected ways to refer to familiar concepts. This assumption of conventionality has been documented in children, primarily via its contrastive implication, namely, that if a speaker uses a form that is different from the one expected in a given context, then that speaker likely has a different concept in mind (Clark, 1988). A number of studies have shown that children indeed draw this kind of inference when a conventional *form* is expected but is not used (Diesendruck, 2005; Diesendruck & Markson, 2001; Henderson & Graham, 2005). One of the central goals of the present studies was to address whether the extent to which a *source* has proven to be knowledgeable of conventional forms affects children's tendency to infer contrastive intents.

The results of the present studies reveal that it does. In Study 1, when a speaker proved knowledgeable of familiar names, then his subsequent request for the referent of a novel label was taken by children as indicative of an intent to refer to a novel—rather than a familiar—object. Children drew this inference to a significantly lesser extent when the speaker had manifested ignorance of the conventional names of familiar objects. Study 2 confirmed these findings and provided evidence that children's inferences, particularly those about an ignorant speaker's requests, were not driven by considerations of playfulness or silliness but rather considerations of knowledge states (see also Koenig & Harris, 2005, on this point).

A social-pragmatic account of these findings is that children expected a knowledgeable speaker to know the names of familiar objects and expected such a speaker to use these conventional names if intending to refer to the familiar objects. Given that the speaker used novel names, children inferred that the speaker had a contrastive intent in mind. In turn, given that the ignorant speaker proved not to know the conventional names of familiar objects, children relaxed their expectation of conventionality toward him and thus did not as decisively draw a contrastive inference in response to his use of a novel label. The present findings cannot determine whether evidence for knowledge reinforced an assumption of conventionality, evidence for ignorance weakened it, or both. What is crucial for the present purposes, however, is that children modulated their contrastive inferences based on their assessments of speakers' knowledge states.

A previous study (Diesendruck, 2005) had shown that children withhold an assumption of conventionality from a speaker who does not speak the language in which children were taught a novel name. The present findings add to that by revealing that children's modulation of an assumption of conventionality operates even within a single language and may lead children to doubt that a speaker knows even the names of highly familiar objects. On a separate issue, these findings add to a growing number of studies indicating that children's avoidance of lexical overlap is not driven by lexical constraints (Golinkoff et al., 1994; Markman & Wachtel, 1988; Merriman & Bowman, 1989). Rather, children are willing to accept two names for an object, especially in cases where an assumption of conventionality regarding the speakers cannot be upheld (Diesendruck, 2005; Sabbagh, Wdowiak, & Ottaway, 2003).

The primary goal of Study 3 was to assess the leniency of children's assumption of conventionality. As Clark (1997) has advocated, an assumption of conventionality has to be flexible enough to allow speakers to deviate from rigid expectations of what should be said without treating them as outcasts in one's linguistic community whose knowledge of the language cannot be trusted. The results of Study 3 confirmed that children respond to a speaker who refers to familiar objects with peculiar yet linguistically correct labels in the same way in which they respond to a speaker who uses conventional familiar labels to name those objects. In other words, the peculiarity in the labels used by Study 3's speaker to refer to familiar objects did not throw children off and did not lead them to withhold an assumption of conventionality towards that speaker.

A comparison of these results to those in Studies 1 and 2 ignorant conditions, and those reported by Diesendruck (2005), intimates that children are quite resistant to abandoning an assumption of conventionality. In particular, children seem to uphold an assumption of conventionality toward an otherwise mature speaker of a language who momentarily mislabeled familiar objects (ignorant condition of Study 1) or who provided peculiar but correct labels to familiar objects (unusual condition of Study 3). In turn, children withhold an assumption of conventionality toward an immature speaker of a language who momentarily mislabeled familiar objects (ignorant condition of Study 2) or a speaker who does not know the language at all (Diesendruck, 2005). In sum, children might operate with the default assumption that mature speakers of the child's native language are knowledgeable of the conventional forms prevalent in the language.

It is important to point out that the above conclusion may be true only of the particular aspect of conventionality assessed in the present studies. That is, children may have a lenient assumption that speakers ignorant of certain familiar object labels nonetheless know the names of other *familiar* objects in their language. It is possible, nonetheless, that children would treat such speakers as untrustworthy teachers of *novel* labels and thus would not treat novel labels used by them as conventional. A few studies are consistent with this possibility (Birch et al., 2008; Buresh & Woodward, 2007; Graham et al., 2006), but the issue of leniency in light of atypical labeling has not been directly addressed in this regard.

Study 4 evaluated whether children respond in a similar way to users who violate the conventional functions of objects as they do to speakers who violate the conventional names of object. The findings from that study confirmed that children indeed treat these two cases equivalently. Children in Study 4 were just as sensitive to the knowledge state of object *users* when inferring which object a user had in mind for performing a *function*, as they were to the knowledge state of object *labelers* when inferring which object a speaker had in mind as the referent of a *label*. Namely, they drew contrastive inferences when a user was knowledgeable more often than when the user was ignorant. It is important to note that while in the present study knowledge of function was instantiated by the puppet *naming* the function—as opposed to actually *performing* it—studies by Casler and Kelemen (2005, 2007) found that children draw contrastive inferences also in cases where the functions are performed. In other words, we believe that the patterns revealed in the present study are indeed representative of how children reason about the mapping of functions to objects.

An additional finding from Study 4 was that, just as in the case of label, children manifested some resistance to abandoning an assumption of conventionality toward object functions altogether. Specifically, even children in the ignorant condition of Study 4 selected the novel object as appropriate for performing a new function more than would be expected by chance. Again, it is as if children reasoned that while the user might not know what the specific familiar objects in the familiarization phase are for (e.g., saying that a spoon is for cutting), he must know, *in general*, what familiar objects are for (e.g., that a plate is not for making noise). Thus, momentary evidence for ignorance of conventions merely weakens children's default assumption in this case as well.

The idea that a reasoning process that invokes an assumption of conventionality and inferences about users' intentions underlies children's assignment of functions to objects is consistent with a number of recent findings regarding artifact categories in children. First, this conclusion is consistent with the notion that children's concepts of artifacts are informed by beliefs regarding the artifacts' intended function (Bloom, 1996; Diesendruck, Markson, & Bloom, 2003). Children do not read off functions from objects directly but rather via guessing what somebody meant the object to be. Second and more central to the present proposal, the conclusion is consistent with findings that by 2½ years of age, children believe that objects have unique purposes, which are known by all members of a culture (Casler & Kelemen, 2005). Children not only expect others to know what objects are for, but, as the present findings indicate, they draw contrastive inferences about users' intended function based on their assessment of users' knowledge of conventional functions.

A crucial question this conclusion invites is what is the scope of an assumption of conventionality? One way to address this question is by evaluating the processes by which children come to develop an assumption of conventionality. According to one proposal, conventionality results from children's limited capacity to entertain disparities in the knowledge states of different individuals (Sabbagh & Henderson, 2007). In other words, conventionality is a manifestation of children's overgeneralization of their knowledge states onto others—that is, if they know something, then others probably know it as well (see also Birch & Bloom, 2003, on this so-called curse of knowledge). This proposal seems to imply that children's assumption of conventionality is fairly general in application. Challenging this proposal are findings that children *do* modulate their assumption of conventionality depending on others' knowledge state (see present studies; Diesendruck, 2005; Sabbagh et al., 2003) and on the specific forms used (e.g., the cases of proper names, Diesendruck, 2005; and facts, Diesendruck & Markson, 2001). In fact, recent studies reveal that even prior to their second birthday, infants expect object names to be shared by distinct individuals but do not hold such expectation regarding preferences (Graham et al., 2006) or goals (Buresh & Woodward, 2007). In other words, there are limits to the scope of children's assumption of conventionality.

A second proposal is that an assumption of conventionality derives from parental input. In particular, Callanan and colleagues have suggested that the way in which parents label objects when speaking to children (Callanan & Sabbagh, 2004) and the way in which parents demonstrate the uses of objects to children (Callanan, Siegel, & Luce, 2007) may endorse the notion that there is *a best way* to label and use objects. According to this proposal, conventionality would be limited to knowledge forms about which children receive this type of rich parental input.

A third proposal for the origin of conventionality with implications regarding its scope, focuses on cognitive capacities available to children from early in development. Two capacities, in particular, seem relevant to the development of an assumption of conventionality: (a) children's understanding of intentions, as already hinted above, and (b) children's capacity to detect statistical regularities in the input. Notice that while compatible with an input account, this proposal emphasizes what the child brings to the task of inferring conventionality, rather than how the input may be so structured as to facilitate this inference.

There is a vast literature indicating that already prior to their second birthday, children interpret people's actions as intentional or goal directed (Gergely, Nadasdy, Csibra, & Biro, 1995; Meltzoff, 1995; Woodward, 1998). It has further been found that an understanding of intentions is involved in young children's inferences about word meanings (Akhtar & Tomasello, 2000; Baldwin, 1991; Bloom, 2000) and, as noted above, artifact concepts (Bloom, 1996). The proposal is that children's monitoring of adults' actions in terms of intentionality might help them determine which "human products" are conventional and which are not. Evidently, this would not be sufficient for such a determination, but it might nonetheless be necessary.

In terms of children's statistical learning capacity, it has been shown that even prior to their first birthday infants are capable of picking out patterns in a stream of stimuli (Saffran, 2003). The idea being put forth here is that detection of stability in the way people refer to or use objects may contribute to children's assumption that an object label or function is conventional. In fact, Siegel and Callanan (2007) found that children's determination of what an object was for was influenced by the number of people said to use the object in a specific way.

One of the implications of grounding an assumption of conventionality in terms of broader cognitive capacities is that we can then draw on the accumulating knowledge about the development of these capacities to explain, and generate hypotheses about, patterns regarding the development of conventionality. For instance, in none of the studies reported here was there an effect of age on children's performance, nor an interaction between age and experimental condition. That is, children within a broad range of ages between 3 and 4 years of age responded similarly in our tasks. In contrast to this null result, there are inconsistencies with regard to the effect of age among studies assessing children's willingness to learn new information based on speakers' reliability. A possible reconciliation of these inconsistencies has to do with the nature of the tasks. In particular, there do not appear to be age differences in tasks that require children to rely primarily on their assessments of others' knowledge in order to infer others' intended behavior (e.g., the present studies; Birch et al., 2008; Jaswal & Neely, 2006; Koenig et al., 2004; explicit judgment task). In turn, age differences were found in tasks that required children to predict a speaker's future behavior (e.g., Koenig & Harris, 2005) or in which children had to make subtle calculations about a speaker's state of knowledge (Pasquini, Corriveau, Koenig, & Harris, 2007). In a sense, this distinction seems analogous to ones made in the theory-of-mind literature between explaining behavior in terms of mental states versus predicting behavior in terms of mental states (e.g., Bartsch & Wellman, 1989).

The conclusion regarding conventionality is that one of the crucial capacities that undergo development in the preschool years is not so much the capacity to *assess* others' state of knowledge but rather the capacity to *apply* productively and originally that assessment in pertinent real world situations. Consistent with this conclusion, recent studies show that even prior to their second birthday, infants may be capable of assessing others' knowledge states (Onishi & Baillargeon, 2005), interpret people's behavior in terms of knowledge states (Moll, Koring, Carpenter, & Tomasello, 2006), and expect others to share certain knowledge states (Buresh & Woodward, 2007). It would be valuable for future studies to develop paradigms in order to assess children's capacity to apply conventionality flexibly.

A further implication of this latter proposal is that the knowledge forms that are treated by children as conventional are those that, while arbitrary and thus without a transparent meaning, nonetheless tend to be intentionally produced and stably represented. By many accounts, these characteristics are precisely what define culture (e.g., Csibra & Gergely, 2006; Tomasello, Carpenter, Call, Behne, & Moll, 2005). Thus, one can speculate that other cultural forms, such as symbolic representations, norms, or communicative signs, will also be treated as conventional by children. In this sense, the research program that investigates the development of children's assumption of conventionality meshes with the program investigating children's acquisition of culture.

Children Monitor Individuals' Expertise for Word Learning

David M. Sobel
Brown University

Kathleen H. Corriveau
Harvard University

Two experiments examined preschoolers' ability to learn novel words using others' expertise about objects' nonobvious properties. In Experiment 1, 4-year-olds (n = 24) endorsed individuals' labels for objects based on their differing causal knowledge about those objects. Experiment 2 examined the robustness of this inference and its development. Four-year-olds (n = 40) endorsed labels from confederates who accurately predicted objects' nonobvious internal properties but not nonobvious external properties. Three-year-olds (n = 40) performed at chance levels in both cases and were less likely to recognize the informants' expertise, suggesting that they might be unable to monitor individuals' expertise. These data suggest that children's ability to learn from testimony is necessary for their understanding of the relevance of an individual's expertise.

As adults, we rely on others' knowledge to learn and to make inferences about the world. We count on mechanics to diagnose and repair our cars because they know more about the functions of fuel-injection systems and carburetors. We allow doctors to advise us on medical decisions because they know more about how diseases cause symptoms and are affected by treatments. We hope our political leaders can effect change in social issues, the economy, or foreign affairs because of their greater experience or deeper knowledge of the issues involved. Whether trust is warranted in a mechanic, doctor, or politician depends on our belief that they understand the causal structures critical to a specific knowledge base. This article concerns whether and at what age children can use an individual's causal expertise to make novel inferences. Specifically, we focus on the effect observing another's causal knowledge has on children's subsequent willingness to rely on that person when learning new words.

The importance of "trust" in word learning has been studied extensively because there is a conventional, but arbitrary, assignment of lexical items to concepts and objects (e.g., Bloom, 2000; de Saussure, 1966; see Koenig & Harris, 2008, for a review). As such, children must rely on data they observe to learn the meaning of words. This involves recognizing that others are reliable sources of information. Thus, children should use data gained from a reliable source while discounting information that is unreliable. A growing body of research indicates that by the age of 4 (and possibly younger), preschoolers are able to use a speaker's past history of reliability to make inferences about the extension of novel labels to novel objects (e.g., Clément, Koenig, & Harris, 2004; Corriveau & Harris, 2009; Jaswal & Neely, 2006; Koenig, Clément, & Harris, 2004; Koenig & Harris, 2005; Pasquini, Corriveau, Koenig, & Harris, 2007). Four-year-olds also assume that adults tend to be reliable by default (e.g., Corriveau, Meints, & Harris, 2009) as well as register the role of uncertainty in word learning (e.g., Sabbagh & Baldwin, 2001). These data all suggest that children trust adults to provide them with accurate lexical information and discount that information when the adult is a less reliable source (but see Nurmsoo & Robinson, 2009, for a different opinion).

Such inferential ability potentially allows children to develop concepts of expertise. Children develop ontological commitments about other kinds of events they cannot directly observe based on the "patterns of testimony" that they receive (Harris & Koenig, 2006; Harris, Pasquini, Duke, Asscher, & Pons, 2006). More generally, Keil and colleagues have suggested that young children learn that individuals' knowledge forms a "division

of cognitive labor'' (Danovitch & Keil, 2004; Keil, Stein, Webb, Billings, & Rozenblit, 2008; Lutz & Keil, 2002). At relatively young ages, children understand that individuals possess different pieces of knowledge, which potentially cohere around causal principles. Keil et al. (2008), in particular, demonstrated that 5-year-olds recognize that others' knowledge is organized around disciplines that reflect the structure of modern universities. Children understood that someone who knows about a physical property is more likely to know about a chemical one (grouping two natural sciences) than a principle of cognitive psychology (grouping a natural science with a social science).

Understanding this ''division of cognitive labor'' requires that children have access to and can make inferences about their own knowledge. Our goal here is not to investigate the emergence of this metacognitive understanding but rather to consider whether children possess the cognitive ability to monitor individuals as reliable sources of knowledge within a domain. This might be the basis on which the metacognitive division of cognitive labor is built. In particular, we are interested in the consistency between individuals' expertise and the inference children are asked to make based on that expertise. For example, several researchers have found that preschoolers rely on speakers' history of accurately labeling familiar objects when those speakers subsequently provided conflicting information about a novel object's function (Birch, Vauthier, & Bloom, 2008; Koenig & Harris, 2005). Using the more reliable speaker in this circumstance seems logical given the coherence between artifacts' category membership and their functions. Preschoolers often relate these two pieces of information, making inferences about one based on the other (e.g., Bloom, 1996; Gelman & Bloom, 2000; Kemler Nelson, Frankenfield, Morris, & Blair, 2000; Kemler Nelson et al., 1995). The reliability with which an individual categorizes objects should inform children that the individual possesses categorical knowledge about those objects, such as their function. But an individual's history of reliabilty should only be applicable if that reliability is relevant to the inference at hand—as reliable as a plumber might be at fixing a toilet, we might choose to discount his political savvy.

These insights motivated this study. In Experiment 1, we examined whether 4-year-olds could recognize that two individuals were experts in different pieces of causal knowledge. We asked whether 4-year-olds could subsequently use the individuals' expertise when learning the label of a novel object that exhibited a causal property related to only one of the individual's expertise. Several investigations have shown that young children relate objects' causal properties with their category membership, particularly when assigning labels to those objects (Booth & Waxman, 2002; Gopnik & Sobel, 2000; Graham, Kilbreath, & Welder, 2004; Nazzi & Gopnik, 2000). Although some have argued that object labels do not necessarily relate to conceptually deep properties of those objects, like their kind or function (e.g., Smith, Jones, & Landau, 1996), we suggest that children recognize that object labels relate to the conceptual structure indicated by those labels. Thus, we hypothesized that young children would rely on individuals' different causal knowledge judiciously to make inferences about novel objects' labels.

Experiment 2 had three related goals. The first was to examine whether preschoolers used informants' reliability about a different property of objects—its insides or material kind—to make inferences about novel object labels. Several investigations have demonstrated that 4-year-olds, but not 3-year-olds, understand that objects' causal properties or category membership are related to those objects' insides (Gelman & Gottfried, 1996; Gelman & Wellman, 1991; Gottfried & Gelman, 2005; Sobel, Yoachim, Gopnik, Meltzoff, & Blumenthal, 2007). Given this developmental difference, we hypothesized that 4-year-olds, but not 3-year-olds, would relate individuals' accurate histories of describing nonobvious internal properties of objects with their category membership.

But, an individual's reliabilty should only be applicable if that reliability is relevant to the inference at hand. The second goal of Experiment 2 was to consider whether children treated any set of reliable actions as relevant to word learning or whether children distinguished between relevant and irrelevant training. To investigate this possibility, we presented another group of 3- and 4-year-olds with informants who possessed different knowledge about an external property of a set of objects. Half of the objects had green stickers on them and half had red stickers. One informant was accurate in identifying which objects had red stickers on them but was ignorant about the other objects; the other informant was accurate in identifying the objects with green stickers on them but was ignorant about the objects with red stickers. Our hypothesis was that this expertise would be irrelevant to the objects' category membership: Neither age group should use the speakers' reliability about these external parts to make inferences about category membership. Furthermore, the 4-year-olds in particular should be more likely to use the speakers' reliability in the insides condition than in the outsides condition.

Experiment 1

Four-year-olds were introduced to two individuals who demonstrated different pieces of causal knowledge about the way in which objects activated a machine. We then showed children a new object whose efficacy on the machine was consistent with the predictions of one of the two individuals. We examined whether children would use the individuals' different knowledge to decide which informant to turn to when making an inference about the label of the new object.

Method

Participants

Twenty-four 4-year-olds (16 boys and 8 girls, $M = 53.71$ months, $SD = 2.90$) were recruited from a preschool classroom, fliers posted at local preschools, and a list of hospital births. Four additional children were tested but not included in the final analysis: 2 because of experimental error and 2 failed to interact with the experimenter. Most children were Caucasian and from middle- to upper-middle-class families; however, no formal measure of socioeconomic status (SES) was taken. The participants did represent the diversity of the population from which they were sampled.

Materials

The machine was an 8 × 6 × 3 in. box made of black plastic with a white top (see Figure 1). If an object was placed on it, the machine would activate, both by illuminating either red or green light-emitting diodes (LEDs), which were wired into the top of the device, and by playing one of two different musical arrangements. The machine worked via a remote control (hidden from the child), which the experimenter used to control whether the machine activated red or green. All of the objects used activated the machine, but the remote could also "enable" or "disable" the machine, such that other objects that a child might inadvertently put on the machine (e.g., fingers) would not activate it. Eight wooden blocks, all of different sizes, colors, and shapes were used. No block was red or green.

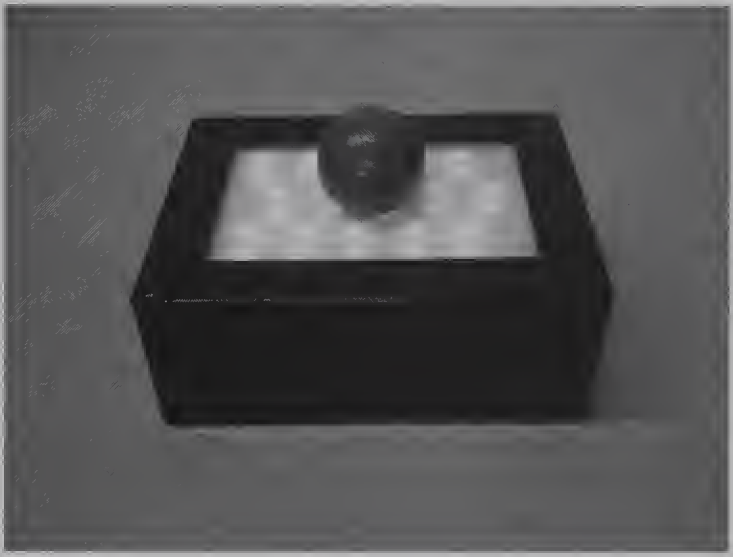

Figure 1. The machine used in the Experiment 1.
Note. The machine would activate by illuminating red or green light-emitting diodes (LEDs) wired into the white top. When the machine activated, it also played one of two songs, dependent on whether it was set to light up red or green. The objects used in Experiment 1 were all wooden blocks without any distinguishable features. The object shown in Figure 1 is an object used in Experiment 2, with a dowel over a cavity, revealing its "inside" (in the insides condition) and with a sticker on the back (not shown), both of which were either red or green.

Procedure

Children were tested in a quiet room at their school or in the lab. The child and experimenter were seated across from each other at a table. The experimenter told the child that they would play a game with two of the experimenter's friends. The two confederates then entered the room and sat on either side of the experimenter. The confederates were always the same gender and never wore red or green clothing. The child was then told that they would all play a game together with the experimenter's machine, which was brought out onto the table. The experimenter said, "This is a special machine. I have some toys. Some toys make the machine go red and some toys make the machine go green, and we're going to try and figure it out. Let's take a look."

Training trials. Children observed six training trials. In each, the experimenter brought out a block (randomly chosen from the set of eight) from under the table. On the first training trial, the experimenter told the child, "Take a look at this toy. I don't know what's going to happen when we put this on the machine, but my friends are pretty smart, so let's ask them." (On subsequent trials, the experimenter just showed the child the new object and said, "Let's ask my friends what this one does.")

The experimenter turned to one of the confederates (counterbalanced across children) and asked "What do you think will happen when we put this on the machine?" Each confederate was given a chance to respond. Prior to the start of the procedure (and unbeknownst to the child), one confederate was designated the *red expert* whereas the other confederate was the *green expert*; we randomly determined who the red expert was for each participant. The red expert always predicted when an object would activate the machine red but was ignorant of objects that made the machine go green (and responded "I don't know" for those objects). Similarly, the green expert always responded correctly for objects that made the machine go green and was ignorant for objects that made the machine go red.

After each confederate stated her belief about what the object would do, the experimenter repeated their claims and then placed the object on the machine, which activated consistent with the expert's claim. Children were then asked to point to the person who was right (i.e., who correctly predicted the event). Corrective feedback was given if necessary. These questions were included as a catch trial—our intention was to replace the data from any child who answered more than one of these questions incorrectly from the final analysis. However, all children answered this question correctly on at least five of the six trials. On three of the six training trials, the object activated the machine red and, on the other three, the object activated the machine green (order was randomly determined). Thus, children saw three trials in which the red expert was accurate and the green expert was ignorant (all about red activation events), and three trials in which the green expert was accurate and the red expert was ignorant (all about green activation events). Children never observed either confederate respond incorrectly.

Test trials. Immediately after the training trials, children then observed two test trials. In each, the child was shown a new object and was told "Let's see what this one does on the machine." The object was placed on the machine without asking either confederate her belief about its efficacy. On one trial, the object made the machine go red; on the other, it made the machine go green. The experimenter narrated the machine's activation for the child (e.g., "Look, this one made the machine go green"). The experimenter then said to the child, "Do you see this toy. I'll tell you a secret. This toy has a special name. I don't know the special name of this toy, but we can ask my friends." Children were then asked the *ask* question, "Who do you want to ask for the special name of the toy, [Confederate 1] or [Confederate 2]?"

After the child responded, the experimenter asked each confederate for the special name of the toy. Each confederate generated a novel label (*dax* vs. *wug* on one trial, *modi* vs. *toma* on the other). Each label was repeated for the child, and then the child was asked the *endorse* question—for example, "What do you think the special name of this toy is called, a *modi* or a *toma*?"

After these two trials, children were asked two *knowledge* questions, "Who knows about things that make the machine go red?" and "Who knows about things that make the machine go green?" These questions were asked to ensure that children remembered the expertise of the two confederates. The location of the red and green experts (with respect to the experimenter) and the particular word labels the experts generated were both counterbalanced.

Results

Overall, children required feedback on ~4% of the training trials, and 18 of the 24 children required no feedback at all. This suggested that children understood the training. Children received a score of 1 on each question if they responded consistently with the confederate with the relevant causal expertise (e.g., if the test object activated the machine green, children were given a score of 1 if they asked the green expert for the special name of the toy on the ask question and endorsed that confederate's label on the endorse question). Preliminary analyses suggest that these scores did not differ between the two ask questions, the two endorse questions, or the two knowledge questions, all McNemar $\chi^2(1, n = 24)$ tests = *ns*, so we combined them. These data are shown in Table 1.

We first analyzed responses on the ask and endorse questions. Only responses on the endorse questions showed a pattern significantly different from chance levels, $\chi^2(2, n = 24) = 6.92$, $p = .031$. The distribution of responses to the ask question was not different from chance, $\chi^2(2, n = 24) = 0.92$, *ns*. Responses to neither of these questions significantly correlated with age.

We next examined responses to the knowledge question. The distribution of responses on this question was significantly different from chance,

Table 1
Distribution of Responses to the Ask, Endorse, and Knowledge Questions in Experiment 1

	Number of correct responses				
	0	1	2	*M*	*SD*
Question type					
Ask	5	11	8	1.12	0.74
Endorse	2	11	11	1.38	0.65
Knowledge	1	2	21	1.83	0.48

with 21 out of the 24 children responding correctly on both trials, $\chi^2(2, n = 24) = 50.00$, $p < .001$. As with the ask and endorse questions, responses did not correlate with the child's age.

Finally, we wanted to be certain that responses to the ask and endorse questions were representative of children who understood the expertise of the informants. We reanalyzed these responses looking only at the children who answered both knowledge questions correctly. These analyses paralleled what was presented earlier: On the endorse question, children used the informants' expertise on 72% of the trials, with a distribution significantly different from chance, $\chi^2(2, n = 21) = 7.72$, $p = .021$. On the ask question, children only used the informants' expertise on 65% of the trials, with a distribution not significantly different from chance.

Discussion

These data suggest that children understood the expertise of the confederates and that 4-year-olds recognize that individuals have access to different pieces of causal knowledge. These data also suggest that 4-year-olds have some understanding that another's knowledge can be used to make novel inferences. In particular, children can use individuals' reliability about objects' causal properties to make inferences about those objects' labels.

Although the pattern of responses on the ask and endorse questions was not significantly different from each other, the distribution of responses to the ask question was at chance levels, whereas responses to the endorse question were significantly different from chance. We suggest two possible explanations for this difference. First, previous investigations (e.g., Birch et al., 2008; Jaswal & Neely, 2006; Koenig & Harris, 2005) presented children with a consistently accurate informant and a consistently inaccurate informant. Here, children were asked to monitor the accuracy of different kinds of knowledge. It is possible that requiring children to monitor both informants' accuracy taxed their metacognitive abilities, making the ask question slightly more difficult than the endorse question. Consistent with this idea, Pasquini et al. (2007) asked children to monitor the relative accuracy between the two informants. When one informant was always correct or always incorrect, 4-year-olds' responses to the ask and endorse questions were both above chance. But when both informants responded with different degrees of inaccuracy (one was accurate on 75% of the training trials, the other on 25%), 4-year-olds showed a similar pattern of performance on ask and endorse questions to the results presented here.

Second, unlike much previous research on children's understanding of others' reliability, we showed children live confederates instead of asking them to make inferences about people on videos, characters, or puppets (Corriveau et al., 2009, used a similar procedure). Regardless of the child's choice on the ask question, the informants generated their labels in a fixed order. Thus, children sometimes chose to ask one confederate, but the other confederate offered her label first. It is possible that children thought the ask question referred to whom the experimenter would ask first for a label. We changed this aspect of the procedure in Experiment 2.

In summary, these data suggest that 4-year-olds can both extract and use differential expertise about the causal properties of objects. Children can monitor the quality of information that they hear from the confederates in order to predict which of the two has the relevant information about that object's category membership. At issue is how children are monitoring this information. Our hypothesis is that children are not only monitoring the informants' accuracy but are also integrating their representation of those individuals' reliability with their existing knowledge of the relevance of that information. As children develop knowledge about what information is important for category membership, they should use that knowledge to interpret the reliability information they observe. In order to understand that a plumber's ability to label pipe is independent of that person's ability to craft domestic policy, one must recognize that the causal relations involved in unclogging a drain are different from the causal relations involved in balancing the federal budget.

However, an alternative possibility is that in Experiment 1, children might have just associated the two causal properties with the two individual informants. On this view, children endorse the red expert's label for the object that activated the machine red because they have learned to associate that individual with objects that have particular efficacy. This suggests that 4-year-olds might treat reliable answers to any kind of question about the objects as relevant to the inferences they are asked to make. Experiment 2 examines whether 4-year-olds use any kind of expertise as relevant to making inferences about objects' labels or if they limit their use of the informants' expertise to information related to category membership.

Also, what about younger children? Experiment 1 showed that 4-year-olds are capable of monitoring informants' causal knowledge to make inferences about category membership. Experiment 2 examined whether younger children have similar monitoring abilities. Given that Pasquini et al. (2007) found that 3-year-olds tend to be unable to track individuals' reliability when both are stochastic, 3-year-olds might struggle tracking informants' knowledge.

Experiment 2

Three- and 4-year-olds were introduced to confederates who possessed different pieces of knowledge about unfamiliar objects. This knowledge was either relevant or irrelevant to inferences about those objects' category membership. Instead of presenting children with objects that had different causal properties, we relied on another property of objects that has been found related to their category membership: insides. In Experiment 2, half of the children encountered two informants who were experts about the internal properties of unfamiliar objects. In particular, one expert always knew whether an object had red insides but was ignorant about objects with green insides; the second expert knew when objects had green insides but was ignorant about the objects with red insides. The other half of children learned that the informants were knowledgeable about whether those objects had a particular colored sticker on the back (an analogous nonobvious external property). Several investigations have suggested that objects' insides are related to category membership whereas this kind of external property is not (Gelman & Wellman, 1991; Gottfried & Gelman, 2005; Sobel et al., 2007). We examined whether children would only use expertise related to category membership (i.e., insides) to make inferences about whom to ask for information about object labels and whose labels they should endorse.

Previous investigations have suggested that children develop an understanding of the relation between insides and category membership between the ages of 3 and 4 (e.g., Gottfried & Gelman, 2005; Sobel et al., 2007). Other investigations (e.g., Pasquini et al., 2007) found that 3-year-olds struggled to recognize the relative accuracy of two informants, suggesting that they might also struggle at accurately keeping track of the informants' expertise regardless of the relevance of that information. Given these findings, we predicted an interaction between age and expertise, particularly for responses on the endorse questions: Four-year-olds should relate the confederates' knowledge to the objects' labels only when shown that the confederates have expertise about the internal properties of the objects, but not the external properties of the objects. Three-year-olds should not use that knowledge in either condition.

Method

Participants

Forty 3-year-olds (19 girls, *M* = 42.95 months, *SD* = 3.46, range = 36–48 months) and forty 4-year-olds (19 girls, *M* = 55.35 months, *SD* = 3.40, range = 49–60 months) were recruited from a set of preschools and a list of hospital births. Most children were Caucasian and from middle- to upper-middle-class families; however, no formal measure of SES was taken. The participants did represent the diversity of the population from which they were sampled.

Materials

Six wooden blocks, each different in shape and color, were used. Each block had a 1/2 in. (diameter) hole drilled into it, covered by a wooden dowel. Behind this dowel was either a red or green plastic pin (three of each color), which gave the appearance of an internal part (labeled "stuff" in the procedure). Each block also had a 3/4 in. sticker on the back colored red or green; the color of the sticker matched the color of the internal part. None of the blocks was red or green. Children either saw the internal part or the sticker, and they did not know about the other property of the block.

Procedure

As in Experiment 1, the experimenter introduced the child to two confederates. Children were told they would play a game with a set of toys. In the *insides* condition, children were told that some toys were made out of red stuff and some toys were made out of green stuff. In the *outsides* condition, children were told that some toys had red stickers on the back and other toys had green stickers on the back.

Training trials. The structure of the training trials was similar to Experiment 1. Children were told that the "friends" knew about the toys, so each was asked what they thought about each toy (i.e., what kind of stuff it was made of, or what color its sticker was) one at a time. The objects always had their door in place and were held and brought out from under the table such that neither the child nor the confederates could see the objects' insides or the stickers. One confederate was always correct about an object containing red stuff or having a red sticker on the back and said "I don't know" otherwise. The other confederate was always accurate about an object containing green stuff or having a green sticker on the back and said "I don't know" otherwise. Thus, on each trial, children were told what each confederate thought, then were shown either the internal or external property of the object, and then were asked, "Who was right?" Corrective feedback was given if children answered incorrectly. There were four training trials, two in which the red confederate was correct and two in which the green confederate was correct (order was randomly determined). This denotes a difference between this experiment and Experiment 1. Because we intended to work with 3-year-olds in this experiment, we were concerned with the length of the procedure, and thus gave children fewer training trials.

Test trials. Immediately after the fourth training trial, two additional blocks were introduced one at a time. Dependent on condition, the child was shown each block's internal or external property. One block had a red inside or outside; the other had a green inside or outside (order counterbalanced). As in Experiment 1, children were told that the objects had special names. On each trial, children were asked the same *ask* question (i.e., "Who do you want to ask for the special name of this toy?"). After the child responded, both confederates were asked what they thought the special name of the toy was, and both generated novel words (e.g., *dax* vs. *wug*). Children were asked a similar *endorse* question (i.e., "What do you think the special name of this toy is: a *dax* or a *wug*?"). Finally, after both trials, children were asked two *knowledge* questions—who knew about the toys made up of red or green stuff, or with red or green stickers? As in Experiment 1, the person who served as the red or green expert was determined randomly, and the side of the experimenter on which the red expert sat and the specific words the experts used to label the objects were counterbalanced across children.

Results

Children required feedback on ~4% of the training trials, and 66 of the 80 children required no feedback at all, suggesting that they understood the nature of the training. Responses were scored in the same manner as Experiment 1. Children's scores did not differ between the two ask, the two endorse, or the two knowledge questions (all McNemar χ^2 tests = *ns*). These data were combined and are shown in Table 2.

We first examined responses to the ask questions by analyzing the scores on this question via a 2 (age group) × 2 (condition: insides vs. outsides) analysis of variance (ANOVA). No significant effect of condition was found, but this analysis did find a significant effect of age group with 4-year-olds responding more accurately in general than 3-year-olds, $F(1, 76) = 7.81$, $p = .007$, partial $\eta^2 = .09$. Nonparametric analysis confirmed this result: Four-year-olds were more likely to ask the informant

Table 2
Distribution of Responses to the Ask, Endorse, and Knowledge Questions by Age and Condition (Insides, Outsides) in Experiment 2

	Number of correct responses				
	0	1	2	*M*	*SD*
Insides condition					
3-year-olds					
Ask	6	12	2	0.80	0.62
Endorse	8	9	3	0.75	0.72
Knowledge	6	3	11	1.25	0.91
4-year-olds					
Ask	3	6	11	1.40	0.75
Endorse	2	8	10	1.40	0.68
Knowledge	3	1	16	1.65	0.75
Outsides condition					
3-year-olds					
Ask	3	13	4	1.05	0.61
Endorse	4	13	3	0.95	0.61
Knowledge	9	1	10	1.05	1.00
4-year-olds					
Ask	3	8	9	1.30	0.73
Endorse	6	9	5	0.95	0.76
Knowledge	6	1	13	1.35	0.93

with the appropriate expertise across the conditions, Mann–Whitney *U* = 532.00, *z* = −2.81, *p* = .005, *r* = −.31.

A similar ANOVA performed on responses to the endorse questions revealed a slightly different pattern. Again, no significant effect of condition was found, but a main effect of age group was present with 4-year-olds in general responding more accurately than 3-year-olds, *F*(1, 76) = 4.41, *p* = .039, partial η^2 = .06. In addition, a significant interaction between age group and condition was found, *F*(1, 76) = 4.41, *p* = .039, partial η^2 = .06.

Further investigation revealed that 4-year-olds were significantly more accurate on responses to the endorse question than 3-year-olds in the insides condition, *t*(38) = 2.94, *p* = .003 (one-tailed), Cohen's *d* = 0.95, but showed no significant difference in responses to these questions in the outsides condition, *t*(38) = 0.00, *ns*. Four-year-olds were also more accurate in the insides than the outsides condition, *t*(38) = 1.97, *p* = .028 (one-tailed), Cohen's *d* = 0.64, whereas 3-year-olds' responses were not significantly different between these conditions, *t*(38) = 0.35, *ns*. Nonparametric analyses confirmed these results: Four-year-olds were more likely to use the informants' expertise than 3-year-olds in the insides condition, Mann–Whitney *U* = 107.00, *z* = 2.69, *p* = .005 (one-tailed), *r* = .43, but not the outsides condition, Mann–Whitney *U* = 199.00, *z* = 0.03, *ns*. Similarly, 4-year-olds were more accurate in the insides condition than the outsides condition, Mann–Whitney *U* = 135.00, *z* = 1.89, *p* = .040 (one-tailed), *r* = .30, whereas 3-year-olds showed no difference in responses between these conditions, Mann–Whitney *U* = 166.00, *z* = 1.02, *ns*.

We then examined each group's distribution of responses compared with chance. Only 4-year-olds in the insides condition generated distributions of responses different from chance, χ^2(2, *n* = 20) = 9.60, *p* = .008, for the ask questions and χ^2(2, *n* = 20) = 7.20, *p* = .027, for the endorse questions, all other χ^2(2, *n* = 20) values < 4.41, *ns*.

Four-year-olds were more likely to respond accurately to the knowledge question than 3-year-olds. However, this difference was only marginally significant, *t*(78) = 1.74, *p* = .086, Cohen's *d* = 0.39. This suggests that 4-year-olds might have been better able to monitor the two informants' knowledge. To ensure that the older children's above-chance performance in the insides condition was not just due to this group recognizing who had causal expertise, we explored each group's distribution of responses to the knowledge question. Both age groups responded differently from chance across both conditions on these questions, all χ^2(2, *n* = 20) values > 12.29, all *p*-values < .01. Inspection of Table 2 shows that whereas most 4-year-olds answered these questions accurately, 3-year-olds responses were more bimodally distributed. Thus, we were concerned that the younger children did not understand the expertise information available to them in the training.

As a result, we reanalyzed responses from only the children who responded correctly on the two knowledge questions. This analysis was similar to the analyses presented earlier: Four-year-olds in the insides condition showed a pattern of response significantly different from chance on the endorse questions, χ^2(2, *n* = 16) = 6.38, *p* = .041. On the ask questions, these children's responses were only different from chance at a marginally significant level, χ^2(2, *n* = 16) = 5.50, *p* = .064.

Discussion

Experiment 2 found that 4-year-olds could monitor informants' expertise about both internal and external properties of objects, but they used this information judiciously. They only asked for and endorsed the labels generated by the insides experts. Three-year-olds had slightly more difficulty monitoring informants' expertise. Nevertheless, even the 3-year-olds who did so successfully did not make the same inferences as the older children, particularly in the insides condition.

Why did 4-year-olds use the insides experts as sources of knowledge for the objects' labels, but not the outsides experts? In Experiment 1, we suggested that children recognized that there is a link between objects' causal properties and their category membership. Here, we make a similar argument that 4-year-olds recognize that objects' insides are related to their category membership, whereas the nature of a sticker placed on the back of an object is independent of its category.

An alternative possibility is that children do not make a principled inference about the informants' knowledge of the category membership of the objects. Instead, they simply recognize that knowledge about insides indicates that the individuals are more familiar with the objects than knowledge about outsides. Birch and Bloom (2002), for example, suggested that preschoolers use familiarity to make inferences about individuals' proper names. Although this is a possibility, familiarity and knowledge of category membership seem confounded. In both conditions, the confederates are knowledgeable about a nonobvious property of the object that is revealed during the course of the experiment. If children believe that the confederates in the insides condition are more familiar with these objects because of the nature of the property, then they must recognize that the property is relevant to the objects' conceptual structure.

It is important to note that the inferences 3-year-olds made were different from those made by 4-year-olds. There are two possible reasons for this difference. One is that the younger children were unable to register the different expertise between the two informants. Although 3-year-olds struggled with the knowledge question compared to 4-year-olds, this difference was not significant. Even those 3-year-olds who responded with 100% accuracy on the knowledge questions performed at chance on the ask and endorse questions. These responses potentially reflect their not recognizing the relation between objects' internal or external parts and category membership. The 3-year-olds' data do suggest that children are not responding based on recognizing that one informant is more familiar with one set of objects; Birch and Bloom (2002) found that 2-year-olds could make inferences about familiarity. Future research should attempt to tease apart children's knowledge of conceptual structure from the simpler idea that children register that one individual is more familiar with the objects.

General Discussion

Several experiments have found that preschoolers use informants' past reliability when learning conventional or constructed information. We expand on these findings in two ways. First, children appear to use individuals' ability to predict objects' causal efficacy accurately to make subsequent inferences about a new object's label. By age 4, children can transfer their understanding of speakers' reliability about an object's properties to another inference regarding that object. This is consistent with investigations that have demonstrated that children make inferences about object's intended functions based on speakers' reliability about familiar objects' labels (Birch et al., 2008; Koenig & Harris, 2005).

Second, there appears to be a limit to the extent young children will transfer this knowledge. When shown that individuals were knowledgeable about different internal properties of objects, 4-year-olds used that expertise to make inferences about the label of a new object with the same insides. When shown individuals with expertise about a nonobvious external property, 4-year-olds failed to use that information systematically to make the same inference. Younger children did not use either piece of information. These data are consistent with previous research suggesting that children do not relate object's insides with their category membership or causal properties until age 4 (Gottfried & Gelman, 2005; Sobel et al., 2007). The results from Experiment 2 suggest that 4-year-olds use informants' expertise only when it is relevant to the inference they are asked to make.

These data are also consistent with the hypothesis that 4-year-olds are simply better at monitoring multiple sources of information, similar to the way in which 3-year-olds struggle to understand cases where both informants have probabilistic levels of accuracy (i.e., neither informant is always right or always wrong). Pasquini et al. (2007) and other investigations that consider 3-year-olds' inferences given uncertain data (e.g., Corriveau et al., 2009) interpret their findings as 3-year-olds mistrusting informants who have made any error, regardless of the comparative frequency of those errors. Although children never observe an informant err in these experiments, the younger children might be more likely to treat the experts' ignorance as an incorrect response, given that there is no a priori reason for one informant to only know about one kind of causal property.

Future research should attempt to determine whether the developmental difference observed in Experiment 2 was a result of 3- and 4-year-olds' emerging information-processing abilities or their ability to understand that the informants' expertise is related to the inference(s) they are asked to make. One possibility would be to introduce 3- and 4-year-olds to pictures of familiar stimuli from two distinct classes (e.g., animals and artifacts) and two confederates. One confederate would accurately label all of the animals and be ignorant about the artifacts' labels; the other would show the reverse knowledge. If both 3- and 4-year-olds clearly distinguish animals from artifacts (e.g., as suggested by Gelman, 2003; Rosengren, Gelman, Kalish, & McCormick, 1991, among others), both age groups should have little difficulty when asked who could provide labels for pictures of novel animals and artifacts. This would suggest that such information-processing difficulties are not a likely explanation. In contrast, if a similar developmental difference to Experiment 2 is found, the development of these information-processing abilities is a more likely explanation.

Another question that emerges from these experiments is the exact expectations children have about the relations between objects' causal properties, insides, and category membership. For example, most studies of the relation between insides and category membership present children with a conflict between the object's insides and perceptual similarity (e.g., Gelman & Wellman, 1991; Sobel et al., 2007). In these cases, 3-year-olds use perceptual similarity as a guide to category membership, whereas 4-year-olds use the object's insides. We do not believe that 3-year-olds have no understanding of the relation between object's insides and category membership, but for this object set (simple artifacts that were similar to the ones used by Sobel et al., 2007), 3-year-olds might have less insight into the relation between insides and labels. An open question is whether 3-year-olds would respond differently if the artifacts were made more complicated so that the relevance of their insides was clearer. If preschoolers are just developing the ability to monitor informants' expertise, then a manipulation like this should not matter. If, instead, they are integrating that ability with their understanding of relevance, this might improve 3-year-olds' use of the informants' expertise.

One conclusion we can draw from these data is that by the time children are 4, they possess some of the cognitive abilities to distinguish reliable informants among different domains of knowledge. This might be the basis of the more metacognitive ''division of cognitive labor'' findings by Keil and colleagues in which children recognize that individuals have access to different pieces of knowledge, related to domains in which they are shown to be experts. This is consistent with the fact that 4-year-olds in both experiments showed at least some differences in the distributions of responses to the ask and endorse questions. Deciding what the object is called (the endorse question) requires the child to choose which of the confederates generated the accurate label. In contrast, deciding who knows about the label (the ask question) potentially requires the child to choose which confederate would generate the accurate label, which might require better access to the process by which the child would make this decision.

To conclude, there is little doubt that young children can rely on other people as sources of causal knowledge. Children clearly learn language (or at least word referents), science, religious concepts, and the nature of extraordinary beings by relying on the information provided by others. However, how this is accomplished is not well understood. Harris and Koenig (2006) point out that ''children might . . . be equipped with heuristics or strategies for assessing the quality or plausibility of the testimony that is made available to them'' (p. 519). The present data suggest that children's causal knowledge is part of the ''heuristics and strategies'' that Harris and Koenig suggest are critical to learning from testimony. By the age of 4, children are not just using the most reliable source of information but rather are using their own causal knowledge to judge whether that reliability is relevant.

Child Development, March/April 2010, Volume 81, Number 2, Pages 680–681

Manuscripts Accepted for Publication

Family Socioeconomic Status and Consistent Environmental Stimulation in Early Childhood, Robert Crosnoe, Tama Leventhal, R. J. Wirth, Kim Pierce, and Robert Pianta.

Defining Best Practice in Care and Protection of Children in Crisis-Affected Settings: A Delphi Study, Alastair Ager, Lindsay Stark, Bree Akesson, and Neil Boothby.

Inconsistency With Prior Knowledge Triggers Children's Causal Explanatory Reasoning, Cristine H. Legare, Susan A. Gelman, and Henry M. Wellman.

Children's Tattling: The Reporting of Everyday Norm Violations in Preschool Settings, Gordon Ingram and Jesse Bering.

Conversation, Development and Gender: A Study of Changes in Children's Concepts of Punishment, Patrick Leman and Marina Bjornberg.

Integrating Different Perspectives on Socialization Theory and Research: A Domain-Specific Approach, Joan Grusec and Maayan Davidov.

Children's Sleep and Adjustment Over Time: The Role of Socioeconomic Context, Mona El-Sheikh, Ryan J. Kelly, Joseph A. Buckhalt, and J. Benjamin Hinnant.

Antecedents and Correlates of the Popular-Aggressive Phenomenon in Elementary School, Philip Rodkin and Glenn I. Roisman.

The Effects of the 1999 Turkish Earthquake on Young Children: Analyzing Traumatized Children's Completion of Short Stories, Elif Celebi Oncu and Aysegul Metindogan Wise.

Individual and Peer Group Normative Beliefs About Relational Aggression: Developmental Changes and Prediction of Relational Aggression, Nicole E. Werner and Laura G. Hill.

Gender, Values, and Occupational Interests Among Children, Adolescents, and Adults, Erica Weisgram, Rebecca S. Bigler, and Lynn S. Liben.

Children's Understanding of Social-Cognitive and Social-Communicative Aspects of Discourse Irony, Eva Filippova and Janet Wilde Astington.

The Head Bone's Connected to the Neck Bone: When Do Toddlers Represent Their Own Body Topography? Celia A. Brownell, Sara R. Nichols, Margarita Svetlova, Stephanie Zerwas, and Geetha Ramani.

Connecting Cues: Overlapping Regularities Support Cue Discovery in Infancy, Sarah Sahni, Mark Seidenberg, and Jenny Saffran.

Mexican-Heritage Children's Attention and Learning From Interactions Directed to Others, Katie G. Silva, Maricela Correa-Chávez, and Barbara Rogoff.

The Development of Social Essentialism: The Case of Israeli Children's Inferences About Jews and Arabs, Dana Birnbaum, Inas Deeb, Gili Segall, Adar Ben-Eliyahu, and Gil Diesendruck.

Parent Involvement and Children's Academic and Social Development in Elementary School, Nermeen El Nokali, Heather J. Bachman, and Elizabeth Votruba-Drzal.

Do Effects of Early Child Care Extend to Age 15 Years? Deborah Vandell, Jay Belsky, Margaret Burchinal, Laurence Steinberg, Nathan Vandergrift, and NICHD Early Child Care Research Network.

I Like Me if You Like Me: On the Interpersonal Modulation and Regulation of Preadolescents' State Self-Esteem, Sander Thomaes, Albert Reijntjes, Bram Orobio de Castro, Brad J. Bushman, Astrid Poorthuis, and Michael J. Telch.

An Eye for Detail: An Event-Related Potential Study of the Rapid Processing of Fearful Facial Expressions in Children, Petra Vlamings, Lisa M. Jonkman, and Chantal Kemner.

Experience-Based and On-Line Categorization of Objects in Early Infancy, Marc Bornstein and Clay Mash.

On the Progression and Stability of Adolescent Identity Formation, Wim Meeus, Rens van de Schoot, Loes Keijsers, Seth J. Schwartz, and Susan Branje.

Dogs, Bogs, Labs, and Lads: What Phonemic Generalizations Indicate About the Nature of Children's Early Word-Form Representations, Erik Thiessen and Meagan N. Yee.

Investigating the Development of Core Cognitive Skills in Autism: A 3-Year Prospective Study, Elizabeth Pellicano.

Home Media and Children's Achievement and Behavior, Sandra Hofferth.

The Effects of Maltreatment and Neuroendocrine Regulation on Memory Performance, Dante Cicchetti, Fred A. Rogosch, Mark L. Howe, and Sheree L. Toth.

Interracial and Intraracial Contact, School-Level Diversity, and Change in Racial Identity Status Among African American Adolescents, Tiffany Yip, Eleanor K. Seaton, and Robert M. Sellers.

Child Care and the Development of Behavior Problems Among Economically Disadvantaged Children in Middle Childhood, Elizabeth Votruba-Drzal, Rebekah Coley, Carolina Maldonado Carreno, Christine Li-Grining, and P. Lindsay Chase-Lansdale.

Children's Classroom Engagement and School Readiness Gains in Pre-Kindergarten, Nina C. Chien, Carollee Howes, Margaret Burchinal, Robert Pianta, Sharon Ritchie, Donna Bryant, Richard Clifford, Diane Early, and Oscar Barbarin.

Early Elementary School Adjustment of Maltreated Children in Foster Care: The Roles of Inhibitory Control and Caregiver Involvement, Katherine Pears, Philip A. Fisher, Jacqueline Bruce, Hyoun K. Kim, and Karen Yoerger.

Children's Understanding of Ordinary and Extraordinary Minds, Jonathan Lane, Henry Wellman, and E. Margaret Evans.

What Paradox? Referential Cues Allow for Infant Use of Phonetic Detail in Word Learning, Christopher Fennell and Sandra R. Waxman.

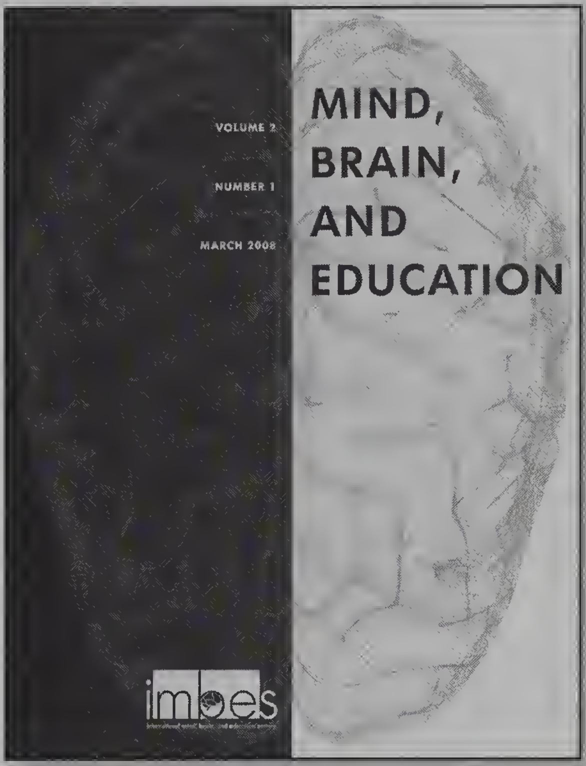
Contagious Yawning in Autistic and Typical Development, Molly Helt, Inge-Marie Eigsti, Peter J. Snyder, and Deborah A. Fein.

Tolerance of Practices by Muslim Actors: An Integrative Social-Developmental Perspective, Maike Gieling, Jochem Thijs, and Maykel Verkuyten.

Structure and Strategies in Children's Educational Television: The Roles of Program Type and Learning Strategies in Children's Learning, Deborah L. Linebarger and Jessica Taylor Piotrowski.

Bridging the Gap: Solving Spatial Means–Ends Relations in a Locomotor Task, Sarah Berger, Karen E. Adolph, and Alisan E. Kavookjian.

Sex Categorization Among Preschool Children: Increasing Utilization of Sexually Dimorphic Cues, Kerri Johnson, Leah Lurye Murphy, and Louis G. Tassinary.



MIND,
BRAIN,
AND
EDUCATION

Edited by
KURT FISCHER *(Editor-in-Chief),*
and **DAVID DANIEL**
(Managing Editor)

The official journal of the International Mind, Brain, and Education Society

Mind, Brain, and Education, recognized as the 2007 **Best New Journal** in the Social Sciences & Humanities by the Association of American Publishers' Professional & Scholarly Publishing Division, encourages submission of papers from the variety of fields relevant to connecting mind, brain, and education in research, theory, and/or practice. The central purpose of the journal is to provide a forum for accessible presentation of basic and applied research on learning and development, including analyses from biology, cognitive science, and education.

Notice to Contributors

Child Development publishes empirical, theoretical, review, applied, and policy articles reporting research on child development. Published by the interdisciplinary Society for Research in Child Development (SRCD), the journal welcomes relevant submissions from all disciplines. Further information is available at http://www.srcd.org/cd.html.

Types of Articles

Child Development considers manuscripts in formats described below. Inquiries concerning alternative formats should be addressed to the Editor prior to submission. All submissions are expected to be no more than 40 manuscript pages, including tables, references, and figures (but excluding appendices). Authors should provide a justification if the submission is substantially longer. Unless the editor finds that justification compelling, the submission will be returned to the author for shortening prior to editorial review.

Empirical articles comprise the major portion of the journal. To be accepted, empirical articles must be judged as being high in scientific quality, contributing to the empirical base of child development, and having important theoretical, practical, or interdisciplinary implications. Reports of multiple studies, methods, or settings are encouraged, but single-study reports are also considered. Empirical articles will thus vary considerably in length, but should be no longer than 40 manuscript pages; text and graphics should be as concise as material permits. All modes of empirical research are welcome.

Empirical reports are reserved for short cutting-edge empirical papers that are no longer than 4,000 words in length (including text, tables, footnotes, appendices), which advance research and knowledge in an area through noteworthy findings and/or new methods. For manuscripts that require longer descriptions of methods and results, authors should use the Empirical article format.

Reviews focus on past empirical and/or on conceptual and theoretical work. They are expected to synthesize or evaluate a topic or issue relevant to child development, should appeal to a broad audience, and may be followed by a small number of solicited commentaries.

Essays describe original concepts, methods, trends, applications, and theories; these may also be accompanied by solicited commentaries.

Child Development and … are articles that provide readers with tutorials about some new concept or academic specialty pertinent to research in child development. These papers should review the major definitions, methods, and findings of the concept or specialty and discuss past or potential links to child development.

From another perspective is a format in which papers on a focal topic, written by different authors, are published simultaneously. Papers represent diverse perspectives (e.g., authors whose work represents different populations; different disciplines; different theories, methods, or analytic tools). In some cases, calls for submissions on particular topics will be disseminated through SRCD (via e-mail or SRCD publications), and submissions will undergo normal editorial review. In some cases, a submitted manuscript (e.g., an empirical article) may be selected as a lead article for this format, with invited commentaries providing additional perspectives. The editors also welcome suggestions from readers for topics for this format.

Manuscript Submission

Child Development invites for consideration manuscripts that are neither identical to nor substantially similar to work published or under review elsewhere. In the submission cover letter, please provide details about other published or submitted papers having substantial overlap (including data sets) with the new CD submission to enable editors to judge whether the new submission is sufficiently distinct from other work to warrant consideration. Please note if the paper is posted on a website, see http://www. srcd.org/web posting. html. Editors retain the right to reject manuscripts that do not meet established ethical standards for research or dissemination.

Manuscripts should be submitted electronically to the Child Development Online Submission Site at www.srcd.org /CDsubmit/ as a Word or WordPerfect file. Please also submit a cover letter that contains the name(s) of the author(s) and affiliation(s), and the street address, telephone, fax, and electronic mail address of the corresponding author. A corresponding author's submission to *Child Development* implies that all coauthors have agreed to the content and form of the manuscript and that the ethical standards of SRCD have been followed (see the *Child Development* website or pp. 283–284 of the 2000 SRCD Directory). Any financial interest or conflict of interest must be explained to the Editor in the cover letter. The corresponding author is responsible for informing all coauthors, in a timely manner, of manuscript submission, editorial decisions, reviews, and revisions. Please note that if your submission (or its revision) is accepted for publication, each author must submit a signed Exclusive License Form (http://www.srcd.org/Documents/Publications/CD/cdcopyright.pdf) before the manuscript can enter production. Planning ahead to meet this requirement is especially important for manuscripts with multiple authors.

The manuscript file should be formatted with double-spaced, 12-point type, and should include a single paragraph abstract of 100-120 words. Please follow all guidelines on format, style, and ethics provided in the Publication Manual (6th ed.) of the American Psychological Association. Figures included with initial submissions will not be returned. Therefore, please submit only electronic files or copies of figures. If color artwork is submitted, and the authors believe color art is necessary to the presentation of their work, the submissions letter should indicate that one or more authors or their institutions are prepared to pay the substantial costs associated with color art reproduction. Authors should keep a copy of all correspondence, files, and figures to guard against loss.

Manuscript Review

If you have any questions about your submission, please inquire at cdev@srcd.org or call (734) 926-0615. Each manuscript is handled by the Editor or an Associate Editor who consults with one or more Consulting Editors and/or ad hoc reviewers who have relevant expertise. To ensure blind review, cover sheets are removed before review; authors should avoid including any other information about identity or affiliation in submissions. Copies of the submission and associated correspondence are retained in the SRCD archives. For accepted manuscripts, authors are required to prepare a 300-500 layperson's summary for public dissemination purposes. Details are provided to authors as part of final processing.

There is no charge for publication in *Child Development* unless tabular or graphic materials exceed 10% of the total number of pages. Charges are also levied for changes in proofs other than correction of printer's errors. Any inquiries relating to charges or business matters (including reprint orders) should be addressed to Wiley-Blackwell, *Child Development*, Production Coordinator, 350 Main Street, Malden, MA 02148, (781) 388-8200.

Inquiries and suggestions regarding editorial policy may be addressed to: Dr. Jeffrey J. Lockman, Editor, *Child Development*, Department of Psychology, Tulane University, 2007 Percival Stern Hall, New Orleans, LA 70118-5698, lockman@tulane.edu. *Please do not send electronic or paper manuscripts to the above address.* Doing so will delay the processing of your manuscript.

Note to NIH Grantees

Pursuant to NIH mandate, Society through Wiley-Blackwell will post the accepted version of Contributions authored by NIH grantholders to PubMed Central upon acceptance. This accepted version will be made publicly available 12 months after publication. For further information, see www.wiley.com/go/nihmandate.

MONOGRAPHS OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT

Recent

A DYNAMIC CASCADE MODEL OF THE DEVELOPMENT OF SUBSTANCE-USE ONSET
- *Kenneth A. Dodge, Patrick S. Malone, Jennifer E. Lansford, Shari Miller, Gregory S. Pettit, and John E. Bates* (Serial No. 294, 2009).

FLEXIBILITY IN EARLY VERB USE: EVIDENCE FROM A MULTIPLE-*N* DIARY STUDY
- *Letitia R. Naigles, Erika Hoff, and Donna Vear* (Serial No. 293, 2009).

MARITAL CONFLICT AND CHILDREN'S EXTERNALIZING BEHAVIOR: INTERACTIONS BETWEEN PARASYMPATHETIC AND SYMPATHETIC NERVOUS SYSTEM ACTIVITY
- *Mona El-Sheikh et al.* (Serial No. 292, 2009).

THE EFFECTS OF EARLY SOCIAL-EMOTIONAL AND RELATIONSHIP EXPERIENCE ON THE DEVELOPMENT OF YOUNG ORPHANAGE CHILDREN
- *The St. Petersburg–USA Orphanage Research Team* (Serial No. 291, 2008).

UNDERSTANDING MOTHER-ADOLESCENT CONFLICT DISCUSSIONS: CONCURRENT AND ACROSS-TIME PREDICTION FROM YOUTHS' DISPOSITIONS AND PARENTING
- *Nancy Eisenberg et al.* (Serial No. 290, 2008).

DEVELOPING OBJECT CONCEPTS IN INFANCY: AN ASSOCIATIVE LEARNING PERSPECTIVE
- *David H. Rakison and Gary Lupyan* (Serial No. 289, 2008).

THE GENETIC AND ENVIRONMENTAL ORIGINS OF LEARNING ABILITIES AND DISABILITIES IN THE EARLY SCHOOL YEARS
- *Yulia Kovas, Claire M. A. Haworth, Philip S. Dale, and Robert Plomin* (Serial No. 288, 2007).

THE PRESERVATION OF TWO INFANT TEMPERAMENTS INTO ADOLESCENCE
- *Jerome Kagan, Nancy Snidman, Vali Kahn, and Sara Towsley* (Serial No. 287, 2007).

CHILDREN'S QUESTIONS: A MECHANISM FOR COGNITIVE DEVELOPMENT
- *Michelle M. Chouinard* (Serial No. 286, 2007).

BEST PRACTICES IN QUANTITATIVE METHODS FOR DEVELOPMENTALISTS
- *Kathleen McCartney, Margaret R. Burchinal, and Kristen L. Bub* (Serial No. 285, 2006).

FOUNDATIONS OF SELF-AWARENESS: AN EXPLORATION THROUGH AUTISM
- *R. Peter Hobson, Gayathri Chidambi, Anthony Lee, and Jessica Meyer* (Serial No. 284, 2006).

OUR CHILDREN TOO: A HISTORY OF THE BLACK CAUCUS
OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT, 1973–1997
- *Diana T. Slaughter-Defoe, Aline M. Garrett, and Algea O. Harrison-Hale* (Serial No. 283, 2006).

PARENTAL SUPPORT, PSYCHOLOGICAL CONTROL, AND BEHAVIORAL CONTROL:
ASSESSING RELEVANCE ACROSS TIME, CULTURE, AND METHOD
- *Brian K. Barber, Heidi E. Stolz, and Joseph A. Olsen* (Serial No. 282, 2005).

BEING HURT AND HURTING OTHERS: CHILDREN'S NARRATIVE ACCOUNTS
AND MORAL JUDGMENTS OF THEIR OWN INTERPERSONAL CONFLICTS
- *Cecilia Wainryb, Beverly A. Brenl, and Sonia Matwin* (Serial No. 281, 2005).

CHILDHOOD SEXUAL ASSAULT VICTIMS: LONG-TERM OUTCOMES AFTER TESTIFYING IN CRIMINAL COURT
- *Jodi A. Quas, Gail S. Goodman, Simona Ghetti, Kristen Weede Alexander, Robin Edelstein, Allison D. Redlich, Ingrid M. Cordon, and David P. H. Jones* (Serial No. 280, 2005).

THE EMERGENCE OF SOCIAL COGNITION IN THREE YOUNG CHIMPANZEES
- *Michael Tomasello and Malinda Carpenter* (Serial No. 279, 2005).

TRAJECTORIES OF PHYSICAL AGGRESSION FROM TODDLERHOOD TO MIDDLE CHILDHOOD:
PREDICTORS, CORRELATES, AND OUTCOMES
- *NICHD Early Child Care Research Network* (Serial No. 278, 2004).

CONSTRAINTS ON CONCEPTUAL DEVELOPMENT: A CASE STUDY OF THE ACQUISITION OF
FOLKBIOLOGICAL AND FOLKSOCIOLOGICAL KNOWLEDGE IN MADAGASCAR
- *Rita Astuti, Gregg E. A. Solomon, and Susan Carey* (Serial No. 277, 2004).

ORIGINS AND EARLY DEVELOPMENT OF HUMAN BODY KNOWLEDGE
- *Virginia Slaughter, Michelle Heron, Linda Jenkins, and Elizabeth Tilse* (Serial No. 276, 2004).

MOTHER CHILD CONVERSATIONS ABOUT GENDER: UNDERSTANDING THE ACQUISITION OF ESSENTIALIST BELIEFS
- *Susan A. Gelman, Marianne G. Taylor, and Simone P. Nguyen* (Serial No. 275, 2004).

Child Development

CHILD DEVELOPMENT (ISSN 0009-3920), one of three publications of the Society for Research in Child Development, Inc., is published bimonthly by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to *CHILD DEVELOPMENT*, Journal Customer Services, John Wiley & Sons Inc., 350 Main Street, Malden, MA 02148-5020.

Information for Subscribers: *Child Development* is published in six issues per year. Institutional subscription prices for 2010 are: Print & Online: US$670 (US), US$938 (Rest of World), €608 (Europe), £479 (UK). Prices are exclusive of tax. Asia-Pacific GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www3.interscience.wiley.com/aboutus/journal_ordering_and_payment.html#Tax. The price includes online access to the current and all online back files to January 1st 1997, where available. For other pricing options, including access information and terms and conditions, please visit www.interscience.wiley.com/journal-info.

Delivery Terms and Legal Title: Prices include delivery of print journals to the recipient's address. Delivery terms are Delivered Duty Unpaid (DDU); the recipient is responsible for paying any import duty or taxes. Legal title passes to the customer on despatch by our distributors.

In This Issue

What Is an Effective Parent?

What does it take to be an effective parent? In a theoretical essay, **Grusec and Davidov** (p. 687) bring together various theories of effective parenting by proposing a domain approach to socializing children. In so doing, they suggest that rather than following a single approach to effective parenting, parents operate at different times in different domains (the researchers identify five) that are characterized by different kinds of relationships (for example, protector–protected and teacher–student). Effective parents are those who can figure out in which domain their children are operating and respond in ways that are appropriate to that particular area, with each condition calling for a different form of parenting (comfort, discipline, teaching, etc.). The researchers also note that in each of the domains, parenting is not simply top-down because children also influence their parents' behavior as well as respond to it in a variety of ways. The analysis can help inform research as well as parenting and intervention programs.

Parsing the Environment

Languages are structured and systematic, with recurring and predictable patterns that infants can figure out. **Sahni, Seidenberg, and Saffran** (p. 727) sought to determine whether babies could use one such statistical cue in language to discover an additional, connected cue and thus help them learn language. They conclude that babies are born statisticians, noting that 9-month-olds can use these cues, and in so doing, isolate new cues. Not only can they use these methods to figure out the important patterns in the language, they can use statistical learning to discover the complex structure of language. The study informs our understanding of how very young children acquire language.

Identifying separate entities as belonging to the same group or category is a key skill in developing abstract concepts and acquiring vocabulary. **Bornstein and Mash** (p. 884) ask a number of important questions about the basic processes that very young infants use to categorize, including: Do the methods for assessing category formation in the laboratory reflect the learning that young infants do in more natural environments, such as home? They find that 5-month-olds who saw objects in the laboratory for the first time formed categories of those objects very quickly. However, they also find that natural experience with objects at home is reflected in how children categorize in the laboratory, with infants bringing prior experience to bear in the laboratory setting. By suggesting that infants can learn new categories on the fly, as well as retain and apply categories previously experienced, the findings give us a better understanding of human cognition and development.

Lasting Effects of Child Care

Do children's early child care experiences have any long-term effects on them as adolescents? In the latest installment of the NICHD Study of Early Child Care and Youth Development, **Vandell et al.** (p. 737) sought to determine if early child-care quality, quantity, and type predict children's achievement and behavior problems at age 15. They find that the effects of early child care at age 15 are comparable in size to those previously observed in early childhood and elementary school. Specifically, the longitudinal study of more than 1,300 adolescents finds that teens who attended higher-quality child care scored higher on tests of cognitive and academic achievement than teens who attended lower-quality care. Furthermore, teens who spent more hours in early child care reported more risk taking and greater impulsivity than teens who spent fewer hours in care. The study, the first to document long-term effects of routine, nonrelative care in a large sample of children from economically diverse families, extends the findings of previous research on the topic.

Rodkin and Roisman (p. 837) used longitudinal data on more than 1,000 children from the NICHD study to find that in third to sixth grade, many so-called "tough kids" have an extensive history of early child care before starting school. Tough kids were defined as children who are, perhaps paradoxically, very aggressive and very popular

with their peers. The study defined extensive child care as averaging 32 hours a week from birth to age 4½, compared to 24 hours a week for others. The findings take into account such factors as gender, ethnicity, mothers' education and sensitivity, and the quality of child care. The study helps illuminate the longer-term effects of extensive child care.

In a study on the quality of child care for children in home-based care, **Gunnar, Kryzer, Van Ryzin, and Phillips** (p. 851) find that child-care providers' behavior is associated with how well children do at child care and how much of the stress hormone cortisol is in their systems. The researchers looked at about 150 mostly White 3- and 4-year-olds in full-time home-based care, comparing their levels of cortisol at home and in child care. Similar to children in center-based care, preschoolers in family day care had elevated levels of cortisol at child care, compared to days when they were at home. Those whose child-care providers were intrusive and over-controlling had larger elevations in cortisol at child care. In girls, this rise was associated with more vigilant and anxious behavior, while for boys it was associated with more angry and aggressive behavior. In contrast, children whose providers were warmer and more supportive showed behavior that was less vigilant, anxious, angry, and aggressive. The findings add to our understanding of how children process stressors in home-based child care, highlighting differences between boys and girls.

Jumping to Conclusions

The belief that all members of a social category (e.g., members of one race) are fundamentally the same, and that you can therefore generalize from one member to all members of a social category is arguably at the foundation of stereotypes, prejudice, and even certain ideologies. **Birnbaum, Deeb, Segall, Ben-Eliyahu, and Diesendruck** (p. 757) carried out two studies of more than 250 kindergarteners, second graders, and sixth graders from three cultural groups in Israel. They find that in Israeli society, this belief is already in place by kindergarten, that its development varies across cultural groups, and that it comes primarily from how language marks the categories rather than from how members of the categories appear visually. By shedding light on the developmental and cultural processes underlying social categorization, the study shows how certain social categories can become powerful sources for children's generalizations about people.

Another study looked at this issue from the perspective of gender. Do men and women tend to work in different fields (think engineering vs. nursing) because they endorse different values? **Weisgram, Bigler, and Liben** (p. 778) examined individuals' occupational values, occupational interests, and perceptions of values associated with different jobs. They studied more than 500 American children (ages 5–10), adolescents (ages 11–17), and young adults (ages 18–23). They found that individuals tended to associate masculine jobs with money, power, and altruism, and feminine jobs with family values. The study also looked at individuals' interest in jobs they encountered for the first time. These ''novel jobs'' were described as being performed by either men or women, and as fulfilling different kinds of values (like wanting to make a lot of money or wanting to have time for one's family). At all ages, interest in novel jobs was influenced by the gender of workers and by the values the jobs were said to fulfill. Overall, the findings suggest that sex differences in occupational values contribute to sex segregation of jobs.

The Physical and Psychological Selves

When do children begin to think about their bodies as they appear to others—as distinct objects, with physical characteristics and parts that are located in specific places? **Brownell, Nichols, Svetlova, Zerwas, and Ramani** (p. 797), based on their study of more than 60 toddlers, find that children are developing a topographic map of their own bodies between 20 and 30 months of age. They define knowledge of body topography as knowing where specific body parts are located, and knowledge about how body parts are arranged or organized in relation to one another. The conclusion—that by age 2½, children have a beginning knowledge of their own bodies' size, shape, and structure—shows us that children's understanding of the self continues to develop in an increasingly refined way in the preschool years.

Past research that has looked at interpersonal influences on children's self-esteem in the long term has found that children's self-esteem is dependent on how much they are liked by others. **Thomaes et al.** (p. 811), looking at interpersonal influences in the short term, find that children's self-esteem can wax and wane as a result of how much they are liked by others in the present. The finding is based on a study of more than 330 eight- to twelve-year-olds in the Netherlands. It suggests that self-esteem is a so-called sociometer, a psychological gauge of how much you are currently valued and accepted by others, and that it is highly dynamic and reacts to current social context, not a stable characteristic as had been previously thought. The study can help inform support programs for socially vulnerable youths.

Relational Aggression

We know that aggression in children causes problems for both those who are aggressive and those who are victimized. In a longitudinal study, **Werner and Hill** (p. 826) examined relational aggression, in which children use relationships to cause harm by, for example, excluding others or spreading rumors. Based on research on more than 240 third through eighth graders, they find that what children think about this type of aggression and what their peers think can influence behavior. Specifically, children's approval of relational aggression grew from elementary to middle school, children who were more approving of this type of behavior engaged in more of it the following year, and students in peer groups that supported the behavior became increasingly aggressive over time. Many schools have programs on physical aggression, but children and adults tend to view relational aggression as more acceptable than physical aggression; these findings provide information for designing school programs.

Counting Sheep, Losing Sleep

Researchers are increasingly interested in the ties between children's sleep and their cognitive and emotional development. **El-Sheikh, Kelly, Buckhalt, and Hinnant** (p. 870) studied how sleep disruptions (namely, the amount, quality, and schedule of sleep) affect children's adjustment. After examining more than 140 children in third to fifth grades, they find that children from poorer families and African American children had higher levels of externalizing symptoms (such as aggression and delinquency) and internalizing symptoms (such as depression, anxiety, and low self-esteem) when they slept poorly. Conversely, when these children slept better, their levels of symptoms were similar to those of other children. This research adds to the mounting evidence linking sleep to day-to-day functioning in childhood, and highlights the role of sleep in a wide range of behavioral problems in high-risk children.

Watch Closely

Children learn a lot from interactions around them that are not addressed directly to them. For example, they learn language by hearing others speak. Do children who are included in the work and social activities of their communities have more opportunities to learn in this way? **Silva, Correa-Chávez, and Rogoff** (p. 898) studied 40 sibling pairs between 5 and 11 years old. Mexican-heritage U.S. children whose families likely are familiar with indigenous Mexican practices paid closer attention to activities around them and learned more. In contrast, Mexican-heritage U.S. children from immigrant families with extensive involvement in Western schooling and practices were not as observant and did not learn as much. The study's findings point to the value of enhancing children's opportunities to learn through observation.

Getting at the Meaning

How early do children understand irony? **Filippova and Astington** (p. 913) studied more than 70 English-speaking Canadian children ages 5, 7, and 9, as well as 24 English-speaking adults. They find that overall, 5-year-olds lagged behind older children in understanding irony, although they did understand some aspects of irony in some conditions—for example, they realized that a sarcastic comment actually means the opposite of what is said. The 7- and 9-year-olds, while able to judge how nice, mean, and funny irony is as well as adults can, were well behind adults in figuring out the ironic speaker's intention or motivation. The study sheds light on early communicative development.

We all like to know why things happen, and children often look for explanations by asking questions, while also making up their own explanations. To determine what motivates children to generate explanations, **Legare, Gelman, and Wellman** (p. 929) studied 80 preschoolers. They find that events that do not square with what they know to be true (i.e., that are inconsistent with prior knowledge) and require them to process new information are a powerful trigger for children to construct explanations. In their search for deeper explanations, they describe what has happened by focusing on underlying reasons that might not be obvious. The research highlights the role that explanations may play in the learning process.

Tattling and Talking

Young children frequently "tattle" on other children who have done something they consider wrong. In the first systematic research to focus on tattling in preschool settings, **Ingram and Bering** (p. 945) find that children (they studied 3- and 4-year-olds in Northern Ireland) tattle to the teacher about once a day and are more likely to tell teachers about bad behavior (hitting someone, damaging property, fighting during playtime) than about behavior that is just different. They also find that children tell the truth in their reports, are more likely to tattle when they themselves are the victims, and vary considerably in their motivations for tattling. And they find that the tattlers are rarely ignored by adults, who support them and intervene when necessary. The study helps us understand the role of tattling, which the authors call an important form of social communication for many young children.

To explore the relations among gender, conversation, and children's concepts of punishment, **Leman and Björnberg** (p. 958) studied about 130 British 9-year-olds. The children listened to stories in which a child had done something wrong, were asked to choose a fair punishment and, in some cases, discussed the topic with other children. Eight weeks later, the children decided on the fairness of the punishment again. Both immediately and 8 weeks later, children who discussed the story with peers made more mature judgments about fairness than those who did not. The researchers suggest that peer conversations can promote moral development because they stimulate children to reflect on a topic after the conversation. Moreover, although the content of the conversations was not influenced by gender, conversation dynamics *were* strongly affected, with boys using more negative interruptions than girls, and children changing their behavior based on whether their conversation partner was a girl or a boy. The study sheds light on how and why peer instruction spurs development and learning.

Promoting Development

The more that environments stimulate children cognitively and intellectually when they are young, the higher their achievement in elementary school. That is what **Crosnoe et al.** (p. 972) find, based on a longitudinal analysis of more than 1,300 children followed from birth in the NICHD Study of Early Child Care and Youth Development. The researchers evaluated children's homes and child care/preschool settings when the children were 4½ years old, studied their first grade classrooms, and evaluated reading and math test scores through fifth grade. Results: What matters is not so much whether parents support children's learning at home or children are stimulated by their teachers in preschool or elementary school but instead whether all *three* things occur. Finally, even though children from advantaged families are more likely to experience this convergence of support for learning across the contexts of their lives, low-income children may benefit more from it. The study has implications for policy, suggesting the value of boosting coordination among parents, preschool classrooms, and elementary schools.

Promoting parent involvement has been a major component of efforts to improve school performance. Extending past research that has focused on parent involvement among preschoolers, **El Nokali, Bachman, and Votruba-Drzal** (p. 988) sought to learn how parent involvement affects children's academic, social, and emotional well-being in elementary school. Based on data from the NICHD study, the researchers examined more than 1,300 children from birth to fifth grade. Children whose parents were more involved across elementary school had fewer problem behaviors and better social skills but showed no changes in achievement. In suggesting that parents continue to wield considerable influence on children's development through elementary school, the study has implications for policies to encourage involvement.

Memory and Order

In school and life these days, children are called on to memorize more and more related and unrelated information. Eight- to 10-year-olds do so by rehearsing words, either individually or together as part of a set. In a longitudinal look at about 75 German second graders, **Lehmann and Hasselhorn** (p. 1006) find that as they get older, children increasingly rehearse several words together. This in turn helps them recall the words by leading them to remember a specific recall order that corresponds to the order of the words when they were presented. The authors' in-depth analysis offers insights into the ways youngsters are developing and improving their capabilities to organize and remember information as they enter into middle childhood.

Integrating Different Perspectives on Socialization Theory and Research: A Domain-Specific Approach

Joan E. Grusec
University of Toronto

Maayan Davidov
The Hebrew University of Jerusalem

There are several different theoretical and research approaches to the study of socialization, characterized by frequently competing basic tenets and apparently contradictory evidence. As a way of integrating approaches and understanding discrepancies, it is proposed that socialization processes be viewed from a domain perspective, with each domain characterized by a particular form of social interaction between the object and agent of socialization and by specific socialization mechanisms and outcomes. It is argued that this approach requires researchers to identify the domain of social interaction they are investigating, to understand that phenotypically similar behaviors may belong to different domains, and to acknowledge that caregivers who are effective in one type of interaction may not be effective in another.

Developmental psychologists have a long history of interest in how children are socialized or assisted to become mature, competent, and contributing members of the social community. Topics studied and theoretical approaches taken have been diverse. Possibly as a reflection of this diversity, interconnections among various approaches are remarkably few, in spite of the general concern with how agents of socialization support children's development in social, emotional, and intellectual areas. Thus, there has been little attention to understanding how diverse approaches are linked and/or overlap in their implications for the developmental process. This article addresses how such an integration might be accomplished and how various theoretical and research threads might be brought together into a unified conceptualization. We do this by elaborating on a domain-specific approach to the analysis of socialization.

The notion of domain specificity is particularly popular in cognitive psychology, where it has become increasingly clear that information processing is not a unitary, domain-general process. Rather, information from different content areas or types of stimuli is seen as being processed by specialized modules, each of which has evolved to accomplish a recurring important task or function (e.g., face recognition, numerical thinking, grammar processing; Duchaine, Cosmides, & Tooby, 2001; Hirschfeld, 1996; Sperber & Hirschfeld, 2004). Each of these processing modules therefore mediates the acquisition and regulation of a different kind of knowledge or skill, and each is governed by specific processes and mechanisms. A domain analysis has been also applied to socialization, with the realization that different caregiver–child interactions mediate the acquisition of different socioemotional skills and tendencies (Bugental, 2000; Bugental & Goodnow, 1998). The domains in this case are different forms of social relationships or social interaction: Children interact with caregivers and other socialization agents in a variety of ways and contexts, and these interactions can be meaningfully partitioned into several distinct types or domains (Bugental & Goodnow, 1998; Maccoby, 1999). The notion that social relationships—and more specifically, parent–child relationships—are modular has important implications for socialization: Each aspect, or domain, of parent–child interaction is seen as fostering socialization in a different way. Thus, there is no general, all-purpose principle or mechanism of socialization, but rather each form of relationship between the object and the agent of socialization serves a different function, involves different rules and mechanisms for effecting behavior change, and facilitates different outcomes. We note that these domains of social interaction differ from the social knowledge domains explored by

Turiel and his colleagues (1983, 1998), an observation to which we shall return below.

Which domains or forms of social interaction can be identified, between people in general and between children and caregivers in particular? Based on his theoretical and ethnographic work, Fiske (1992) identified four basic types of social relations between individuals: communal sharing (where people treat all members of a category as equivalents, sharing resources and benefits), authority ranking (where people treat one another as hierarchically ordered along a social dimension), equality matching (where people exchange benefits and keep track of imbalances), and market pricing (where people interact based on values determined by a market system). Although this framework is informative for a domain-specific analysis of socialization, it focuses on social relations in general rather than on types of interaction between children and agents of socialization more specifically. For the latter we turn to Bugental and her colleagues (Bugental & Goodnow, 1998; see also Bugental, 2000; Bugental & Grusec, 2006). Based on a review of prior theories and research, they identified four kinds of relationships that exist between agents and objects of socialization, each providing a specific context for socialization. These four domains are: attachment relationships (proximity between caregiver and child in times of stress to maintain the child's safety), social identity relationships (shared identity with members of one's in-group and the acquisition of group norms and routines), hierarchical relationships (caregivers' use of their greater control of resources in order to facilitate children's compliance and discourage disobedience), and reciprocal relationships (mutual, reciprocal exchanges of benefits and positive affect between functional equals). Furthermore, Bugental and her colleagues have reviewed extensive evidence indicating the specificity of these domains. Thus, each type of relationship differs in its evolutionary underpinnings, developmental course, rules of social interaction, regulatory mechanisms including the neurohormonal processes that are activated, type of social information that is sought, and nature of the socialization tasks involved. In the current article we elaborate on this work in several ways. First, we offer some refinements of the typology of domains. Second, we illustrate how this domain analysis helps to bring together the seemingly disparate lines of research on socialization. Third, we focus on what effective parenting entails in each domain, thus unpacking the construct of parental responsivity (Bugental, 2000; Goldberg, Grusec, & Jenkins, 1999). Fourth, we discuss which child outcomes are of greatest relevance to each domain and review evidence supporting domain-specific linkages. Finally, we discuss the implications of a domain approach for the study of socialization, highlighting promising avenues for future research.

In our discussion, we focus on the socialization of children, although noting that any novice who becomes part of a new group, regardless of age, must go through a process of socialization. We also focus on socialization in the family and on parents as primary agents of socialization, observing that although socialization also occurs in other contexts, there is a compelling argument that its primary context is the family (Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000). Nevertheless, our analysis of socialization is applicable beyond the family and discussion is confined to the family primarily for the sake of simplicity and because of space limitations. This article begins with a very brief overview of the history of socialization research. It does so for two reasons. First, such a survey highlights the need for bringing together a diversity of approaches that have never been well integrated. Second, such a survey reveals the major themes that have emerged thus far in socialization research, and how they can be meaningfully divided into specific domains.

Socialization Research in Historical Perspective

Reinforcement, Secondary Drives, Discipline, and Parenting Styles

Initial empirical work on socialization was carried out by theorists who were concerned with children's internalization of values, that is, their taking over of the standards and behaviors of society as a means of self-regulating or guiding their own actions. Taking their lead from stimulus-response learning theory principles, they argued that acquired drives underlie most of socialization, with caregivers and their actions taking on secondary reward value through their pairing with primary drive reduction. In this way a dependency drive, as well as a drive to be like or to identify with the parent, develops (Sears, 1957). Much of their work focused on discipline (punishment and reasoning) and its role in the control of children's behavior (Sears, Maccoby, & Levin, 1957). Interest in discipline has continued to the present, with ongoing comparisons of the effectiveness of various discipline techniques for conscience and other forms of social development (e.g., Grusec & Goodnow, 1994;

Hoffman, 1970; Lepper, 1983). Also important is the notion that effective discipline involves the minimization of the child's perceptions of external control so as to promote the child's feelings of self-direction, one aspect of the notion of autonomy (Grolnick, Deci, & Ryan, 1997). One exception to the predominant position that stresses the goal of internalization of "self-chosen" values came in work on behavior management (e.g., Patterson, 1982). This work demonstrated that effective control of external reinforcement contingencies by parents was an important aspect of socialization.

Another related approach appeared in work on parenting styles. Again, the focus was on how parents could best control their children in order to achieve positive socialization outcomes. Firm but responsive control was shown to be generally better than strict and harsh control, or than a lax, laissez-faire approach (Baumrind, 1971). Recent work on parenting styles has focused on behavioral control (monitoring of children's behavior in a context of clearly stated rules) and psychological control (manipulation of children's emotions), with behavioral control associated with better socialization outcomes (Barber, 1996).

We note that common to all these lines of work is that they focus on the relationship between the child and the caregiver as an authority figure who seeks to control or correct the child's behavior. We therefore label this the control domain. It is conceptually similar to Bugental and Goodnow's hierarchical power domain and to Fiske's authority ranking social model.

Observational Learning, Intent Participation, Rituals, and Routines

Bandura and Walters (1963), in what can be seen as a precursor to a domains approach, argued that there are different types of learning, governed by different sets of basic principles. They emphasized the role of observational learning, over that based on reinforcement and acquired drives, as the most fundamental form of learning for humans, and one in which a wide variety of social behaviors are acquired (such as aggression, self-regulation, resistance to temptation, delay of gratification, and moral judgment; Bandura, 1977). Taking a social cognitive stance, Bandura postulated attentional, symbolic, and memorial processes as the underlying mechanisms in observational learning. Moreover, and importantly, he and his colleagues demonstrated that observational learning occurred independent of anticipation of rewards: Children cannot be kept from learning what they have seen (Bandura, Grusec, & Menlove, 1966). Thus, the study of socialization moved from a focus on identification seen as the result of an acquired, secondary drive to a focus on more cognitive mechanisms.

The emphasis on observational learning currently reappears in the attention of anthropologists to learning through intent participation. This is a form of socialization that involves children's close observation and listening-in during valued cultural activities and practices, with the expectation of future participation and the knowledge that such learning is essential for group participation (Lave & Wenger, 1991; Rogoff et al., 2007). Observation with intent participation appears to play a central role in cultures where children are incorporated into adult activities in their community (as opposed to being segregated in formal schooling), but can be a powerful means of socialization in a Western industrialized context as well (e.g., Odden & Rochat, 2005; Rogoff et al., 2007). Researchers interested in cultural practices have stressed that by keenly observing and later participating in group practices, rituals, and routines, children develop their social identity—they develop a sense of belonging to their community and cultural group, and the understanding of what it means to be a member of their in-group (Miller & Goodnow, 1995). Much of this appears to occur in the context of children's most immediate group—the family. Indeed, there is long-standing evidence for the important role of family rituals and routines in conveying to children a sense of social identity and belonging ("this is who we are"), as well as a connection to past and future generations and to the larger social group (Fiese et al., 2002; Wolin & Bennett, 1984).

These lines of thinking and research share a common focus on children's observation and participation in group practices. We therefore label this the group participation domain and note that it overlaps considerably with Bugental and Goodnow's (1998) social identity domain (see also Bugental's, 2000, coalitional group domain). It can also be seen as including certain aspects of Fiske's communal sharing social model.

Attachment Theory

Attachment theorists studied early parent–child relationships and their impact on the child's security, development of the ability to cope with distress, and social competence (Ainsworth, Blehar, Waters, & Wall, 1978). The theory emerged from an ethological and evolutionary perspective rather than the social learning and social cognitive perspectives characteristic of early socialization researchers (Bowlby, 1969/1982). Attachment researchers were interested in how children are brought into the social community or socialized, but whereas social learning theorists such as Sears (1957) had seen the wish to be near the parent as a learned dependency drive, the principles of attachment theory led to different predictions about the impact of parental responsiveness. Thus, for example, attachment theorists argued that parents who responded to the crying of infants ultimately would have babies who cried less whereas learning theorists predicted they would cry more. Because of their opposing principles, attempts to integrate attachment and social learning and social cognitive theory have been virtually nonexistent (Grusec & Ungerer, 2003). We conceptualize attachment theory and relevant work as pertaining to the protection domain, that is, to interactions in which children need and seek comfort, protection, and support from caregivers, and caregivers act to protect children from harm and distress. This domain is conceptually similar to Bugental's attachment domain, and our label reflects the view that protection is a central element of attachment. This domain includes components of Fiske's communal sharing model.

Reciprocal Compliance

There was one notable exception to the failure of social learning, social cognitive, and attachment theorists to take note of each other's thinking. Observing that compliant children were more likely to have caregivers who were responsive to their needs and the proposal that this link was mediated by children's secure attachment (Stayton, Hogan, & Ainsworth, 1973), Maccoby and Martin (1983) suggested instead a direct link between the two: They proposed that parental compliance with children's reasonable needs, wishes, and requests elicits the child's compliance with parental requests in turn, reflecting an inborn tendency to reciprocate the actions of others. This was a route to compliance that differed from that of attachment theorists because it did not involve attachment or protection. In addition, it did not involve the assumption that children and parents were always in conflict and that the latter therefore needed to control the former, but rather that children and parents can cooperate willingly with one another and pursue shared goals. A considerable body of research has since explored the role of parents' positive responding in a context of mutuality (see Kochanska, 2002). We view this direction of theory and research as pertaining to another form of social interaction, that in which children and caregivers cooperate as equals, exchanging and reciprocating one another's bids and favors. We label this the reciprocity domain, similar to Bugental and her colleagues. This domain incorporates components of Fiske's equality matching and communal sharing models.

Teaching and Scaffolding

A final approach to understanding socialization comes from work on instruction and teaching, specifically, on how a more experienced individual works with or guides a less experienced one to acquire more advanced knowledge and skills (Vygotsky, 1978). Central to the notion of guided learning is that the teacher must work within the child's zone of proximal development by presenting problems that are just modestly beyond the child's current level of functioning. As a result of these dialogues the child is able to internalize the language used by the more knowledgeable person and thus develop a more advanced understanding of the task at hand. Although Vygotsky believed that guided learning applies to the acquisition of culturally relevant knowledge and skills in general, most of the research in this area has focused on how children are taught to master cognitive problems. Some evidence for the applicability of supported or guided learning to other types of tasks exists, however. As an example, Turner and Berkowitz (2005) have argued that scaffolding is strongly implicated in moral development and character education. As well, in recent years, there has been a great deal of interest in how parents talk to their children about social and emotional issues, with the plausible assumption that these discussions can also have a didactic purpose in facilitating children's more advanced knowledge and ability in these areas (see Laible & Panfile, 2009, for a review). We view teaching interactions as involving unique features and a distinct context for socialization, and label this domain the guided learning domain. This domain does not clearly map onto Fiske's models, nor does it appear in Bugental's typology. Although it may be interpreted as implicitly subsumed under Bugental and Goodnow's social identity domain, we argue that one-on-one teaching interactions are different in important ways from observation and participation in group rituals and routines (see below).

Integration

This overview underlines the fact that approaches to the study of socialization have been fragmented. Moreover, we note that although children's relationships with parents and other socialization agents have always been at the center of socialization research, each line of study has typically focused on a different aspect of the relationship or a particular way of relating to others (hierarchical power, common group membership, provider/receiver of protection, equal partnership, or teacher/student), that is, on a different domain of social relationships. And work in each domain has called on a different set of principles of learning (reinforcement and punishment, observational learning and social identity, innate tendency to form attachments, reciprocity, and guided learning) to explain how socialization occurs. This fragmentation can be resolved, however, by adopting a domain approach to socialization. By viewing socialization not as involving a single, general mechanism but rather as a collection of different processes pertaining to different elements of the parent–child relationship, seemingly inconsistent lines of research and theory can be brought together. By acknowledging the complexity of the parent–child relationship and the notion that each of its components, or domains, provides children with different opportunities to learn about life and to develop competence, disparate pieces of knowledge can be integrated.

Two caveats are in order. First, our proposed typology of domains is not necessarily exhaustive, as other domains might become evident when research on socialization progresses. Second, although we are presenting the five domains in their prototypic, or pure, form, we also believe that many real-life interactions reflect combinations of or overlaps among domains (see a relevant discussion later in this article). This is consistent with Fiske's (1992) notion that the four elementary models of social relations he identified can be combined in different ways to reflect more complex social situations. Outlining the unique and distinctive features of each domain seems an important first step, however, before considering more complex combinations.

If, as we have argued, socialization involves a variety of domains, then this has implications for the way socialization research is conducted. First, if different principles operate in different domains then researchers need to ensure they identify the domains in which agents and objects of socialization are functioning before talking about the nature of effective socialization. Thus, the notion of ''sensitive and responsive parenting'' requires more precise definition because what constitutes sensitivity and responsivity in one domain may not constitute it in another. Similarly, it is not enough to speak of ''positive socioemotional development'' or ''behavioral adjustment'' because these global terms encompass various aspects relevant to different domains. As well, researchers need to be aware that child outcomes that have surface similarity may belong to different domains, a fact precluding the automatic assumption that phenotypically similar events can be treated as equivalent. Also, researchers (and others) need to be conscious of the fact that agents of socialization who function well in one domain may not necessarily function well in others: While there may be ''good'' parents and ''bad'' parents, one would expect to find many parents who are good in some domains and less good in others. We will elaborate on each of these proposals later in the article.

General Features of Socialization

Before describing features of the five domains relevant to socialization and evidence for the specificity of processes, we make some general observations about the socialization process and the domain approach. As well, we briefly elaborate on differences between the domains of interaction approach discussed in the present article and another influential domain approach in the area of social development, that of domains of social knowledge (Turiel, 1983, 1998).

Socialization, as noted above, is the process by which children acquire the social, emotional, and cognitive skills needed to function in the social community. They acquire these skills through their social interactions for which they have been biologically prepared (Bugental, 2000). As noted above, interactions in each of the five domains involve distinct socialization processes and are pertinent to different child outcomes, which we describe in more detail in the next part of this article. Importantly, socialization is a bidirectional process (Kuczynski, 2003), and this is true in each of the five domains as well as in a more general sense. First, in each domain of social interaction, children have a significant impact on what parents do and on the nature of the interaction. For example, child characteristics influence whether or not parents can easily sooth and comfort the child (protection domain), whether the child makes many requests and bids for attention (reciprocity), how frequently the child's behavior needs to be controlled and which method is most effective (control), what cultural practices and rituals the child is most drawn to (group participation), or how the child needs to be taught in order to master a new task and how quickly he or she can learn (guided learning). Socialization is thus a complex process of interaction between child and parent behavior. In every domain different features of the child that are both environmentally and genetically determined (e.g., temperament, age, past experiences) significantly alter parenting behavior and its effects on children (Grusec & Goodnow, 1994; Grusec & Hastings, 2007). Second, in a more general sense, and very importantly from the perspective of the present article, any parenting effort can be effective only when it is appropriately matched to the domain of interaction in which the child is situated. Thus, the child's need and motivational state must be taken into account for effective socialization to occur. For example, if children are punished when the reason for their behavior is that they are in distress or do not know any better, or if children are comforted when they are not distressed, or guided when they are not motivated to learn or already possess the knowledge that the caregiver is trying to impart, then these parenting interventions are likely to be counterproductive because they are not domain appropriate. According to our domain approach, then, children are important and active contributors to their own socialization.

We also take the position that the domains of socialization presented in this article are universal because they have evolved to solve problems experienced in the human environment of evolutionary adaptedness (Bugental, 2000). Nevertheless, cultural differences are also expected in at least two respects. First, there can be variation in the degree to which a given domain of interaction is frequently engaged in or emphasized in different cultures. For example, guided learning is more widespread in cultures that rely heavily on formal schooling, whereas other cultures may utilize group participation processes to a greater extent (observational learning, intent community participation; Odden & Rochat, 2005; Rogoff et al., 2007). Even in the latter cultures, however, guided learning, though less frequently used, appears to be important in facilitating culturally valued skills that are too complex to master independently (Gauvain, 2005). Second, culture can influence the nature of successful rearing in a given domain of interaction: Certain practices that are successful in one cultural context may appear to be less so in another culture, probably because of different meanings attached to those practices or different goals of socialization emphasized by each cultural group. High levels of rigid control, for example, seem to be more detrimental in Western cultures than in Asian cultures because, in the former, they tend to be associated with parental rejection and lack of warmth, whereas in the latter, they reflect parental care and a desire to instill the important values of hard work, self-discipline, and obedience (Chao, 2002). These differences in emphasis, frequency of use, and in the meanings and consequences of parenting actions, however, do not detract from the basic notion that there are different routes to socialization operative in different domains of interaction and that a parenting practice as interpreted by the child must be appropriate to the domain in which the child is functioning.

Finally, we note that there are both differences and connections between our domains of interaction analysis and Turiel and his colleagues' domains of social knowledge analysis. With respect to differences, the latter line of work focuses on different types of social knowledge (e.g., differentiation among moral, conventional, prudential, and personal issues) and the different forms of reasoning associated with each. The emphasis is on cognition and on how children through their various life experiences acquire a differentiated understanding of different kinds of social issues. The focus of the present article is on different types of interaction with agents of socialization and the different pathways to socialization supported by each of those distinct forms of interaction. The emphasis is on the values, motivations, and skills that children acquire through their social interactions, which then guide their behavior and facilitate their ability to adapt to and function well in their society. Nevertheless there are connections between the two approaches. Most importantly, the fact that children reason differently about different classes of social activities alerts socialization researchers to the fact that not all behaviors are equivalent and that some may be more difficult to modify than others or require different approaches to modification. The personal and prudential domains, for example, are believed by children to involve those activities where authority figures have less right to intervene or interfere than are the moral and social conventional domains (Smetana, 1997). Given that activities in these former domains are considered to be under personal jurisdiction, therefore, it stands to reason that they should be difficult to modify, particularly in the control domain where the parent acts as an authority figure. In the guided learning domain parents act as teachers, and to be effective in this capacity they must understand the child's construal or perception of the situation under discussion. There is evidence, for example, that reasoning or arguments that match the child's way of thinking about a particular class of behavior are more effective than those that do not: Reasoning that refers to harm to others is evaluated more positively in the case of moral misdeeds and reasoning that refers to the maintenance of social order more positively in the case of social conventional misdeeds (see Grusec & Goodnow, 1994; Smetana, 1997, for discussions of this link). Thus, despite their different foci, the two domain approaches do complement one another.

Domains of Socialization: Features and Child Outcomes

We turn now to a description of the five domains relevant to socialization, including discussion of the conditions under which each domain is activated, the nature of the relationship involved in each domain, the different parenting behaviors required as a function of the domain, the child outcomes associated with each domain, and the mechanisms accounting for linkages between parent behavior and child outcome. The order of presentation is loosely guided by developmental considerations. We have chosen to present the protection domain first given that the child's need for protection and the caregiver's provision of protection occurs from the very beginning of life. Mutuality/reciprocity comes next, also because of its appearance early in the life of infants (Adamson & Bakeman, 1991). Control follows as it becomes more necessary once children increase in their mobility and desire for mastery of the environment during the 2nd year of life. Guided learning interactions likely become more prominent toward the end of the 2nd year with the development of language and the accompanying ability to understand and internalize complex explanations (Vygotsky, 1978; see also Thompson, Laible, & Ontai, 2003). Finally, we consider group participation, noting that adherence to the rules of group life and the desire for ritual becomes particularly strong in the 2nd to 4th years of life (Emde, Biringen, Clyman, & Oppenheim, 1991).

Protection

Features of the domain. Many species have evolved so that the young maintain proximity to their caregivers, particularly when they are in danger and need protection. In turn, caregivers have evolved to provide this protection to their offspring, an arrangement that increases the likelihood that parental genes are passed into the gene pool. The protection interaction domain is activated by cues that the child is under real or potential threat, leading the child to seek, and the parent to give, help and support. When caregivers respond sensitively to children's needs for protection, children develop a sense of security and can rely on the caregiver in times of need, whereas insensitive responses lead to lack of confidence in the availability of parental support, and thus to either excessive minimization or augmentation of distress signals (Ainsworth et al., 1978). In the protection domain, then, appropriate parenting involves responding in a way the child perceives to be comforting or helpful when distressed. Perception is important because what is comforting or helpful depends on a variety of features including the child's developmental status and temperament. Other forms of positive parenting such as reciprocity, appropriate discipline, teaching/guided learning, or facilitation of group participation should not contribute to the child's feelings of being protected or secure and able to react appropriately to threat. Similarly, protection and comforting would not be appropriate forms of parenting, as we shall argue subsequently, when the child was not operating in the protection domain. Features of the protection domain are summarized in Table 1 where the parent–child relationship is described as involving provider and recipient of protection, alleviation of the child's distress as the required parent behavior, and confidence in protection as the operative mechanism.

Child outcomes in the domain. An important outcome of appropriate parental protection is that children develop greater ability to respond appropriately to stress and to self-regulate their distress. This ability is at least partially mediated by the normal development of important neurobiological systems, which can be impaired if caregivers are repeatedly insensitive to infants' distress (Gunnar, 2000). In addition, anticipating that support will be available also renders potentially stressful situations less threatening for the child. Indeed, a great deal of research indicates that, compared to their insecurely attached peers, securely attached

Table 1
Domains of Socialization: Parent–Child Relationships, Parental Behavior, and Mechanisms

Domain	Nature of parent–child relationship	Parental behavior that is required	Mechanism of socialization
Protection	Provider–recipient of protection	Alleviate child's distress	Confidence in protection
Reciprocity	Exchange/equality	Comply with child's reasonable requests and influence attempts	Innate tendency to reciprocate
Control	Hierarchical	Use discipline method best suited for achieving parental goal	Acquired self-control
Guided learning	Teacher–student	Match teaching to child's changing level of understanding	Internalization of language and approach used by the teacher
Group participation	Joint members of the same social group	Enable child to observe and take part in appropriate cultural practices	Firm sense of social identity

children, who are assumed to have experienced more sensitive caregiving in the protection domain, are more competent at regulating their distress and negative affect (e.g., Cassidy, 1994). Another outcome is greater empathic capability: Well-protected children are better able to respond empathically to the plight of others because they are able to regulate their own empathic arousal and therefore remain focused on the other's plight rather than on their own personal distress (Davidov & Grusec, 2006a; Eisenberg, Wentzel, & Harris, 1998). This ability to appreciate the emotional plight of others facilitates children's prosocial behavior (Eisenberg & Fabes, 1998) and can also reduce antisocial behavior because the negative consequences of one's actions for others are more easily comprehended (Eisenberg et al., 1999). Finally, the directives and commands of a supportive and reassuring caregiver are more likely to be seen as a sign of caring and, as a result, more likely to lead to compliant behavior (Bretherton, Golby, & Cho, 1997), at least when these directives pertain to children's safety and well-being (see below). It also happens that when caregivers comfort their children they may coincidentally provide models of prosocial and caring practices customary in their culture, and that when they are sensitive to their children's need for protection they may also scaffold their children's acquisition of effective coping strategies (Gottman, Katz, & Hooven, 1996; Thompson, 1994). These latter observations demonstrate how interconnected different domains can be during the socialization process, but do not detract from the message of domain-specificity, because protection is the only domain where making the child feel safe and protected is the key parenting action.

Reciprocity

Features of the domain. This aspect of the parent–child relationship emerges not when the child is distressed but rather when parent and child are interacting as equal-status partners and accommodating one another's wishes as can occur, for example, during play. Reciprocity can take the form of specific exchange of favors (''tit for tat'') as well as nonconditional mutuality, both of which occur in families (Parpal & Maccoby, 1985). From an evolutionary perspective such exchange makes sense because the provision of benefits to kin simultaneously benefits one's own reproductive success, and reciprocal help among nonkin is also often necessary for survival and reproductive success (Hamilton, 1964). In the reciprocity domain, caregivers, by cooperating with children's reasonable demands and bids for attention, set up the conditions whereby children are more likely to cooperate in return. As the parent's willingness to accommodate is reciprocated by the child, the two become attuned and responsive to the needs of each other, sharing common goals that result in a cooperative existence. Child responsiveness in the domain of reciprocity thus reflects a genuine interest in compliance. Indeed and quite importantly, if parents were mistakenly to tangibly reward compliance when it occurs in this domain, external consequences would become salient and the child's motivation to comply would be undermined (Deci & Ryan, 1985). Exchanging or sharing of positive affect also often characterizes these reciprocal interactions (Kochanska, 2002; Parpal & Maccoby, 1985), perhaps because the mutual attunement can be highly pleasing for both interaction partners.

In the reciprocity domain, then, appropriate parenting involves accommodating the child's reasonable requests for compliance. Other forms of positive parenting such as responsiveness to distress, appropriate discipline, guided learning, or encouragement of group participation should not facilitate reciprocated cooperation. Similarly, parental compliance would not be appropriate when the child was not operating in the reciprocity domain. Table 1 describes features of this domain: a parent–child relationship of equality; effective parent behavior, one of compliance with reasonable requests from the child; and a mechanism reflecting the innate tendency of humans to reciprocate favors.

Child outcomes in the domain. Outcomes in this domain involve children's eager willingness to comply with parental requests. Indeed, there is considerable evidence for the importance of parental compliance and mutual reciprocity in socialization. Mothers' willing cooperation with their children's wishes and following of their children's lead during a play interaction predicted children's willing compliance with those mothers during a subsequent clean-up task (Lay, Waters, & Park, 1989; Parpal & Maccoby, 1985). Kochanska and her colleagues (e.g., Kochanska & Aksan, 1995; Kochanska & Murray, 2000) also find that mutually compliant and harmonious relationships during early childhood are predictors of positive social behavior in later childhood. There is also evidence that early cooperative play is associated with fewer conduct problems (Gardner, Ward, Burton, & Wilson, 2003) and that boys whose interactions with their mothers are positively responsive and interconnected have less conflict with their mothers and are less likely to engage in antisocial behavior (Criss, Shaw, & Ingoldsby, 2003). Several proximal mechanisms have been proposed to explain increases in child cooperation and compliance in the presence of parental compliance. One suggestion is that allowing children to control the nature of interactions increases positive mood and thereby encourages positive behaviors (Lay et al., 1989; Parpal & Maccoby, 1985). Alternatively, maternal responsiveness may make the child's identity more salient in an exchange relationship and thereby increase the availability of cooperative scripts in the child's relationship schemas (Parpal & Maccoby, 1985).

In sum, appropriate caregiving in the reciprocity domain results in "receptive compliance." Maccoby and Kochanska and their colleagues have distinguished between situational and receptive compliance, suggesting that the former is more likely to occur when children and parents are in conflict and children do not voluntarily go along with parental requests. In the case of receptive compliance, the child conforms willingly with a parental directive, reflecting a genuine interest in furthering the needs of the dyad.

Control

Features of the domain. From an evolutionary perspective it is important for human social groups to develop definitions of and sanctions for deviance in order to achieve social harmony (Boehm, 2000): To function well within their group individuals must come to accept and obey cultural rules, a requirement that often necessitates the inhibition of personal desires. Children learn these important cultural lessons largely in the control domain. Thus, the control domain involves interactions in which the goals of children and caregivers conflict—children want one thing and caregivers another. This typically happens when children misbehave or are noncompliant as well as during caregiver–child conflict in general. In this domain parents take advantage of those resources over which they have greater control to modify the actions of their children, both to ensure their children's reproductive capability and to encourage socially acceptable behavior. Although good arguments are made for the considerable power that children exert in their relationships with parents (e.g., Kuczynski, 2003), parents do have an arsenal of resources that includes social and material rewards, physical punishment, withdrawal of rewards and privileges, social disapproval, social isolation, and superior knowledge and experience to persuade through reasoning. Thus, they can make use of this power imbalance in various ways to discourage their children's antisocial or undesirable behavior and encourage their prosocial behavior.

There are challenges to be met in this process. First, as noted above, most socialization theorists interested in control have argued that the amount of control being administered must be sufficient to produce the desired behavior but, at the same time, not so forceful or autonomy-threatening that it undermines internalization (Bugental & Grusec, 2006; Deci & Ryan, 1985). This minimization of coerciveness is necessary because an important (although not only) goal of socialization in the control domain is to have children internalize values, that is, to take over parental/societal values as their own so that external pressure or force is no longer necessary: The perception that standards and attitudes guiding behavior have been self-generated is the hallmark of internalization (Hoffman, 1970). An already noted exception to this perspective is Patterson who is less concerned with internalization and who argues that behaviors controlled by external contingencies simply become habitual through repetition (Patterson & Fisher, 2002). In addition, some have argued that internalization of self-chosen values is a less important goal in collectivist cultures, where people's actions are viewed as a reflection of their social roles and obligations rather than their autonomous choices (e.g., Schwartz, 1994). Proper behavior that has been chosen by or for the sake of others, such as behavior motivated by the child's respect for authority or sense of duty toward parents, is therefore highly desirable in these cultures (although a sense of autonomy may still be important in these contexts as well; see Helwig, 2006).

A second challenge in the control domain has to do with the large range of individual differences among children and their misdeeds or antisocial acts. Just as there are differences in what children find distressing and comforting in the protection domain, so too are there differences in what children respond to positively in the control domain. Although earlier work attempted to identify those discipline interventions that work best for all children in all situations, subsequent work has yielded a more complex picture of interactions between specific discipline interventions and features of child and situation. Among the variables shown to moderate the effects of parental control strategies are the child's developmental status, sex, temperament, mood, self-perceptions, and nature of the misdeed committed (Grusec & Goodnow, 1994). As a result, successful parenting in this domain cannot be reduced to the use of a particular ("best") discipline method but rather appears to involve the parent's knowledge of how the particular child views the discipline situation and utilization of that knowledge to select the control strategy that can best achieve the parental goal.

In the control domain, then, appropriate caregiving involves exerting the appropriate amount and manner of authority needed in order to modify the child's behavior in accordance with the socialization agent's goals. If these goals include internalization, this must involve making sure not to overly threaten that child's sense of autonomy; if the goal is habitual compliance, then effective control of reinforcement contingencies is more central; if the goal is deference to authority, then emphasizing the child's social roles and duties is appropriate. Other forms of positive caregiving such as responsiveness to distress, reciprocity, guided learning, or facilitation of group participation should not be very effective at bringing about change in children's behavior and attitudes when children misbehave or are reluctant to cooperate. Similarly, parental discipline, even when mild, would not be appropriate when the child was not operating in the control domain. Table 1 summarizes features of this domain including a hierarchical parent–child relationship, parent discipline that is suitable for achieving the parenting goal, and the acquisition of self-regulation or self-control as the mechanism governing socialization outcomes.

Child outcomes in the domain. Outcomes in the control domain involve children's moral and principled behavior, that is, doing the right thing even when it requires inhibiting one's conflicting goal or desire. Consistent with the discussion above, such behavior can take at least two forms. One is proper conduct that is due to internalization of values. Children engage in principled action because they believe that these actions are self-generated, autonomous, and inherently correct. Thus their behavior is internally motivated and occurs in the absence of surveillance. It is in this case that standards and attitudes are most resistant to change. They can be questioned and they will still be staunchly maintained. Presumably they are subject to modification but not without some effort. A second outcome in the control domain is behavior motivated by more external reasons, such as the child's respect for authority, or the anticipation of rewards or punishments. These can also include "internal" (or introjected) rewards and punishments such as the need to be viewed positively by others or to avoid feeling shame or guilt (Deci & Ryan, 1985; Grolnick et al., 1997). Nor does this second outcome reflect a failure of socialization if it is intended by the agent of socialization. In both cases, however—internally and externally motivated appropriate conduct—socialization depends on the greater control of resources by one member of the dyad than by the other.

Guided Learning

Features of the domain. In the domain of guided learning, socialization agents support children's learning of cognitive, physical, vocational, social, or emotional skills that can improve their ability to adjust and function well in their cultural group. From an evolutionary point of view, social interactions involving teaching and guided learning carry a clear advantage for adaptation. Human beings are less strong physically than many other species and so their superior intellectual skills evolved in order to aid their survival, skills that often require teaching and training. They are also born more immature than most other species and thus they have a protracted period of dependency, which gives caregivers a length of time during which they can pass on information (Gauvain & Perez, 2007). In addition, the human capacity for language enables socialization agents to teach highly complex ideas and skills through verbal communication.

Successful socialization in the guided learning domain requires first that the task being taught is within the child's zone of proximal development; that is, it is a task that the child cannot yet perform independently but could master with the aid of a more experienced other (Vygotsky, 1978). Second, the teacher needs to support, or scaffold (Wood, Bruner, & Ross, 1976), the learning by adjusting his or her guidance to the child's changing skill level and understanding. The teacher's involvement is thus gradually reduced until the child is able to perform the task independently. For this to occur, the teacher needs to assist the child in developing more advanced ways of construing the activity or subject matter at hand; thus, the teacher and student arrive at a shared understanding of the task, or intersubjectivity, and the child internalizes the language, and hence the approach, used by the teacher (e.g., Puntambekar & Hübscher, 2005; Vygotsky, 1978).

In the guided learning domain, then, effective parenting involves the provision of the suitable structure, information, strategies, and feedback that children need in order to learn and improve their skills. Other forms of positive parenting such as responsiveness to distress, reciprocity, appropriate discipline, and encouragement of group participation should not facilitate children's acquisition of complex knowledge and skills that are difficult to learn independently. Similarly, the provision of information within the child's zone of proximal development would not be appropriate when the child was not operating in the guided learning domain. In Table 1 we note that the parent–child relationship in this domain is one of teacher and student, that effective parent behavior requires teaching that is matched to the child's changing level of understanding and mastery of the task (within the zone of proximal development), and that the mechanism of learning is the child's internalization of the language and approach used by the more knowledgeable other.

Child outcomes in the domain. Outcomes in the guided learning domain involve the acquisition of the knowledge or skills being scaffolded (Gauvain, 2005). Moreover and importantly, because sensitive scaffolding allows children to comprehend and become aware of the parent's conception of the issues, strategies being used, and internal processes involved (metacognition and emotion), it has the potential to promote a deep understanding and internalization of the relevant topic or skill (e.g., Gauvain, 2005; Neizel & Stright, 2003; Vygotsky, 1978; see also Thompson et al., 2003).

Although the outcomes assessed in this domain have typically involved cognitive abilities (Gauvain, 2005; Mattanah, Pratt, Cowan, & Cowan, 2005), evidence suggests that guided leaning can also facilitate the acquisition of social and emotional skills. Gottman et al. (1996) have shown that parents' emotional coaching of their children (e.g., teaching their child regarding the nature of emotions, the appropriate expression of emotions, and strategies for managing them), assessed in an interview, predicted children's more adaptive physiological as well as behavioral regulation of emotions. Similarly, maltreating mothers' inability to provide coaching regarding how to cope with emotionally arousing situations contributed to their children's poorer coping with negative affect (Shipman & Zeman, 2001). Studying young infants' interaction skills, Vandell and Wilson (1987) demonstrated that maternal scaffolding of social play was linked to infants' subsequent ability to engage in competent social interaction with siblings and peers. Scaffolding by older siblings also facilitated infants' subsequent social play with peers (see also Leve & Fagot, 1997, for a link between parental scaffolding and peer competence at a later age). As another example, Laible (2004a, 2004b) has shown that mothers who talk to their young children about emotion-laden past events in a coherent and elaborative manner and who scaffold the conversations by providing detail, structure, and feedback, have children who show a more advanced understanding of emotions (see also Fivush, Haden, & Reese, 2006; Laible & Song, 2006; Thompson et al., 2003). Turner and Berkowitz (2005) have argued that many common practices of moral and character education (e.g., "plus-one" moral discussions, class meetings) strongly implicate key elements of scaffolding. Thus, guided learning appears to foster socioemotional as well as cognitive competencies. Another potential outcome of effective scaffolding may involve children's greater confidence regarding their own abilities (Mattanah et al., 2005).

Group Participation

Features of the domain. In the group participation domain, socialization agents can promote children's participation in cultural practices. Humans have an inherent desire to be part of their social group(s), and parents can foster and channel this motivation to facilitate socialization. Evolutionary theorists have suggested that the motivation to be part of the group is located in the need to rely on the larger social group for assistance and for resources (e.g., Brewer, 1999). As the in-group becomes larger and more depersonalized, it becomes necessary to demarcate its boundaries so that benefits or trust are not inadvertently bestowed on the out-group. Thus, symbols and behaviors that differentiate members of the in-group from the out-group become important and are seen not just as different from the out-group's but also as better (Brewer, 1999). Evidence for the importance of group participation to young children comes from children's preference for in-group members and their more positive evaluations of the in-group (Bennett et al., 2004; Dunham, Baron, & Banaji, 2008), their greater perceived similarity to in-group members (Bennett & Sani, 2008), their distress when they are unable to reproduce the behavior of others (Kagan, 1982), and their eagerness to take part in the rituals and routines of their family and classroom (McNamara & Humphry, 2007; Spagnola & Fiese, 2007).

In the group participation domain, children and parents interact as members of a common social group, with parents serving as representative in-group members who convey to children what their group membership, or shared social identity, entails. Thus, parents promote routines, habits, and rituals for the family that reflect and embed many in-group expectations and norms. They also serve as models from whom children learn by observation much about social customs and cultural practices. Importantly, interactions in this domain do not involve the careful scaffolding of children's learning that is characteristic of the guided learning domain. Rather, in this domain children are socialized simply by being exposed to or included as participants in group practices. As noted earlier, the proposal that imitation is a primary form of learning came originally in the work of Bandura and his colleagues (e.g., Bandura, 1977), and subsequent work on learning through intent participation and on rituals and routines has provided an emphasis on group practices (e.g., Fiese et al., 2002; Miller & Goodnow, 1995; Rogoff et al., 2007). Group participation interactions also do not involve the conflict between caregiver and child that is part of the control domain, because these are situations in which children are eager and motivated to participate in their group.

Thus, in the group participation domain, by providing children with opportunities to observe how things are done in the group and by encouraging routines and rituals that reflect and instill these norms, caregivers support children's acquisition of expectations about a myriad of social actions, such as gender-based behavior, how to dress, where to eat and sleep, what is appropriately done in public and what can only be done in private, and so on. Caregivers can further influence this process indirectly by managing the child's environment so as to prevent exposure to undesirable models and routines and encourage exposure to desirable ones. Accordingly, to the best of their ability, parents select the neighborhoods in which their children live and the friends with whom their children interact as well as their access to media presentations. Another important feature of this domain is that children can belong to, and may wish to participate in, different social categories and groups. Caregivers can influence which in-groups are seen as more central or important (e.g., same ethnicity or nationality or religious or political affiliation) as well as which reference group is seen as most pertinent at different points in development or for different aspects of behavior (e.g., same-sex peers, older siblings, adults), with consequences for which practices and norms children will adopt.

If caregivers facilitate children's participation in group-relevant practices and norms—through the routines and rituals they promote, their own modeling, and their encouragement of children's exposure to and identification with other positive models — then children are more likely to adopt desirable social customs without questioning. If caregivers are inconsistent, or promote behaviors that are not socially acceptable, then adoption of group norms and identity will be less successful. Other forms of positive parenting such as responsiveness to distress, reciprocity, appropriate discipline, and guided learning should not facilitate children's automatic adoption of customs and attributes characteristic of the group. Similarly, parental emphasis on ritualized activities or encouragement of similarity to others would not be effective when the child was not operating in the group participation domain. As summarized in Table 1, in this domain the parent–child relationship involves membership in the same social group (with the parent, or another socialization agent, functioning as an exemplary in-group member), appropriate parent behavior is that which enables and encourages the child to watch and take part in desirable cultural practices and customs, and the underlying mechanism for socialization is the child's firm sense of social identity—feeling part of his or her social group(s) and knowing "who we are and what we do."

Child outcomes in the domain. Outcomes of effective parenting in the group participation domain involve conformity to and adoption of practices and routines associated with the group. These attitudes and behaviors are readily acquired because they are viewed simply as "the way things are done" and are strongly entrenched because of frequent repetition. This form of learning—through observation and routine—is powerful because the expectations it produces about appropriate standards of behavior are often unexamined and thus relatively impervious to articulation or change (Bourdieu, 1977). Once questioned, however, they lose their hold and may therefore become more prone to rejection than are attitudes and behaviors acquired in the control and guided learning domains. The latter may be more resistant to change or more strongly internalized because they result from apparent self-choice or from a deep intellectual understanding of the issues involved.

Evidence for Specificity

What evidence is there for domain specificity? The empirical evidence is not systematic in nature, given a general lack of interest by many researchers in the different facets of parenting or in a comparison of their utility for particular outcomes. We have searched for studies that do make a comparison and organized them into the different domains whose existence we have hypothesized.

Protection

Del Carmen, Pederson, Huffman, and Bryan (1993) compared sensitive caregiving in the protection domain (maternal soothing and comforting of infants' distress) at 3 months of age with events that we suggest involve the domains of reciprocity (exchanges of positive affect) and guided learning (interactions involving physical objects). They found that comforting predicted attachment security at the end of the child's 1st year, whereas the other forms of responsive parenting did not. More recently, and utilizing a larger sample, McElwain and Booth-LaForce (2006) found that maternal sensitivity to infant distress at 6 months, but not sensitivity to nondistress, predicted later attachment security. Similarly, Leerkes, Blankson, and O'Brian (2009) found that maternal sensitivity to distress at 6 months, but not sensitivity to nondistress, predicted fewer behavior problems and greater social competence in toddlerhood, and, for highly temperamentally reactive children, better affect regulation. As well, Rodriguez et al. (2005) found that maternal responsiveness during an emotionally demanding or stressful task was predictive of children's ability to self-regulate or delay gratification 3 years later, whereas responsiveness during a task that was not emotionally demanding did not predict self-regulation. Davidov and Grusec (2006a) reported that responsiveness to distress predicted self-regulation of negative affect as well as empathy and prosocial behavior toward others in distress whereas warmth did not. Finally, Hubbard and van IJzendoorn (1991; see also van IJzendoorn & Hubbard, 2000) attempted to explain their failure to replicate Bell and Ainsworth's (1972) findings: Unlike Bell and Ainsworth, they found that infants subsequently cried more, not less, when their mothers responded promptly to their crying. Hubbard and van IJzendoorn hypothesized that prompt response to significant distress cries should lead to less crying in young infants whereas a similar prompt response to instrumental cries or mild discomfort should predict greater amounts of crying. This proposition is certainly consistent with a domain-specific approach if one assumes that significant distress cries are associated with the protection domain and mild or instrumental cries with the control domain. In sum, then, we suggest there is evidence that a range of behaviors that are influenced by maternal responsiveness to distress, that is, by parenting in the protection domain, are not influenced by mutual reciprocity, guided learning, or discipline/control. As well, they are not influenced by responsiveness to nondistress or to warmth, variables that appear to involve more than one domain, as will be discussed below.

Reciprocity

Evidence for specificity in this domain comes from three studies. Parpal and Maccoby (1985) reported that, compared to mothers who played as they normally did, mothers who were trained to minimize directions and questioning during a play period, allowing their children to lead the interaction, had children who subsequently complied more with their requests. In contrast, maternal expressions of warmth in this same situation did not contribute to children's compliance. In a second study, Davidov and Grusec (2006b) showed that children whose mothers were more likely to comply with their requests and bids for attention were in turn more likely to comply willingly with a maternal request to clean up a playroom. Mothers' knowledge regarding their children's reactions to discipline strategies did not contribute to children's willing compliance. Third, Davidov and Grusec (2008) found that mothers' willingness to cooperate with their children's requests, as assessed in an interview, predicted children's receptive compliance with maternal requests, whereas maternal responsiveness to distress did not. In sum, then, we conclude that receptive compliance is influenced by mutual reciprocity but not by responsiveness to distress, discipline, or warmth.

Control

Pettit, Bates, and Dodge (1997) reported that gentle discipline predicted fewer behavior problems and greater social skillfulness (e.g., awareness of the impact of one's actions on others) in children whereas warmth and involvement in children's contacts with peers did not. Davidov and Grusec (2006b) found that mothers who were knowledgeable about the way their children reacted to discipline were better able to induce their children to comply after they had initially refused. On the other hand, mothers who were high in compliance with their children's requests were no more or less able to induce such compliance following initial protest. Many years ago, Hoffman (1970), on the basis of a survey of the research literature, concluded that certain forms of discipline worked well in promoting inhibition of antisocial behavior whereas there was little evidence that observing the restrained behavior of other group members produced such inhibition. Finally, we include the suggestion of Hubbard and van IJzendoorn (1991) that limit setting (e.g., nonresponding) reduces instrumental crying (but not distress cries), whereas a protective, comforting response yields the opposite pattern. In sum, then, we suggest there is evidence that a range of behaviors that are influenced by control and discipline are not influenced by reciprocal compliance, enabling the child to observe appropriate cultural practices, responsiveness to distress, or warmth.

Guided Learning

Laible (2004b) reported that maternal scaffolding (evidenced by an elaborative discourse style) during conversations about emotion-laden topics predicted children's behavioral internalization in a resistance to temptation task, whereas security of attachment (presumably reflective of sensitivity in the protection domain) did not. Similarly, Bornstein and Tamis-LeMonda (1997) found that mothers who responded either physically or verbally in an unobtrusive way when their infant was orienting visually to a person or an object or vocalizing (most likely an example of scaffolding) showed better attention span and symbolic play, whereas responsiveness to distress did not predict attention span or quality of symbolic play. Laible and Song (2006) observed that mothers' elaborative style (scaffolding) when discussing emotion-laden past events with their young children had a significant main effect on children's emotional understanding, whereas shared positive affect during the interaction—a measure primarily reflective of reciprocity—did not. Successful cognitive functioning has been predicted by parental scaffolding but not parental warmth and control (Mattanah et al., 2005) or maternal sensitivity and warmth during play or children's attachment security (Mulvaney, McCartney, Bub, & Marshall, 2006). As well, Bigelow, MacLean, and Proctor (2004) found that mothers' level of scaffolding of infant play was unrelated to their degree of following the infant's lead during play (a behavior relevant to the reciprocity domain), with scaffolding appearing to be more strongly linked to more advanced forms of infant play. In sum, it appears that a variety of outcomes influenced by teaching and guided learning are not influenced by other features of caregiving, including responsiveness to distress, reciprocity, control, and warmth.

Group Participation

Grusec, Goodnow, and Cohen (1997) reported that children who did work around the house on a routine basis (e.g., automatically setting the dinner table every night) showed greater spontaneous concern and consideration for others both in the family and in other settings than did children who did work around the house primarily in response to parental directives and requests. If one assumes that routinely helpful children were operating in the group participation domain while doing household work whereas those who were helpful in response to requests were operating in the control or reciprocity domain, then there is support for the contention that spontaneous concern for others is influenced by group participation and not by reciprocal compliance or discipline. The only other study we have found that enables a comparison between parenting in the group participation and in other domains is by Friedman and Weissbrod (2004), who reported that emerging adults' intentions to initiate family rituals in their future families was significantly correlated with the degree to which their same-sex parent promoted family rituals while they were growing up, but not with other dimensions of parenting such as controlling behavior or caring that reflected responsiveness to distress and warmth. Thus, there is initial evidence that behaviors that are influenced by observation of and participation in group practices are not influenced by other features of caregiving including reciprocity, control, responsiveness to distress, and warmth.

Joint Contributions

As well as studies linking different parenting characteristics to different outcomes, there are also some that find independent contributions of these different parenting characteristics to the apparently same outcome. We would have to argue, of course, that the apparently same outcome in these cases reflects a combination or aggregation of similar but not identical outcomes arrived at by different routes or processes. Accordingly, parental responsiveness to distress and parental warmth made distinct contributions to preschoolers' general competence as rated by teachers (Roberts & Strayer, 1987). An elaborative, scaffolding discourse style during discussions of past emotional events and attachment security both made unique contributions to children's emotional understanding (Laible, 2004b), and elaborative discourse and shared positivity both contributed uniquely to children's positive representations of relationships (Laible & Song, 2006). Finally, research into family meals, an important family routine/ritual, has shown that the frequency of joint family meals predicts fewer health-risking behaviors among adolescents even after controlling for other predictive dimensions of parenting such as parental warmth and support in times of need (Eisenberg, Olson, Neumark-Sztainer, Story, & Bearinger, 2004; Fulkerson et al., 2006).

Summary

We have argued that there are five domains involved in the socialization process: protection, reciprocity, control, guided learning, and group participation. Effective parenting in each of these domains requires different behaviors from parents, and a different type of parental responsiveness and sensitivity. There is considerable initial evidence to support the contention that socialization processes differ in these five domains, although additional research is obviously greatly needed. Finally, we have argued that each domain is linked primarily to different socialization outcomes: effective coping during stressful situations and greater empathy and trust in the protection domain, receptive compliance and cooperation in the reciprocity domain, internalized values and situational compliance or deference to authority in the control domain, acquisition of culturally relevant complex knowledge and skills in the guided learning domain, and a sense of social identity and ready adoption of forms of social custom in the group participation domain.

Implications for Socialization Research and Theory

The notion that socialization occurs in different domains of social interaction that are governed by different psychological processes, rather than one domain governed by one set of processes, has implications for the conduct of socialization research and theorizing. The first is that researchers need to specify the domains to which the parenting and child outcome variables they are studying belong in order to identify what specific parenting actions are related to what specific child outcomes. Such specification is needed to provide appropriate hypotheses for testing. The second implication has to do with the quality of parenting: There is no reason to suppose that parenting in different domains of interaction will be of the same quality. Thus, parents who perform well in one domain involving one form of interaction with their child may not necessarily function well in another domain involving a different kind of relationship or interaction with the same child. We discuss these implications in turn.

Parenting and Child Outcome Variables Need to Be Differentiated According to Domain

Close attention to the domains in which agents of socialization and children are operating is not always evident in current work. We discuss examples of parenting and child variables whose more careful separation might serve to sharpen understanding of socialization processes.

Parenting Variables

Responsiveness and sensitivity, warmth, and harshness are parenting variables that continue to attract considerable attention from socialization researchers (Maccoby, 2007). Each of these is considered in turn with respect to how it relates to the five domains of social interaction.

Responsiveness and sensitivity. Parental responsivity is measured in many ways, with each way not necessarily predictive of the same outcomes. Explicit recognition of this fact appears in recent work by Landry, Smith, and Swank (2006) and by Bornstein, Tamis-LeMonda, Hahn, and Haynes (2008). Landry et al. distinguished among four forms of parental responsiveness to infants (acceptance of the infant's needs, positive affective input, support for the infant's foci of attention, and conversation) and found that the different forms of responsiveness were not intercorrelated and that they predicted different child outcomes. Bornstein et al. distinguished different forms of maternal responsiveness (e.g., affirmations, descriptions, imitations/expansions) to four different types of infant bids, and found that these types of responsiveness were not intercorrelated and followed different developmental trajectories. Although the forms of responsiveness identified in these studies are not all directly relevant to socialization, and the classifications are somewhat different from our domain approach, these findings highlight the fact that "responsiveness" or "sensitivity" can assume a variety of different forms and, therefore, the importance of delineating and unpacking the different aspects of this construct. In the case of socialization, these include: sensitive responding to the child's distress in the protection domain, willing cooperation with the child's reasonable requests and bids for attention and influence in the reciprocity domain, responding to the child's misdemeanors in a manner that takes into account the child's construal of the discipline situation in the control domain, providing information and structure within the zone of proximal development that is suitable to the child's current level of functioning in the guided learning domain, and responsiveness to the child's need to be included in the group and to observe and take part in valuable group activities in the group participation domain.

Warmth. Warmth is frequently operationalized as hugging, kissing, expressing affection, expressing positive affect, and praising (e.g., Robinson, Mandleco, Olsen, & Hart, 1995; Rohner, 2005). From the perspective of this article, then, warmth as it is frequently assessed appears to include a number of features that are relevant to different domains. Reciprocation and mutual sharing of positive affect and affection between caregiver and child are relevant to the reciprocity domain. Contingent social reinforcement, or praise, when delivered in order to convey caregiver approval or direct the child's behavior, belongs to the control domain. Positive affect and affection expressed as part of family celebrations and rituals reflects the group participation domain. In addition, kissing, hugging, and other displays of affection that are aimed at comforting an upset child reflect responsiveness to distress and are thus part of the protection domain. If each of these facets of warmth is associated with a different domain it is clear that the variable needs to be unpacked more carefully.

Harshness. Harsh parenting can involve severe punishment, coldness and rejection, intrusiveness, and nonsympathetic reactions to distress. But severe punishment appears relevant to the control domain whereas rejection and nonsupportive behavior may be relevant to the protection or reciprocity domains, depending on whether the rejection pertains to distress or to bids for attention and compliance. Likewise, intrusiveness may pertain to the control, reciprocity, or protection domain, depending on the manner and context in which it is expressed.

Child Outcome Variables

We discuss four child outcome variables in the context of a need for specificity of operationalization.

Compliance. Compliance is a dependent variable that actually has attracted considerable attention with respect to differentiation of its forms. Internalization, as discussed above, is generally operationalized as compliance with parental values in the absence of surveillance (Grusec, 1997). This form of compliance belongs in the control domain. Maccoby and Kochanska and their colleagues (e.g., Kochanska & Aksan, 1995; Maccoby & Martin, 1983) have distinguished between two kinds of compliance that occur when the socialization agent is present—situational and reciprocal or committed—with the former more obviously occurring in response to external pressure and belonging to the control domain, and the latter part of a cooperative and mutually responsive relationship that belongs in the reciprocity domain. And what of compliance in the protection domain? Attachment theorists suggest that children who are securely attached are more likely to be compliant because they trust their parents to ask for compliance that is in their own best interests (Bretherton et al., 1997). The evidence is mixed, however. For example, secure toddlers are more likely to comply with parental directives when they are in a room with potential safety hazards (e.g., an electric fan; Londerville & Main, 1981) or with maternal suggestions during a challenging problem-solving task (Matas, Arend, & Sroufe, 1978), but there is little suggestion that they are more likely to clean up a playroom or not touch attractive forbidden toys (Matas et al., 1978; Van der Mark, Bakersmans-Kranenburg, & van IJzendoorn, 2002). One testable hypothesis, then, is that children who are securely attached, having parents who are responsive to their distress, are more likely to comply when compliance involves their own safety. Similarly, they might be more willing to accept parental direction when in need of protection or support. Thus compliance as a function of trust in the parent to make benevolent demands may extend only to situations that involve the child's protection from harm or distress.

Externalizing problems. Socialization is frequently assessed with the measurement of behavioral problems such as failure to comply and aggression. One widely used measure of these behavioral problems is the Child Behavior Checklist (Achenbach, 1991). This is a well-regarded instrument that continues to show excellent reliability and validity. Nevertheless, it does not differentiate among behaviors that may be linked with different domains. For example, defiance seems relevant to processes in the control domain, whereas cruelty might be linked to the protection domain through deficits in the development of empathy.

Affective self-regulation. Measures of affective self-regulation often do not differentiate between positive and negative affect, or between types of negative emotion (e.g., Shields & Cicchetti, 1997). Our analysis would suggest that negative emotion such as distress or fear is part of the protection domain, negative emotion such as anger part of the control domain, and positive affect such as enjoyment and pleasure part of the reciprocity or group participation domain.

Prosocial behavior. The term *prosocial behavior* is often used to denote a wide range of desirable or "nice" interpersonal behaviors such as helping, sharing, cooperating, befriending, and showing empathy or sympathy with familiar or unfamiliar peers and adults (e.g., Weir & Duveen, 1981). Moreover, children's own conceptions of what it means to be nice overlap only partly with researchers' common operational definitions of prosocial behavior (Greener & Crick, 1999). Given the multitude of behaviors subsumed under this term, researchers need to pinpoint more narrowly the aspect of prosocial behavior of interest to them and its relevant predictors. For example, empathic responding to another's distress is relevant to the protection domain, friendliness and cooperation with familiar others to the reciprocity domain, and inhibiting one's self-interest for the benefit of others, as in sharing or trying to be fair in games, to the control domain.

Distinguishing Among Parenting Variables and Child Outcomes

It is clear that differentiation of apparently similar behavior into different domains is highly desirable. Certainly, if the parenting variable represents a mixture of domains and the child outcome variable is also an amalgam of different domains, then some relation between the two might be expected. But stronger and more conceptually meaningful relations should emerge when domains are more clearly pinpointed. Coincidentally, the knowledge gained by such a fine-grained approach also would be highly useful for the development of effective parenting interventions, by outlining which parenting behaviors are most relevant to, and which are unlikely to impact, specific child problems.

How might researchers go about distinguishing among child outcomes, many of which appear to be similar in form even if they have been acquired in different domains? One way is to consider why children engage in a specific action by, for example, being aware of features of the situation and context in which the behavior takes place (Mischel & Shoda, 1995). As an example, we use Hubbard and van IJzendoorn's (1991) suggestion that strong and mild distress cries should be distinguished, as they pertain to different domains (protection and control, respectively). Similarly, the researcher should be able to identify prosocial behavior that is routinized and polite from that which stems from genuinely expressed empathic concern or from internalized principles of concern for others. A way of doing this would be to ask children why they had behaved in a given way. Reasons for helping actions stemming from the protection domain might include expressions of empathy for the plight of the recipient, those from the control domain might include statements concerning right and proper behavior, and so on.

Quality of Parenting May Not Be the Same in All Domains

Finally, a domain analysis suggests that parents may be successful in one domain of interaction but not in another. Some, for example, may be very good at assuming the role of protector and responding to their children's distress but less good at assuming the role of disciplinarian and applying appropriate levels of control. Some may excel at interacting as equals and complying with their children's requests but be less good as representative members of the joint social group and at providing them with opportunities to observe and participate in desirable group practices. This differential ability occurs because adaptive parenting in each domain of interaction requires different abilities, sensibilities, and resources from parents. These abilities may be linked to different personality characteristics that, of course, are at least partially genetically mediated as well as influenced by past and present environmental influences. In addition to these unique abilities there may also be characteristics of parents that influence their effectiveness in more than one domain. For example, parents who have difficulty with regulation of their own negative emotion may be less adept at soothing and calming their children's distress as well as less able to deal appropriately with an affect-laden discipline situation. That could explain why parents who have nonautonomous attachment representations, a predictor of insensitivity to their children's distress, also tend to be inflexible and psychologically controlling in discipline situations (Verschueren, Dossche, Marcoen, Mahieu, & Bakermans-Kranenburg, 2006). Similarly, parental intrusiveness can potentially negatively impact parenting in several domains, such as the parent's ability to respond sensitively to distress, to go along with the child's wishes, to provide the appropriate amount of guidance in a teaching interaction, or to enable sufficient autonomy in the control domain. As well, lack of social support or high levels of stress are likely to adversely impact parenting in each of the five domains. As a result, some overlaps in parental competence across domains are to be expected. But alongside such commonalities there is also important intraindividual variability in parental competence as a function of domain, and there are specific processes that are unique to each domain. We suggest that domain-general variables should be differentiated from domain-specific variables if developmentalists are to gain a truly adequate understanding of mechanisms involved in socialization.

Interplay Between Domains

Our analysis should not be taken to imply that processes within each domain are isolated from those in other domains. Such a compartmentalized view is overly simplistic: What occurs in one domain of interaction can certainly be affected by processes in another. We briefly discuss four potential kinds of interplay between domains. One type of interplay has in fact been alluded to throughout this article, and it involves instances in which each interaction partner operates in a different domain; for example, a child seeks comfort and reassurance (protection) but the parent interprets the same situation as a power struggle and responds with discipline (control). As noted earlier, parental efforts are unlikely to be effective in these situations, and may well have detrimental effects, because they are not domain appropriate and thus do not address the child's needs. A second type of interplay is when the interaction combines features of two or more domains for both participants. As noted earlier, Fiske (1992) also acknowledged that various real-life situations constitute more complex combinations of the basic relationship models, or domains. Some familiar examples are when a parent comforts and teaches a child how to self-regulate distress (a combination of protection and guided learning), when a parent combines punishment with informative explanations regarding proper behavior (a combination of control and guided learning), or when a parent enforces prohibitions in order to protect the child from harm (combining features of control and protection). A third form of interplay occurs when the interaction moves in quick succession from one domain to another, as when a reciprocal play interaction suddenly turns into a control situation (due to misbehavior) or when a temper tantrum (control) is soon followed by a need for comfort (protection). In these situations, the preceding interaction provides the situational context for the subsequent interaction in the other domain, with potential carryover or interactive effects. A final type of interplay between domains occurs when experiences and skills acquired in the past in one domain affect current interaction in another domain. Here one domain serves as a broader (rather than immediate) context for another. For example, parents should encounter difficulty when trying to teach (either in the control or guided learning domain) a value or behavior that is contrary to one that has been learned in the group participation domain. Thus inducing or teaching children to have healthy eating habits should be challenging when they have been exposed to disorganized mealtime routines or unhealthy eating practices at home, and convincing children that boys and girls can become anything they want can be difficult when they have frequently observed and participated in cultural rituals and routines emphasizing traditional gender roles. Another example of this type of overlap is the finding that early attachment security moderated the relation between maternal use of minimal power assertion and children's conscience development (Kochanska, Aksan, Knaack, & Rhines, 2004): One possible explanation for this finding is that early effective parenting in the protection domain facilitated children's trust in the mother and their ability to regulate negative emotion, and these capacities enabled them later on to attend to maternal gentle directives and arguments in control interactions.

Clearly, there are many possibilities for a complex interplay between domains. In this article we have focused on outlining the processes within each domain, because our main goal was to offer a framework that integrates the seemingly disconnected foci found in the socialization literature. The ultimate challenge for those interested in socialization, however, would be to gain better understanding not only of the separate pathways within each domain but also of the intricate ways in which these pathways combine and interact with one another.

Concluding Remark

Our suggestions in this article run counter to the thinking of some socialization researchers who see considerable interconnectedness between different aspects of socialization (see, e.g., Forman, Aksan, & Kochanska, 2004). The notion of such interconnectedness is an important one to pursue, but we maintain that a comprehensive research agenda must also include attention to important distinctions between these different aspects. There is indeed a growing body of research, described in this article, that indicates the promise of such an approach.

Commentary and Challenges to Grusec and Davidov's Domain-Specific Approach

Judy Dunn
King's College London

J. E. Grusec and M. Davidov's article (this issue) about domains of parenting and their links with different aspects of childhood outcome raises both interesting questions and challenges. Four of these concerns are discussed in relation to early childhood. First is the issue of bidirectionality. Recent studies highlight the contribution of individual differences in children, and of dyadic measures that include both child and parent, to the quality of parent–child relationships. Second, the specification of domains can be problematic, given the evidence of overlap between domains, and of combinations of different domains in real-life interactions. Third, developmental issues need to be addressed, as do cultural and cohort influences. Finally, children need to be considered as family members who monitor interactions between other family members, learn from and influence these others. The challenge to their account posed by models of family environments that include effects not shared by siblings merit attention.

The call for us to clarify the links between different aspects of parents' interactions with their children and those children's outcome is a welcome one. To differentiate between the various features of the relationship between child and parent clearly deserves attention. All too often the parent–child relationship is characterized in broad brush strokes, to the neglect of many aspects of what can clearly be a complex relationship. And the developmental issue of how key features of parent–child relationships in early childhood may change as children grow up is also still not well understood. Grusec and Davidoff (this issue) set out clearly specific hypotheses about the domains of parenting that they view as key and then examine which aspects of parenting are related to different aspects of child outcome. They have done us a real service in setting out their hypotheses and in summarizing what evidence there is for their key domains of socialization and the hypothesized links with outcome. In this commentary, the discussion is organized around four general topics in early childhood: first, the bidirectionality of influences between child and parent; second, the specification of domains of socialization; third, developmental issues raised by their model; and fourth, the significance of children as family members.

Bidirectionality

First, a general point concerning bidirectional effects. Until recently most research into socialization and parenting has focused on what parents do with or say to their children, and their feelings about them, rather than on the dyadic *relationship* between parent and child (for a notable exception, see Laible & Thompson, 2007), or the significance of bidirectional patterns of influence within this relationship. The classical scheme outlined by Baumrind (1971), based on the two dimensions of parental acceptance versus rejection and controlling versus permissiveness, is an example that has had huge influence and has led to an accumulation of evidence linking parenting as measured in a unidirectional way to differences in children's outcome. But differences in parents' behavior with their children may well be a response to differences in the *children's* behavior, both concurrently and in the history of their interactions over the longer term. Hinde pointed out decades ago that no measure of a parent's behavior can be considered to be independent of the history of previous interaction with the child, just as no aspect of the child's behavior toward the parent can be assumed to be independent of the history of their interaction (see, e.g., Hinde, 1979, 1987). He has argued moreover that we should take account of the contribution of

individual differences in parent–child relationships (both parent-to-child and child-to-parent interactions) to the cultural level of analysis.

We have to take seriously the contribution of individual differences in children to the relationship between child and parent. This was initially brought to my attention in a longitudinal study in which we conducted extensive home observations of babies from birth over the first 5 years of life (Dunn, 1977), and one of the relational processes we studied was the responses of mothers to their children when they cried—a classic aspect of maternal sensitivity (Ainsworth, Blehar, Waters, & Wall, 1978). However, it was clear that to treat this response to crying as a measure of sensitivity, we had to also take account of how much the particular baby had been crying and how irritable or difficult to soothe he or she was. We found that if the baby was one who relatively rarely cried, *and even so the mother was slow to respond to the crying*, this measure of maternal response was indeed an aspect of maternal insensitivity that related to other behavior that could be characterized as insensitive. However, if the baby was one who cried a great deal in the early weeks, and was difficult to soothe, a mother who over time became slow to respond to crying was not in other aspects of interaction insensitive (Dunn & Richards, 1977).

In the last 5 years there have been a series of investigations of bidirectional associations of parent–child relationships, brought together, for instance, in 2008 in a special issue of the *Journal of Abnormal Child Psychology*. The studies differ in the samples studied and in the breadth of measures; however, the commentary in the special issue highlights that "the studies cohere in providing clear evidence of bidirectionality: Child and youth adjustment difficulties contribute to declines in parent–child relationship quality over time, just as negative parenting (and parental depression) contributes to increases in child and youth adjustment problems over time" (Pettitt and Arsiwalla, 2008, p. 715).

Grusec and Davidoff acknowledge the "important and active contribution" children make to their own socialization; a feature of their model is the emphasis on the child's interpretation of parental practices and the relevance of the parental practices to the current domain in which the child is acting. However, the emphasis of their model remains chiefly on parental impact. In the domain of control, for example, they comment on the parent's arsenal of resources and the imbalance of power between child and parent. But there is little discussion of *dyadic* measures of the relationship, such as the meshing and involvement of the two partners, their mutual responsiveness or warmth, or the connectedness of their communication. In contrast, Laible and Thompson (2007) discuss how a broad quality of the parent–child relationship such as warmth "enhances or diminishes young children's receptivity to the socialization initiatives of others and in this manner also affects the responsiveness of others to the child" (p. 183). Laible and Thompson usefully distinguish between relational processes that are under parental control, those that are under children's control, and those that are under dyadic control. In the last category, for example, the conversations between child and parent play a key role in early social and moral understanding and in the development of conscience (Thompson, 2006). The development of moral sensitivity is one area among many where focusing on children's contribution to family conversations provides a perspective on the growth of understanding that differs from that of the Grusec and Davidoff model and could usefully be incorporated in the model.

This development of moral sensitivity is also a clear area for distinguishing cultural differences in socialization. For instance, a comparison of preschool children growing up in Pennsylvania and those in Cambridge, England (Dunn & Brown, 1991) highlighted a number of differences in explicit and implicit messages about the social world that were evident in mother–child conversations in control situations in the two cultural groups. Notions of harm, responsibility, culpability, principles of positive justice, and excuses of intent were all in place with these preschoolers, and this understanding was central to the children's reasoning in the power politics of the family. The children were already participants in conversations about the social rules and roles of their world, and this was evident not only in their disputes but also in their jokes, stories, and pretend play (Dunn, 1988). The two cultural groups differed both in the topics of the prescriptions and in their form. In Pennsylvania, the rights of the individual were frequently stressed; in Cambridge, the emphasis was on harm to others, politeness, and appropriate behavior. In the Pennsylvanian families, prohibitory messages were addressed to a child in terms of his or her personal actions and were less likely than those in Cambridge to include an evaluative message. Mothers made reference to *individual responsibility* such as "You put your toys away—you got them out!" "You get off the table!" In contrast, attempts to control the English children were less often focused on the individual child and often made references to general principles, as in the comment made by a mother to a 3-year-old: "Tables are not for walking!"

The issue of dyadic measures of child and parent, and their role in the development of social understanding, has been persuasively argued for by Tomasello and his colleagues in the context of research on the significance of joint engagement and attention (Behne et al., 2008; Tomasello, Carpenter, Call, Behne, & Moll, 2005). They show that joint engagement is "a powerful way for very young infants to develop an understanding of other people, in particular to come to know what others have and have not experienced" (Behne et al., 2008). It is not immediately clear how this joint engagement would be assigned to one of the five domains of socialization specified by Grusec and Davidoff—the second issue we consider.

Specification of Domains of Socialization

The notion of domains has been particularly developed in relation to cognitive development: Information from different content areas is suggested to be processed by specific modules, each of which is responsible for the acquisition and regulation of different features of knowledge (Keil & Wilson, 1999). Grusec and Davidoff apply this approach to socialization, with the proposal that each domain of the parent–child relationship is key for a particular aspect of socialization.

The question is: How many domains should be specified? Grusec and Davidoff's typology is fivefold: The domains are protection, reciprocity, control, guided learning, and group participation. In each of these domains, it is argued, different parental behavior is required for "effective socialization." Each domain is presented as prototypic. Yet as the authors note, in real-life interactions there are often combinations or overlaps among the domains. Both the advantages of such a typology (such as clarity and the opportunity to test hypotheses for evidence) and its disadvantages (how to deal with the evidence of overlap between domains in real-life interactions, for instance, and how to relate the account to other theoretical specifications of domains) are evident. Different theorists focus on different domains, and it is not simple to test the empirical basis for these different domains.

The specification of domains leads to some claims that appear inconsistent. In the protection/security domain for instance, Grusec and Davidoff view aspects of positive parenting such as reciprocity, appropriate discipline, and teaching/guided learning as *not* contributing to children's feelings of security. In the reciprocity domain, they argue that responsiveness to distress "should not facilitate reciprocated cooperation." In the control domain there are also similar arguments put forward by Grusec and Davidoff about what parental behavior is *not* effective in controlling children—and again these include some inconsistencies that may surprise the general reader. Responsiveness to distress, reciprocity, or facilitation of group participation are not viewed as processes that contribute to control. One wonders why distracting the child by play or conversation, or through humor should be excluded as a control strategy.

Developmental Issues

It would be useful to have data that could clarify how the prominence of different domains and how relational processes *within* domains may change as children grow up. In the 1980s, in the longitudinal study in Cambridge referred to above the children were growing up in families that differed widely in social class, neighborhood, and parental education. We were particularly interested in early individual differences in child–parent interaction, and during the extensive observations made over the babies' first 14 months, individual differences in measures of the mothers' responsiveness to their babies' distress and crying were remarkably stable. This maternal responsiveness to crying in the 1st year was not related to the mothers' educational level or social class. However during the 2nd year, as the children began to understand and use language, a different pattern of individual differences in maternal sensitivity emerged. The stable pattern of responsiveness to distress and crying disappeared, and a new ranking of individual differences in responsiveness to the babies' attempts to communicate emerged, which was clearly related to the mothers' educational level.

Developmental changes were also evident in gender differences and social class differences in parent–child and child–sibling interactions as the children reached middle childhood. These were particularly apparent among the working-class boys, who spent more time out of the family home and on the streets. They were already active members of their peer groups, well before the boys in middle-class families, who spent more time with their parents. Similar social class differences were found at the time in a study of 700 children by Newson and Newson (1976). It is quite likely that such gender and social class differences in peer group associations are less evident today than they were in the 1970s, a note of caution that reminds us that cultural differences in social relationships change over time. For a theoretical model of parenting that has relevance today, the Grusec and Davidoff approach needs to address both the issue of developmental change and the issue of cultural influence, including possible changes in such cultural influences over the decades.

Children as Family Members

The fourth issue raised by Grusec and Davidoff's article concerns children as family members and the complexity of influences on their socialization. From the end of the 1st year, there is evidence for influences on children that involve people other than the mother, father, or chief caretaker. For instance, individual differences in children's early understanding of others' feelings, thoughts, beliefs, intentions—their theory of mind—(noted by Grusec and Davidoff to be key in socialization) are related not only to their participation in conversations about these issues with family members but also to what is happening between their parents and siblings. Both experimental studies and naturalistic observational research have shown the powerful effect on children of witnessing angry interactions between others (Cummings, Zahn-Waxler, & Radke-Yarrow, 1987). Within the family, children are vigilant monitors of the interactions between their parents and siblings. In a study involving naturalistic home observations in families in Cambridge, the children's behavior as 18-month-olds and as 24-month-olds when disputes took place between their mother and older sibling was monitored (Dunn, 1988). These disputes were of much interest to the second-born children. They rarely ignored them but responded to 72% of the disputes at 18 months and to 78% at 24 months. The ways in which they responded varied. In some incidents they simply watched, soberly; in others they imitated the older sibling's prohibited action and laughed. Sometimes they attempted to support one or other of the antagonists. Our analyses showed that the emotion expressed by the disputants was important but the topic on which the disputes were focused was also key (Dunn, 1988). The mastery of cultural matters that takes place during the preschool years evidently reflects the interest of the child as a family member, who is motivated to understand the social ways and prescriptions of her world in part because of the pressure of her relationships within that world.

In families in which there were relatively frequent disputes about control issues between parent and older sibling, the younger siblings' understanding of mind was especially evident over the following months (Dunn, Brown, Slomkowski, Tesla, & Youngblade, 1991). The analysis of which factors were linked to these individual differences in mind reading highlighted the significance of three quite different sets of social processes. One was the extent of mother–child discourse about why people behave the way they do, their feelings and mental states, in which children were involved. The second was the extent of disputes between mother and older sibling that the second-born child had witnessed. And the third was the extent to which the second-born child had been involved in pretend play with the firstborn. There is evidence that over the 3rd and 4th years, cooperative pretend play with an older sibling, and especially with a friend, provides contexts that are especially rich in conversations that involve discussion of other minds, and of why people behave the way they do. Shared pretense with another child, it has been argued by Tomasello and colleagues, is one of the earliest areas in which children enter into "collective intentionality" (Behne et al., 2008). They have also shown, with experimental studies, that explicit discourse about pretending is crucial in the development of reflective understanding of pretense (Tomasello, 1999). Including family members, such as siblings, in analyses of domain approaches for socialization would be one way to construct a more interactive model of parenting. For example, how do siblings respond to parental strategies aimed at another member of the family (such as a sibling) and in what way does the parental strategy get modified when directed to a second-born child, who has witnessed the parent's interactions with the firstborn? Including these analyses would provide a nuanced and full picture of socialization from a domain approach.

In summary, we should be grateful to Grusec and Davidoff for framing their ideas on socialization in systematic fashion. They set out helpfully both the differences and the connections between their model and that of Turiel's (1983) social domain theory. Their account is full of interest and makes many novel points, and it is provocative in stimulating others to reflect on how far and in what ways their own ideas mesh with the model outlined, and how far they differ. The challenges now are many: for instance, to investigate how far the study of other cultures supports their views, and how appropriate their approach is for the new models of family environments such as those stimulated by awareness of how siblings within the same family differ (Plomin, Asbury, & Dunn, 2001).

Modules, Theories, or Islands of Expertise? Domain Specificity in Socialization

Susan A. Gelman
University of Michigan

The domain-specific approach to socialization processes presented by J. E. Grusec and M. Davidov (this issue) provides a compelling framework for integrating and interpreting a large and disparate body of research findings, and it generates a wealth of testable new hypotheses. At the same time, it introduces core theoretical questions regarding the nature of social interactions, from the perspective of both children and their caregivers. This commentary draws on the literature regarding domain specificity in cognitive development, applauds what is innovative and exciting about applying a domain-specific approach to socialization processes, and points to questions for future research. Foremost among these is what is meant by ''domain specificity.''

Grusec and Davidov (this volume) have provided us with a valuable and thought-provoking framework for thinking about socialization, arguing in compelling detail for the importance of domain-specific processes. They lucidly argue that parent–child relationships and mechanisms have been obscured by treating socialization processes as undifferentiated, and provide numerous intriguing examples of distinctions among their hypothesized five domains: protection, reciprocity, control, guided learning, and group participation. It is misleading, for example, to talk about parental ''sensitivity'' to the child, as the nature and focus of that sensitivity differs, depending on whether one is focused on (say) guided learning or reciprocity. When one talks about sensitivity writ large, the evidence is contradictory, the theories are competing, and the correlations are low. Yet when one considers sensitivity from the perspective of distinct domains, seeming inconsistencies are only apparent, and structure emerges at the domain level. Somewhat paradoxically, Grusec and Davidov suggest that the diverse approaches to socialization discussed in the literature can be unified *only* when one accepts that socialization is not a unitary phenomenon.

It is particularly novel and exciting to see the concept of domain specificity extended from the realm of cognition to that of socialization. We have known for decades that cognitive processes and cognitive development are uneven across domains (Hirschfeld & Gelman, 1994). Children are much worse than adults at learning calculus but much better than adults at learning syntax. A child chess expert shows better recall of the placement of chess pieces on a chessboard than a chess-novice adult—while simultaneously performing worse if the recall task includes numbers rather than words. Although thoughtful domain-differentiated models of socialization have also been offered previously (see Bugental, 2000; Smetana, 2006; Turiel, 1983, 2006, for notable examples), Grusec and Davidov imply that domain-general models continue to be dominant. To the extent that domain-general models of socialization have persisted, whereas domain-specific models of cognition (including social cognition) have received more general acceptance, this difference may reveal something interesting about historical assumptions about the nature of socialization and cognitive development.

Advantages to a Domain-Specific Approach

There are obvious benefits of a successful domain-specific perspective. In addition to bringing unity

to what otherwise seems like a dizzying array of approaches, the domain-specific framework possesses the hallmark of a good scientific theory: It is predictive. Many precise, testable claims emerge, as delineated in Grusec and Davidov. For example, children who are securely attached (due to parental sensitivity within the protection domain) are predicted to be more likely to comply in situations that involve their own safety (and thus fall within the protection domain). Furthermore, prosocial behaviors are predicted to vary by domain (e.g., responding to distress vs. friendliness and cooperation vs. inhibiting one's self-interest).

Grusec and Davidov's approach also has the virtue of generativity. Reading through the article, one cannot help but speculate about connections to other issues. Some future research questions might include: Are there stable individual differences with respect to which domain is dominant in a given individual? How might factors such as gender or temperament influence a parent's ease or skill in operating in any particular domain? Within a family system, do different individuals tend to meet different domain needs of the child—with mother, father, sibling, teacher each having a "key" domain? Is there cultural variation in terms of which domains are more consistently valued? How do family-based, childhood experiences within a domain influence later relationships? Which of the domains identified by Grusec and Davidov are found in nonhuman primates or other social organisms, and what does this reveal about human societies?

Another aspect of the approach that is very appealing is that the child's contribution to the social interaction is central. As stated by Grusec and Davidov, "Children are important and active contributors to their own socialization" (p. 692). They also note that the meaning of the behavior must be considered from the child's point of view and that the child's causal construal may be critical (e.g., the very same display of affection can convey protection or group participation). I wish to underscore this point, because it is one that is all too often missed. When focusing on parental contributions to development, a potential danger is that the child is viewed as a passive consumer of adult input—the environment does all the work, and the child is a mere recipient. Conversely, in the cognitive development literature, the emphasis has been on the "child as lone scientist," figuring out the world in the absence of others that support the child's learning, pass knowledge down generations, supply cultural tools, and so on. The domain approach recognizes—indeed, requires—that environmental inputs be matched to child capacities and expectations. As obvious as it may seem, there has been a recent turn to acknowledging the importance of the interaction of the child and others that support the child's learning and development (e.g., Csibra & Gergely, 2009; Gelman, 2009; Harris & Koenig, 2006). Innate skeletal frameworks go hand in hand with learning from experience (Gelman & Williams, 1998); parental input and child biases work together toward a common goal (Markman, 1992),

A theoretically rich proposal, such as that offered by Grusec and Davidov, invariably raises many questions. I will discuss two questions here: What is a domain? And, what is the relation among domains? These questions undoubtedly reflect my own background as a cognitive developmental psychologist with strong interests in the role of parent–child interactions in concept development (see, e.g., Gelman, 2009).

What Is a Domain?

In the field of cognitive development, there have been at least three distinct approaches to domain specificity, with distinctly different claims regarding developmental mechanisms, what is innately specified, how variable the outcome can be, and the role of input (see Hirschfeld & Gelman, 1994; Wellman & Gelman, 1998, for a review). Domain specificity can reflect *modularity*, in which domains have emerged through evolutionary pressures, have innate systems for taking in and processing specific sorts of information, and represent biologically constrained processes (examples include vision, natural language syntax, number, and face recognition). Modular domains are universal, neurologically localized and acquired in the presence of minimal cues; they unfold on a strict maturational timetable; and they experience sensitive periods (Cosmides & Tooby, 2001; Scholl & Leslie, 1999). Domain specificity can also reflect *expertise*, in which domain-specific abilities are highly variable across individuals and emerge through extensive experience (examples include expertise in chess or reading, which profoundly changes the processing capacities of the individuals who engage in these experiences—but only for the domain in question). Expertise-based domain specificity is not innately specified (Chi, 1978; Ericsson, 2005). Finally, domain specificity can reflect *causal theories*. The child starts with skeletal domain-specific principles and ontologies (examples include theory of mind or theory of physical objects), which are then informed by data and evidence so that the child constructs increasingly complex and detailed causal-explanatory understandings (Carey, 2009; Gopnik & Meltzoff, 1997).

Although Grusec and Davidov suggest that socialization domains are modular (''specialized modules, each of which has evolved to accomplish a recurring important task or function [e.g., face recognition, numerical thinking, grammar processing]''; p. 687), at times the socialization domains also appar to have features of theories or expertise, respectively. They are theory-like in incorporating causal explanatory reasoning. For example, in order to discern whether a prosocial behavior is mere politeness or true empathy, one must ask the child *why* he has behaved as he did—in other words, to assess the causal understanding. Similarly, Johnson, Dweck, and Chen (2007) present fascinating experimental evidence that infants with different attachment types possess different causal theories of social interaction, as assessed in their reasoning about third-party characters. Furthermore, the possibility of individual or cultural influences on the salience of different domains suggests that expertise may play an important role. Thus, an interesting empirical question is to examine in more detail some of the features of modular theories (biological foundation, universality, etc.) to see how well they fit the various domains of socialization.

Of course, it is even possible that protection, reciprocity, control, and so on are not, strictly speaking, domains at all but instead ''types''—of relationships, goals, functions, values, or attentional foci. A widely recognized concern in the cognitive literature is that the notion of ''domain'' can be multiplied to include nearly any perceived distinction. Keil (2000) notes: ''It seems more than any pattern of information in the world for which the body has a specialization. Surely innate allergies to poison ivy do not mean we have domain specific constraints on learning about poison ivy, even if those allergies result in all of us learning about poison ivy differently from daisies.'' Similarly, not all differences in social processes can or should rise to the level of ''domain.'' As an example, a review article by Medin, Lynch, and Solomon (2000) elegantly lays out the importance of considering distinctions among different kinds of concepts. They review structural differences, processing differences, and content-laden differences, and make a convincing case that we ignore such variation at our peril. Yet these different *types* of concepts are not different *domains* of concepts.

To be clear, posing the question of whether these domains are modular, or indeed whether they are properly considered domains, does not in any way diminish the value and importance of the typology laid forth in Grusec and Davidov. Rather, the question is to take seriously the notion of ''domain'' and to work through, in systematic fashion, what the implications are of such a view. The innovative approach of dividing up socialization behaviors into distinct types is an important start to what promises to be a rich program of research.

What Is the Relation Among Domains?

One recurring (and fascinating) theme in the article is that the fit between maternal goals and child goals—or lack of fit—has important consequences. Thus, a mother who construes a situation as falling within the control domain, and thus exerts discipline, will miss the mark if her child construes the situation as falling within the protection domain and seeks comfort and soothing. The proposal here seems to suggest that an interaction is largely centered within a particular domain (e.g., control vs. protection, as in the example above), both from the standpoint of the parental input and from the standpoint of the child uptake. This proposal, although plausible, is actually an open empirical question and depends on the relation of one domain to another.

I illustrate the problem with an analogy from considering cognitive domains, specifically, domain-specific causal theories. Consider the hypothetical case of a child who asks why she is not allowed to eat all her Halloween candy in one night. A parent might respond: ''Because I think too much candy will make you sick.'' The causal structure of this information can be firmly located within a domain, in this case biological, as it concerns a nonintentional, natural bodily process: illness. The parent instead could have explained the very same restriction by referring to an internal mental state such as desire (''Because you're going to want to eat more candy tomorrow''), which would place the behavior in a psychological domain. Or, the parent could have explained the restriction by referring to deontic rights or obligations, or appealing to ethical principles (''It's wrong to be greedy, and besides, you need to share your candy with your sister''), which would place the behavior in a moral domain. And so forth. Indeed, much of human activity can be understood within multiple domains, because humans themselves are simultaneously physical, psychological, biological, even spiritual beings. Yet in providing an explanation, the speaker makes a choice as to which causal framework is most relevant. In expressing an explanation, one is forced to choose a particular causal story, located within a particular domain. In this example, the parent selects among domains, representing a particular perspective, and one could well imagine (say) a parent–child mismatch in this regard (e.g., if the child is focused on a psychological rationale [''I want the candy''], whereas the parent focuses on the biological rationale; see Smetana, 1989, for mismatches of this sort in parent–adolescent conflicts).

However, in another sense, a single explanation can be rich with multiple signals that are available to the child, across domains, revealing not only a particular causal framework but also informational cues regarding syntax, speech perception, pragmatics, phonetics, conceptual content, and theory of mind. A single sentence (e.g., ''Because I think too much candy will make you sick'') informs the child about: the biological process of illness, psychological states (''I think. . .''), syntactic constructions in English (the embedded clause), generic nouns (''candy''), parental values, regional accent, and so on. Various kinds and levels of information are bundled into a single, multivalent signal. A child may be interested in talking about candy but is also exposed to and learning about many other things simultaneously. Spelke (2003) has argued that human language is in fact unique among communication systems in permitting the juxtaposition of thought from multiple domains. Whereas a rat can successfully represent both geometric (shape) and nongeometric (color) information about a large-scale space (e.g., a room), only a verbal human can combine the geometric and nongeometric information into a single representation. We have ''a uniquely human combinatorial capacity that serves to conjoin [core knowledge] representations to create new systems of knowledge'' (Spelke, 2003, p. 305).

The question then is, in the realm of socialization, what is the nature of the social signal to the child, in terms of what the parent implies and what the child takes in? Is it more like the first case, in which an interaction is typically located within a single domain, or is it more like the second case, in which multiple strands of signal are available simultaneously? For example, even if a parent intends to control the child and place constraints on the child's behavior, she may simultaneously be sending powerful signals regarding group participation via social-conventional reasoning (''this is the sort of behavior that we do, as members of group X''; see Killen, Sinno, & Margie, 2007), guided learning (teaching about kinds of things in the world, such as candy; see Csibra & Gergely, 2009, for the suggestion that this ''pedagogical'' stance may be uniquely human), even protection (''I don't want you to get sick'') and reciprocity (''I'll let you have one more piece of candy, though, since you asked so nicely''). Grusec and Davidov's framework certainly allows for multiple signals of this sort; in their article they explicitly acknowledge that different domains are highly interconnected. Moreover, in the realm of guided learning in particular, a great deal of implicit instruction takes place in everyday interactions that on the surface may not appear to be pedagogical—occasions in which a child is simply engaged in conversation, or observing another's actions (e.g., Gelman, Taylor, & Nguyen, 2004; Meltzoff, 2002; Tomasello, Carpenter, Call, Behne, & Moll, 2005). Thus, the question is not *whether* domains interact. Instead, the question may be more aptly framed as, which is ''standard operating procedure'': pursuit of a single domain within an interaction or the bundling of messages (both explicit and implicit) in a single interaction?

Conclusions

There is a rich history of domain-specific approaches to cognition, but these approaches are relatively less often applied to social interactions. The approach pioneered by Grusec and Davidov (building on related though distinct work by Bugental, 2000; Smetana, 2006; Turiel, 1983, 2006, among others) raises an important set of questions regarding the structure and process of socialization. Future work would benefit by considering: (a) whether these interaction types or goals are most accurately considered modules, theories, or islands of expertise, and (b) the extent to which the domains overlap or present simultaneously within a social interaction.

Domain Specificity in Social Interactions, Social Thought, and Social Development

Elliot Turiel
University of California, Berkeley

J. E. Grusec and M. Davidov (this issue) have taken good steps in formulating a domain-specific view of parent–child interactions. This commentary supports the introduction of domain specificity to analyses of parenting. Their formulation is an advance over formulations that characterized parental practices globally. This commentary calls for inclusion of definitions of the classification system of domain-specific interactions and criteria for each domain. It is also maintained that Grusec and Davidov's domains of social interaction imply that processes of development are involved, along with socialization; that bidirectionality in parent–child relations needs to be extended to include mutual influences and the construction of domains of social thought; and that conflicts and opposition within families coexist with compliance and social harmony.

One of the mainstays in developmental psychology is the study of families and, especially, the influences of parents on children's development. The long-standing and enduring concern with families among developmental researchers hardly needs justification. Children spend a great deal of time in family interactions and most caregivers in most cultures take major responsibility for the care, protection, nurturance, and guidance of their children in many of life's realms. Because of these features—that children spend so much time, day in day out, with their parents and parental guidance encompasses so many realms—understanding family influences on children's development is a difficult and complex endeavor. It is a difficult and complex endeavor because so much goes on in family life over a period of many years during which children's thought and emotions are changing, their worlds outside the family are expanding, and their relationships with parents are undergoing transformations (Smetana & Turiel, 2003). And with time parents' ideas about children and parenting can change through their experiences as parents (Cowan, Powell, & Cowan, 1998; Sigel & McGillicuddy-DeLisi, 2002). Similarly, children's reactions to their parents can change with time as a consequence of their experiences with parents (Smetana & Turiel, 2003).

Adding even more to the difficulty of studying parenting and development is that the influences of many other activities on both parents and children need to be coordinated with direct family influences (Dunn, 1988). Parents engage in many activities in and out of the family that might bear on their parenting. These include parents' relationships with each other, their work and the financial needs of the family (Crouter & McHale, 2005); their efforts at achieving personal goals in life (and the conflicts that might be involved with goals for their children; Nucci, 2001); and their friendships and recreational activities—and, no doubt, much more. Children, too, engage in many activities in and out of the family that could have a bearing on how they are influenced by parents. These include relationships with siblings and other significant family members (Dunn, 1988), with friends and acquaintances (Rubin, Bukowski, & Parker, 2006), and with teachers, as well as their schooling, recreational activities, and concerns with social networks—and, no doubt, much more.

Global or Domain Specific?

All of this is to say that family life is complicated. Given all these complexities, it is both paradoxical and unsurprising that research into parental influences on children's development has a history

of framing parental practices in general or global ways (Bornstein, 2006; Turiel, 2005). Simplifying the complex is one of the means often used to make matters researchable and comprehensible (especially in a time when parsimony was seen as necessary in scientific explanation). As discussed in the historical overview provided by Grusec and Davidov (this issue), in early formulations general mechanisms of learning such as reinforcement, secondary drives, and modeling were proposed as a means of explaining how parental actions accounted for children's social acquisitions. These learning mechanisms were sometimes seen as ways of simplifying the theoretical formulation put forth by Freud (1923/1960), with its dynamic model of unconscious processes and maturational stages (Bandura & Walters, 1963). This was followed by propositions regarding general or global styles of parenting. These were meant to provide a little more specificity than general mechanisms of learning through categories meant to capture how parents relate to children. Although distinctions between parents were drawn by virtue of the different categories, a particular parent's style was characterized in global terms and as a general type (e.g., primarily involving power assertion *or* love withdrawal *or* induction; alternatively, involving styles that are authoritarian *or* authoritative *or* permissive).

In their bold and forward-looking proposals for a domain-specific approach to socialization, Grusec and Davidov provide needed correctives for some problems, which I list below, in the global accounts of parenting. In my view, the extant global characterizations of parenting and the associated formulations of children's development are limited because of the following shortcomings:

1. That parents are portrayed as usually employing one general orientation in raising and disciplining their children.
2. That the process of parent–child interactions is seen as one-directional, rather than bidirectional and reciprocal.
3. That parents are seen to have the major, overwhelming causal influence on children's development.
4. That it is mainly through parental practices of childrearing that children more successfully or less successfully become competent members of the community (society, culture) through compliance, conformity, accommodation, and adaptation to the group, as well as internalization of rules, rituals, and practices, and deference to authority.

The major corrective that Grusec and Davidov address is to the first problem I listed. They also address issues pertaining to one-directional or bidirectional processes, touch on the question of the major influences of parents, and largely do not address the question of socialization as compliance and accommodation.

Five Domains of Social Interactions: A Good Plan

Grusec and Davidov's domain-specific proposal is a good means for moving away from broad characterizations of parent–child interactions because it is meant to provide an integration of approaches heretofore fragmented, is bolstered by some findings from studies that were not designed to examine domain specificity, and is aimed at providing a framework for research that would be designed to address domain distinctions and verify their validity, and provides a "first step . . . before considering more complex combinations" (p. 691).

As Grusec and Davidov state (p. 701), "There is considerable initial evidence to support the contention that socialization processes differ in these domains, although additional research is obviously greatly needed." The categories they propose for different interactions between parents and children constitute an important advance over the general, broad, and unitary types of parenting previously emphasized in socialization research. In my view, the broad categories fail to capture parents' likely use of different practices for different situations and contexts and the ways they are likely to combine different types of practices.

More generally, it seems to me unlikely that parents would relate in one general fashion to their children regardless of the types of actions or desires on the part of their children in any given situation. There is a good deal of evidence in the psychological literature (developmental or otherwise) that people do not respond in the same ways across situations or contexts (Ross & Nisbett, 1991). There are debates about how to explain contextual variations in thought or action, but a good deal of evidence exists showing that people do not approach the world in a general way or through one type of orientation (Turiel, 1998). People draw priorities and make distinctions in choices and goals—distinctions that likely apply to parenting practices. As I have previously stated in discussing domains of social thought (Turiel, 2005, p. 80):

> Most parents are likely to respond much more strongly, assertively, and with greater efforts at control if a child engages in actions that pose a danger to others or to the self or that are illegal (for example, theft) than if the actions have to do with manners, how to dress, or which play and leisure activities to pursue. In addition, actions that have to do with harm or illegalities are likely to be treated differently from actions that have to do with children's educational pursuits and goals, even when parents regard education as very important and it is taken seriously. . . . Parents who think that a friend may lead their child in undesirable directions will react differently from the choice of a friend they simply do not like.

Grusec and Davidov provide a systematic analysis of the types of differences that they glean from existing research. One of the examples they provide nicely illustrates how global parenting variables are not always predictive of positive outcomes in children and that parents do not generally relate to children in one way. I am referring to the finding (p. 700) that parent scaffolding, but not warmth and control, predicted successful cognitive functioning. However, this example could be taken to mean that the categories are artificial or too restrictive because it might be that a combination of parental practices would best predict outcomes. In this example, it might be that a combination of scaffolding and warmth (and perhaps others) would be more effective in children's learning than one type. This is a question that can be put to empirical test. I believe, however, that Grusec and Davidov are correct in arguing that combinations and overlaps in domains do not invalidate the distinctiveness of the domain categories. If the domains identified are valid, it is necessary to identify and define them in order to understand interactions that involve combinations and overlap. Research on domains of moral, conventional, and personal understandings (referred to by Grusec and Davidov as social knowledge domains) has shown that many social decisions are best explained by assessing the distinct domains and how those are coordinated in situations that involve domain combinations (Killen, 1989; Turiel, 2008).

In discussing research into complex combinations, Grusec and Davidov (p. 691) state, "Outlining the unique and distinctive features of each domain seems an important first step." In my view, to conduct research to ascertain the validity of the domains and to use them for further research on socialization and development, it is necessary to go beyond outlining distinctive features of the domains by formulating systematic definitions of each domain and criteria for their distinctiveness (Chomsky, 1979; Piaget, 1970; Turiel, 1983, 1998). This is to say that researchers need to know a domain when they see one. The best way to know when you see it is to have a classification system that includes:

1. An overriding definition of parent–child interactions that encompasses, at least provisionally, the five domains, that is, the common features of the five domains that render them part of the same classification system. Such features should allow for classification of certain types of actions as domains within the system and other types that do not constitute domains. For instance, Grusec and Davidov do not classify responsiveness, warmth, and harshness as domains, in themselves, but as related to the five domains. An overarching definition of the system of classification would provide a basis for including, say, protection and control as domains and not responsiveness, warmth, and harshness, and
2. Definitions of each of the domains including criteria for what constitutes each domain and distinguishes one from another. Ideally, this would take the form of a coding system to be applied reliably in analyses of parent–child interactions. Such definitions and criteria should specify the salient features of each domain. It is not clear from the Grusec and Davidov presentation if the domains are to be defined by activities of the parents, types of parent–child interactions, goals of parents, and child outcomes, or some configuration of these three.

Bidirectionality, Reciprocity, and Development

Earlier I listed four problems in the global characterizations of parenting and indicated that the domain-specific propositions put forth by Grusec and Davidov mainly serve as a corrective to one problem, that of portraying parenting as global. Through their five domains and their emphasis on socialization, Grusec and Davidov raise questions pertaining to the other problems I listed—which revolve around processes of development and the nature of interactions between parents and children. Given the emphasis Grusec and Davidov place on the idea of bidirectionality in parent–child interactions and on domains that include reciprocity (parents and children interacting as equal status participants and accommodating one another's wishes), guided learning (pertaining to cognitive, social, and emotional understandings), and group participation (bringing in cultural practices and experiences beyond the family), it is surprising that they restrict themselves to socialization as children's outcomes.

Grusec and Davidov (p. 691) define socialization as "the process by which children acquire the social, emotional, and cognitive skills needed to function in the social community." Most of the child outcomes they associate with socialization are couched in terms that involve the child fitting into the existing system. They emphasize compliance with parental requests, acceptance of and obedience to cultural rules, internalization of values (taking on the parental/societal values as their own), adjustment to the group, and acceptance of routines, rituals, social customs, and cultural practices. Interestingly, it is the control domain that is seen to produce outcomes in children's moral and principled behaviors (in contrast with reciprocal relations, which in my view are more likely sources of moral development).

The concept of development should be brought into these analyses. Whereas domains such as protection and control lend themselves to socialization, the other domains lend themselves to a developmental analysis that includes the formation of thought—social and nonsocial—that allows for children to think about their environment, evaluate parental directives and actions, and attempt to influence changes in their social relationships. In this sense, development is not solely compliance and accommodation. Research has demonstrated that moral acquisition does not solely involve an internalization of values from parents and others, but more importantly the construction of concepts of welfare, fairness, and rights pertaining to how people ought to relate with each other (for reviews, see Smetana, 2006; Turiel, 1998). Outgrowths of moral concepts are cooperation and adaptation to the group, as well as thinking about how people should interact and about social arrangements and cultural practices that do and do not meet moral criteria.

A developmental perspective is based on a "strong" view of bidirectionality. The weak view (Kochanska, 1997) is that parents (or other adults) take into account and modify their behaviors in accord with characteristics of the child (e.g., a child's temperament, levels of fear or anxiety, preferences or inclinations). The strong view is that relationships are reciprocal in that there is give and take, communication, even argumentation, mutual influences, and engagement with each others' perspectives (Overton, in press; Piaget, 1970; Selman, 1980; Turiel, in press; Werner, 1957). This is not to say that reciprocal processes involve people of equal status or that the influences are balanced (Piaget, 1932). There are bidirectional processes in parent–child relationships that are not equal but do involve communication and some give and take. With age the imbalances change to the point that during adolescence there is more argumentation, conflict, and mutual influences. This is a realm in which social interactions outside the family, such as among peers, are likely to have an influence on interactions within the family. Indeed, Piaget (1932) maintained that in late childhood and adolescence, peer relations, because of greater equality, were of more influence in the development of moral judgments than adult–child relationships. If this were correct, then such changes in children's moral judgment would likely be applied by them to family interactions.

For adequate analyses of bidirectionality in social interactions and development, it is necessary to take into account children's domains of thought (Nucci, 2001; Smetana, 2006; Turiel, 1983, 2002), as well as domains of social interactions. As Grusec and Davidov state, the work on social domains focuses on different types of social judgment and reasoning and on how children acquire "a differentiated understanding of different kinds of social issues." However, in developmental analyses it is important to connect domains of social thought with social interactions. A number of observational studies demonstrate that the domains of social thinking are associated with different types of social interactions (Killen & Smetana, 1999; Nucci & Nucci, 1982a, 1982b; Nucci & Turiel, 1978; Nucci, Turiel, & Encarnacion-Gawrych, 1983; Tisak, Nucci, & Jankowski, 1996). Parent–child interactions contribute to the formation of domains of social thought (Nucci & Weber, 1995; Smetana, 1989). A developmental perspective that seriously accounts for bidirectionality needs to examine the intersection of the child's domains of thought and social intersections, including ones involving parents and children.

Social Harmony and Social Conflict

The emphasis in socialization perspectives on compliance, accommodation, adaptation, and internalization of values serves to skew characterizations of social interactions in the direction of social harmony and cooperation. This is because the developing child is seen as increasingly complying and accommodating to the group. Insofar as conflicts exist, they are due to a child's inadequate socialization so that he or she has not learned control of impulses nor come to adapt to society. From the socialization perspective conflicts might also occur between groups (societies, subcultures, cultures) that maintain different values and practices.

Although social harmony is a fact of social life, I believe that it is safe to say that conflict is also a fact of social life (Shantz & Hartup, 1992). Social conflicts are not solely a consequence of inadequate socialization nor only manifested by deviants who engage in antisocial behaviors. Social conflicts occur between groups, but they are also prevalent in interactions among members of a group or culture. Intragroup conflicts occur in the work place, political establishments, religions, and friendships (Turiel, 2002). Such conflicts are over many issues pertaining to personal decisions, societal directions, and cultural practices.

Conflicts also frequently pertain to the main topic of Grusec and Davidov's analysis—the family. Family disputes, disagreements, and conflicts occur between spouses (Gottman, Driver, Yoshimoto, & Rushe, 2002) and over how to relate to and raise children (Cowan & Cowan, 1992). Conflicts among adults occur in many cultures—especially patriarchal cultures—over societal arrangements and cultural practices that foster inequalities between males and females (Nussbaum, 1999; Okin, 1989). Research in several non-Western cultures shows that women judge as unfair practices that embed inequalities favoring males (Conry-Murray, 2009; Neff, 2001; Turiel & Wainryb, 2000; Wainryb & Turiel, 1994). Research also shows that women placed in subordinate positions in social hierarchies oppose, resist, and even engage in overt and covert acts of subversion to circumvent unjust practices (Abu-Lughod, 1993; Wikan, 1996). These are examples of how adults oppose in-group norms and practices.

Conflicts and acts of opposition that do not stem from incomplete or inadequate accommodation to parents occur within the family during childhood and adolescence. Children do develop positive social and moral orientations to others, act cooperatively, and adhere to social customs. Children's positive orientations coexist with acts of opposition, conflicts, and defiance of prohibitions established by parents (Dunn, 1987, 1988; Dunn, Brown, & Maguire, 1995). Conflicts and acts of opposition involve efforts on the part of children to evaluate directives from adults (Laupa, Turiel, & Cowan, 1995).

Opposition, resistance, and conflicts do not dissipate with age. In many ways they become more frequent, intense, and differentiated in adolescence. There is a vast literature on conflicts in adolescence, of course. Research relevant to social opposition and resistance include investigations of adolescents' disclosure and nondisclosure of activities to their parents (Kerr & Stattin, 2000; Smetana, Metzger, Gettman, & Campione-Barr, 2006; Stattin & Kerr, 2000) and adolescents' judgments about deception of parents (Perkins & Turiel, 2007). The research has documented that adolescents withhold information from parents in order to spare parents' feelings and to attain a sense of autonomy. Adolescents' decisions regarding disclosure of activities vary by domain (e.g., they are more likely to not disclose with regard to personal decisions than moral or prudential matters). Adolescents judge deception of parents as acceptable in realms they consider outside of legitimate parental authority (e.g., certain personal choices) but not in realms they consider parents to have legitimate authority to control (e.g., prudential matters like safety).

Concluding Remarks

I mention a few studies with children and adolescents that demonstrate that there is a coexistence of harmony and cooperation, on the one hand, and opposition and conflict, on the other hand. When children or adolescents "push back" in the sense that they oppose, criticize, or try to get around parental directives it is not always because they have not been adequately socialized. Some of the time, it is because they perceive some matters differently from their parents in ways that might be carried into productive choices when they grow into adulthood (Turiel & Perkins, 2004). This suggests that parent–child relationships are multifaceted, as are processes of thought, emotions, and development. The domain-specific propositions put forth by Grusec and Davidov provide a useful means for capturing these complexities in research on parent–child interactions. However, there is need for more precise definitions of the classification system and criteria for each domain in order to implement the ideas in research. I also believe that there is sufficient evidence in developmental research for the proposition that parent–child relationships involve the type of bidirectionality that requires taking into account the perspectives of children and how they interpret parental directives and actions. A bidirectional, reciprocal process of social interactions means that the development of thought, emotions, and actions need to be part of research and theory on parenting.

Connecting Cues: Overlapping Regularities Support Cue Discovery in Infancy

Sarah D. Sahni, Mark S. Seidenberg, and Jenny R. Saffran
University of Wisconsin–Madison

The present work examined the discovery of linguistic cues during a word segmentation task. Whereas previous studies have focused on sensitivity to individual cues, this study addresses how individual cues may be used to discover additional, correlated cues. Twenty-four 9-month-old infants were familiarized with a speech stream in which syllable-level transitional probabilities and an overlapping novel cue served as cues to word boundaries. Infants' behavior at test indicated that they were able to discover the novel cue. Additional experiments showed that infants did not have a preexisting preference for specific test items and that transitional probability information was necessary to acquire the novel cue. Results suggest one way learners can discover relevant linguistic structure amid the multiple overlapping properties of natural language.

Natural languages exhibit structure at multiple levels in parallel (e.g., phonological, lexical, morphological, syntactic, and discourse). For the adult listener, this complexity creates temporary ambiguities that must be resolved for speech to be understood. Individual bits of information are imprecise, such as the meaning of words like *bow*, *colon*, *saw*, and *wave*. Such ambiguities are resolved via a constraint satisfaction process that exploits correlations among different types of information (MacDonald, Pearlmutter, & Seidenberg, 1994). While individual cues are often unreliable, combinations of cues are not. The principal characteristic of the constraint satisfaction process is that it allows learners to utilize the correlations of cues. For example, the word *saw* has several meanings (related to seeing, cutting, a tool for cutting, etc.) and is thus highly ambiguous in isolation. Embedded within an utterance such as ''I saw you,'' ''I'' restricts its interpretation to verbs. The object ''you'' further restricts the interpretation to the ''seeing'' meaning, since a person is more likely to be seen than sawed, though the result might differ if the context were a magic show. Similarly, hearing *saw* in a hardware store suggests the noun interpretation of *saw* as a tool. Rapid online comprehension is possible because of our ability to exploit constraints between different types of information (Seidenberg & MacDonald, 1999).

While studies of adult language have investigated how constraints are combined to resolve ambiguities, studies of language acquisition have examined how children use statistical cues to learn their native language. These are complementary issues, the ''constraints'' that are relevant to adult listeners are the ''cues'' by which the child acquires language (Seidenberg, 1997). Seminal work by Saffran, Aslin, and Newport (1996) showed that 8-month-olds are sensitive to the transitional probability (TP) between two syllables (the frequency of the two syllables divided by the frequency of the first syllable) when listening to a fluent stream of speech. This study, and the large body of work that has followed it, suggests that infants are sensitive to statistical regularities that exist in natural languages and can use them to learn aspects of their native language.

Experiments investigating language acquisition via statistical learning have typically focused on infants' abilities to use one statistical cue at a time

(e.g., Curtin, Mintz, & Christiansen, 2005; Saffran et al., 1996). However, natural speech is complex, containing overlapping regularities at multiple levels. For the language learner, this presents a difficult problem: How are these cues discovered? There are many ways speech can be analyzed; how does the child determine which aspects of the input are relevant? Moreover, the fact that any given bit of information may contribute to multiple levels of analysis (e.g., */b/* is the first sound in the word *baby*, the beginning of the first syllable, receives primary stress making it louder and longer, the transition point between the words *the baby*, etc.) creates a difficult learning problem. The complexity of this learning problem is sometimes thought to limit severely the explanatory role played by statistical learning in language acquisition (Yang, 2004).

Alternatively, the constraint satisfaction approach suggests that the complexity of natural language provides a rich system for learning mechanisms to exploit. Linguistic regularities reinforce each other across levels, allowing statistical learning mechanisms to capitalize on multiple cues and redundancies. For example, lexical stress patterns are found in numerous languages of the world. These patterns consist of a specific ordering of strong and weak syllables that occur frequently and can help identify word boundaries or classify groups of words. In English, many words have a trochaic, or strong–weak, stress pattern, as in the words *BAby* and *MOmmy* (Cutler & Carter, 1987). In other languages, it is more common for words to have an iambic (weak–strong) stress pattern, as in the word *guiTAR*. And in some languages stress cannot be used to group syllables or identify word boundaries at all. Because these cues vary from language to language, they must be learned. How then does the infant discover that stress patterns are informative? Strong regularities like lexical stress overlap with other regularities at multiple levels, highlighting and reinforcing their utility. The acoustic regularities (i.e., higher pitch, longer duration, and increased volume) of stressed syllables can draw attention to the beginning of trochaic words. Distributional cues, such as the overrepresentation of trochaic items in speech to English-learning children, ensure that young language learners have plenty of exposure to the pattern. Together these regularities can enhance the accessibility of the lexical stress pattern.

Psycholinguistic studies support the hypothesis that infants are sensitive to the conjunction of multiple probabilistic cues (Gerken, Wilson, & Lewis, 2005; Shi, Werker, & Morgan, 1999). Additionally, studies of infant categorization and conceptual development demonstrate that the natural environment provides infants with a multitude of correlated cues that they are able to exploit (e.g., Bhatt, Wilk, Hill, & Rovee-Collier, 2004; Madole, Oakes, & Cohen, 1993; Rakison, 2004; Younger, 1992; Younger & Cohen, 1986). Finally, connectionist models have shown that simple learning mechanisms that capitalize on structure within a complex system can exploit multiple correlated cues that exist in the infants' world. Computational models have demonstrated that problems such as finding word boundaries (Christiansen, Allen, & Seidenberg, 1998), generating properly inflected forms (Joanisse & Seidenberg, 1999; Mirkovic, MacDonald, & Seidenberg, 2005), and grouping common objects into categories (Rogers & McClelland, 2004) can be solved using multiple cues.

Despite this progress, it remains to be determined how language learners isolate and combine cues given the complexity of human language. In considering this problem, it is helpful to distinguish between two classes of potentially useful cues: language-general cues and language-specific cues. Measures of co-occurrence or predictability between syllables are language-general cues, in that they operate in similar ways across natural languages. For example, transitional probabilities are not specific to any given language (though the units over which these computations are performed are).

Other cues may or may not be useful in any given language and are thus language specific, and must be learned. For example, languages have different lexical stress patterns (iambic vs. trochaic), and in some languages stress patterns do not mark boundaries or help individual units cohere. By 9 months of age, infants typically show sensitivity to a range of language-specific cues (for a recent review, see Saffran & Sahni, in press).

In the domain of word segmentation, previous work suggests that younger infants tend to use language-general cues and later shift to language-specific cues (Thiessen & Saffran, 2003). In a segmentation study using a nonsense language, TPs, a language-general cue operating over novel syllable combinations was placed in conflict with the language-specific stress pattern of English. Six-and-a-half month-olds segmented the fluent speech using the language-general strategy of relying on TPs. In contrast, infants who were 2 months older used language-specific lexical stress patterns (also see Johnson & Jusczyk, 2001). This shift suggests that over time, infants become more sensitive to idiosyncratic cues, learning which regularities are relevant (and, presumably, which are not) for their native language. However, little is known about how this process unfolds.

How might infants discover these language-specific cues? One potential explanation is that language-general cues provide a basis for discovering overlapping or co-occurring language-specific cues. For example, in word segmentation, infants may use their sensitivity to TP cues, which is present early in life (Kirkham, Slemmer, & Johnson, 2002; Teinonen, Fellman, Naatanen, Aklu, & Huotilainen, 2009) to discover language-specific cues that are correlated with TPs.

The present work tested the hypothesis that infants can discover novel cues by exploiting redundancies between language-general and language-specific cues. Nine-month-old infants were exposed to a fluent speech stream that contained two overlapping cues to word boundaries: a language-general cue (TPs) and a language-specific cue (/t/-onsets). TPs are known to be salient to 9-month-old infants. The second cue was specific to the artificial language and therefore novel: Each word in the speech stream began with /t/. Experiment 1 was thus designed to test the hypothesis that infants can use the language-general TP cue to discover the overlapping language-specific /t/-onset cue. The /t/-initial syllables are only informative as a cue to word boundaries due to their overlap with the TP cue; the TP cue positions the /t/-initial syllable at the onset of each word. Consequently, the only way infants can extract this pattern is to use its overlap with the TP cue. We tested infants using items that were all novel relative to the exposure corpus but that varied in their use of the /t/-onset cue. The question of interest was whether infants would be sensitive to the presence of /t/-onsets in the test items. If so, this would provide evidence that infants can isolate individual cues by using redundancies in the speech stream.

Experiment 1

To examine whether infants can use a language-general segmentation cue to discover an overlapping novel language-specific cue, infants heard a fluent speech stream that contained two overlapping cues to word boundaries: (a) dips in TPs at word boundaries and (b) /t/-initial syllables at word onsets. To determine whether infants acquired the novel /t/-onset pattern, test items either adhered to the pattern (began with a /t/-syllable) or violated it (contained a medial /t/). Crucially, these items were previously unheard combinations of syllables from the speech stream (i.e., TP = 0). Therefore, TP information would not allow infants to distinguish between the two types of test items. Instead, successful discrimination hinged on discovery of the /t/-initial pattern present in the speech stream played during familiarization.

Method

Participants. Twenty-four 9.5-month-old monolingual English-learning infants (mean age = 9.5 - months, range = 9.0–10.0) participated in this experiment. All infants were born full-term and had fewer than four prior ear infections and no history of hearing or vision impairments. Data from an additional 8 infants were excluded due to fussiness (4) and parents stopping the experiment (4).

Stimuli. A fluent stream of speech was created from recordings of a female native English speaker who was blind to the structure of the artificial language. The language contained six bisyllabic words: *tohsigh, teemay, tiepu, tukee, tayla,* and *tafo.* A pseudosynthesis technique was used to create the speech stream, which allowed for use of naturally produced syllables while permitting control over coarticulation, duration, pitch, and volume of all syllables in the language. All three-syllable sequences that occurred in the language, both within and between word boundaries (e.g., *tohsigh-tee, sighteemay*), were recorded in a monotone, isochronous register. Medial syllables were spliced out of the three-syllable sequences and concatenated together with no silence between syllables. By using these medial syllables, coarticulation within each syllable and between every pair of syllables in the language was maintained. Syllables were edited prior to concatenation to have the same duration, pitch, and volume. The stream contained 40 repetitions (2 min 17 s) of each word in a pseudorandom order with no word appearing twice in succession (see the Appendix for a transcript of the complete familiarization language). Each within-word syllable pair had a TP of 1.0; between-word syllable pairs had a TP between .1 and .25 ($M = .20$). The speech stream thus contained two overlapping and completely redundant cues to word boundaries: dips in TPs and /t/-onsets.

Four novel test items were constructed from syllables in the artificial language. Two of these items began with /t/ (*tiemay, tohla*), and two contained a medial /t/ (*fota, keetu*). Test items were created from recordings of each bisyllabic item spoken in isolation. Duration, pitch, and volume were edited so that all test items were essentially equivalent.

Procedure. During familiarization, infants listened to the speech stream at a comfortable volume, played over speakers mounted on each sidewall while viewing an unrelated Baby Einstein video. An experimenter then entered the booth, covered the monitor that displayed the video, and placed headphones playing masking music on the caregiver. The test phase began with two practice trials (a recording of piano tones), designed to help the infants learn the contingency between their head-turns and the lights and sounds. The practice trials were followed by 12 test trials, three blocks of each of the four test items (*tiemay*, *tohla*, *fota*, and *keetu*). Infants' ability to discriminate the test items was assessed using the Headturn Preference Procedure (Kemler Nelson et al., 1995). The experimenter was seated outside the booth, observing the infants' head-turns on a closed circuit TV, and controlling the experiment via custom software. Lights were mounted on the center wall (directly facing the infant) and sidewalls. Each trial began with the center light blinking. Once the infant fixated on the light, it was extinguished and one of the sidelights began to blink. When the infant fixated on the blinking sidelight a sound was played from the speaker below the light. On each test trial, an item was repeated until the infant looked away for at least 2 s, or until the item had repeated 15 times. If the infant failed to fixate on the side light for at least 1 s during a test trial, the trial was excluded and an additional trial of that test item was automatically added after the third test block.

Results

We tested infants' ability to discriminate /*t*/-initial from /*t*/-medial test items over the three blocks of testing with a 2 (test item type: /*t*/-initial vs. /*t*/-medial) × 3 (test block: 1, 2, 3) repeated-measures analysis of variance (ANOVA; means shown in Table 1). The main effect of test item type (/*t*/-initial vs. /*t*/-medial) was not significant, $F(1, 23) = 0.975$, $p = .33$. The assumption of sphericity was violated for the Type × Block interaction term (Mauchly's $W = .687$) and so multivariate analyses were used to evaluate the significance of the interaction. With a large violation of sphericity (i.e., when Mauchly's $W < .7$), the statistical power of multivariate techniques tends to be greater than univariate techniques (Keppel, 1991; Mendoza, Toothaker, & Nicewander, 1974). There was a significant interaction between test item type and block, $F(2, 22) = 8.15$, $p = .002$. As shown in Figure 1, the significant interaction reflects a reversal in the direction of preference over the course of testing. The familiarity preference present in the first two test blocks shifts to a novelty preference in the third block. Block interactions and shifts in direction of preference have been previously observed elsewhere in the literature (Gerken et al., 2005) but are not often discussed.

Subsequent analyses focused on the first two blocks (eight test trials), as these looking times are more proximal to the familiarization phase and thus most likely to reflect learning from the fluent speech. A one-way (test item type: /*t*/-initial vs. /*t*/-medial) repeated-measures ANOVA revealed a significant difference in looking times to the two types of items, $F(1, 23) = 6.30$, $p = .02$ (see Figure 2). Infants looked longer to the /*t*/-initial test items, which adhered to the pattern presented during familiarization. Recall that the TPs between syllables in the test items were all zero. Thus, infants could not have discriminated /*t*/-initial from /*t*/-medial test items based on TP cues. These results suggest that infants learned the /*t*/-initial pattern and generalized it to include the novel test items.

Discussion

The results of Experiment 1 suggest that infants were able to exploit the /*t*/-initial pattern,

Table 1
Mean and Standard Errors for Looking Times

	Experiment 1		Experiment 2		Experiment 3	
	/*t*/-initial	/*t*/-medial	/*t*/-initial	/*t*/-medial	/*t*/-initial	/*t*/-medial
Block 1	8.69 (0.80)	7.54 (0.70)	8.44 (0.88)	8.75 (0.70)	8.30 (0.96)	7.75 (0.66)
Block 2	7.45 (0.71)	6.02 (0.75)	7.00 (0.57)	7.56 (0.70)	6.77 (0.56)	6.95 (0.68)
Block 3	4.58 (0.39)	5.94 (0.56)	6.79 (0.68)	6.32 (0.79)	7.18 (0.85)	6.77 (0.73)
Blocks 1 and 2 (averaged)	8.07 (0.58)	6.78 (0.59)	7.57 (0.60)	8.18 (0.53)	7.53 (0.58)	7.35 (0.55)
All trials (averaged)	6.92 (0.46)	6.53 (0.46)	7.40 (0.51)	7.52 (0.48)	7.31 (0.39)	7.09 (0.50)

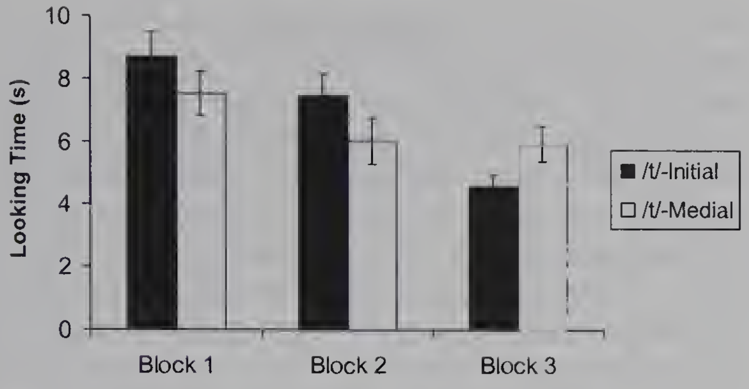

Figure 1. Experiment 1: Mean looking times to /*t*/-initial and /*t*/-medial test items for each test block.

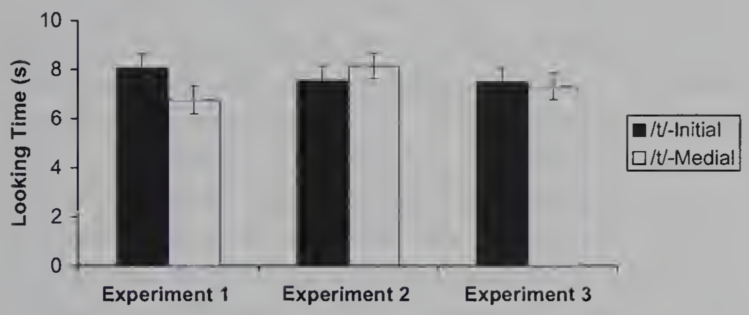

Figure 2. The average looking time for /*t*/-initial and /*t*/-medial items across test Blocks 1 and 2 for all three experiments.

successfully discriminating novel test items that followed the pattern from those that did not. This pattern was not immediately obvious in the input; the speech stream consisted of syllables beginning with /*t*/ alternating with syllables that began with other sounds. In order to discover that the /*t*/ segment signaled word onsets, infants presumably capitalized on the TP cues in the speech stream, which also provided cues to word boundaries. On this view, infants discovered the language-specific /*t*/-onset cue by capitalizing on the language-general TP cue.

One interesting feature of these data is that infants' looking behavior changed over the course of testing. Familiarity to novelty preference switches is not uncommon in infant behavioral studies, though the factors responsible for the shift may vary (Fantz, 1964; Hunter, Ames, & Koopman, 1983). The test items used in this study consisted of novel combinations of syllables from the familiarization language. This introduction of novel items at test forces infants to generalize beyond the training corpus, making it more likely that participants will show a familiarity preference at the outset of testing (e.g., Thiessen & Saffran, 2003). However, during the course of testing, infants received differential amounts of exposure to the test items. Figure 3 depicts the difference in looking times to /*t*/-initial and /*t*/-medial test items across the three test blocks. Initially, infants looked longer to /*t*/-initial items, thus receiving more exposure to them than to the /*t*/-medial items. This pattern of listening during testing may have led the infants to become bored with these items, moving them toward a novelty preference. To test this hypothesis, we examined individual participants' looking preferences across the testing session. Fifteen of 24 participants showed an initial familiarity preference that transitioned into a novelty preference, 5 showed an initial familiarity preference that remained a familiarity preference, and 4 showed an initial novelty preference that remained a novelty preference. A majority of participants showed the predominant pattern of increased exposure to the /*t*/-initial items in the first two blocks with a novelty preference in the third block. A chi-square test confirmed that this pattern of behavior would not be expected by chance ($\chi^2 = 20.3$, $df = 3$, $p = .0001$). This pattern of results suggests that while infants' initial test responses were linked to learning during the familiarization phase, the novelty preference in Block 3 may have reflected infants' experiences during testing.

The findings from Experiment 1 support the hypothesis that infants used low TPs at word boundaries to acquire the overlapping but novel /*t*/-onset pattern. However, there is an alternate explanation for these results: It is possible that infants' behavior reflected preexisting preferences for individual items. A counterbalanced language composed of items that all contain a medial /*t*/ would clarify this issue. However, previous work (Endress, Scholl, & Mehler, 2005) has shown that it may be easier to generalize from patterns that occur at the edges of sequences, as opposed to those

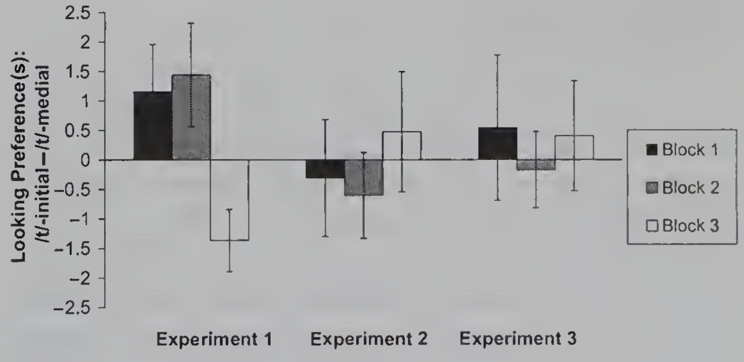

Figure 3. The difference between looking times to /*t*/-initial and /*t*/-medial test items, for each block for all three experiments.
Note. Positive values indicate a familiarity preference; negative values indicate a novelty preference.

occurring medially. Consequently, the two counterbalanced languages might not be equally learnable. A second experiment tested this possibility with a new group of infants, who participated only in the test phase of the experiment. If infants in Experiment 1 had an a priori preference for the /t/-initial test items, infants in Experiment 2 should show a similar pattern of behavior. If infants in Experiment 2 do not show a similar pattern, this would suggest that exposure to familiarization materials that contained the two overlapping cues was necessary to elicit the preference for /t/-initial test items.

Experiment 2

This experiment was designed to test the hypothesis that infants in Experiment 1 listened longer to the /t/-initial test items due to an a priori preference for these particular items. Infants in Experiment 2 were not exposed to the familiarization speech stream, participating only in the testing procedure used in Experiment 1.

Method

Participants. Twenty-four 9.5-month-old monolingual English-learning infants (mean age = 9.5 months, range = 9.0–9.9) participated. Data from an additional 5 infants were excluded from the analyses because of experimenter error (1), fussiness (2), failure to contribute at least two trials for each item (1), and mean looking time to one or both sides less than 3 s (1).

Stimuli. The test items were the same as those used in Experiment 1.

Procedure. There was no exposure phase. The testing procedure was identical to Experiment 1, with 2 practice trials followed by 12 test trials.

Results and Discussion

As in Experiment 1, a 2 (test item type: /t/-initial vs. /t/-medial) × 3 (test block: 1, 2, 3) repeated-measures ANOVA was conducted. There was no significant effect of test item type (/t/-initial vs. /t/-medial), $F(1, 23) = 0.081$, $p = .78$, nor was the interaction between block and test item type significant, $F(2, 46) = 0.35$, $p = .70$ (see Table 1 and Figure 3). These results indicate that infants in Experiment 2 did not discriminate between /t/-initial and /t/-medial test items.

We next conducted a 2 (test item type: /t/-initial vs. /t/-medial) × 2 (group: Experiment 1, Experiment 2) repeated-measures ANOVA over the data from the first two test blocks from Experiments 1 and 2. This analysis was intended to determine whether the behavior of infants differed reliably across the two experiments. The interaction between test item type and group was significant, $F(1, 46) = 6.19$, $p = .017$, suggesting that infants who heard the familiarization materials showed a different pattern of behavior at test than those who did not (see Figure 2).

This between-group analysis, coupled with the within-subject analysis showing no effect of test item type, indicates that infants in Experiment 2 did not have an a priori preference for the /t/-initial items relative to the /t/-medial items. We can therefore attribute infants' behavior in Experiment 1 to familiarization with the fluent speech stream. Nevertheless, it is still unclear which aspects of the familiarization stimuli elicited infants' successful discrimination between /t/-initial and /t/-medial test items. It is possible that, as originally hypothesized, low TPs at word boundaries anchor the alternating /t/ syllables, allowing infants to extract the /t/-onset cue and generalize it to the novel test items. Another possibility is that infants are extracting the extremely regular alternating /t/ syllable pattern (created because each of the bisyllabic words begins with a /t/) and uniformly mapping the /t/ syllable to word onsets. According to this alternative hypothesis, infants could capitalize on a systematic pattern (/t/-onsets) without the aid of another cue. On this account, they detect the regular alternation and map it onto onsets, potentially because onsets are privileged perceptually and/or lexically (e.g., Brent & Cartwright, 1996; Jusczyk, Jusczyk, Kennedy, Schomberg, & Koenig, 1995; Magnuson, Dixon, Tanenhaus, & Aslin, 2007; Marslen-Wilson & Zwitserlood, 1989).

To explore this hypothesis, we designed a new speech stream to determine whether infants could extract the novel /t/-onset pattern without the aid of another cue for bootstrapping. The resulting speech stream did not have low TPs at word boundaries but still contained the /t/-onset pattern. If infants can extract the /t/-onset pattern without an overlapping cue, infants in Experiment 3 should show a significant difference in looking time to /t/-initial items compared to /t/-medial items. However, if TPs played a critical role in the discovery of the novel pattern via bootstrapping, infants should not show a significant difference in looking time to /t/-initial items compared to /t/-medial items in the absence of TP cues.

Experiment 3

This experiment was designed to determine whether the overlapping cue from Experiment 1, low TPs at word boundaries, was necessary for infants to acquire the novel /t/-onset pattern. Infants were exposed to a new fluent speech stream that did not have low TPs at word boundaries but still contained the novel /t/-onset pattern. The procedure and test items were identical to Experiment 1.

Method

Participants. Twenty-four 9.5-month-old monolingual English-learning infants (mean age = 9.5 months, range = 9.1–10.0) participated in this experiment. Data from an additional 17 infants were excluded from the analyses because of parental interference (5), sleepiness (1), external noise (1), fussiness (7), and failure to contribute at least one trial for each item type in every block (3).

Stimuli. A fluent speech stream was created using the procedure and words (*tohsigh*, *teemay*, *tiepu*, *tukee*, *tayla*, and *tafo*) from Experiment 1. Again, all syllables in the language were measured and edited such that duration, pitch, and volume were equivalent for all syllables. Unlike Experiment 1, in which words were repeated in a random order, the words in this fluent speech stream were repeated in exactly the same order 40 times (*teemaytieputukeetafotaylatohsigh**teemaytieputukeetafotaylatohsigh**. . .*; see Curtin et al., 2005, for another example of this method). This method generated a 2 min 7 s stream in which every pair of syllables had a TP of 1.0 and every other syllable in the language began with a /t/. The test items were identical to those in Experiments 1 and 2 (*tiemay*, *tohla*, *fota*, and *keetu*).

Procedure. The experimental procedure was the same as Experiment 1.

Results and Discussion

As in the previous experiments, we first ran a 2 (test item type: /t/-initial vs. /t/-medial) × 3 (test block: 1, 2, 3) repeated-measures ANOVA. There was no significant effect of test item type, $F(1, 23) = 0.07$, $p = .80$, and the interaction with block was not significant, $F(1, 23) = 0.27$, $p = .61$ (see Table 1 and Figure 3). This pattern of results indicates that infants did not differentiate between /t/-initial and /t/-medial test items in the absence of the TP cue. We next ran a 2 (test item type: /t/-initial vs. /t/-medial) × 2 (group: Experiment 1, Experiment 3) repeated-measures ANOVA contrasting the data from the first two test blocks of Experiments 1 and 3. This Test Item Type × Group interaction did not reach significance, $F(1, 46) = 2.87$, $p = .20$ (see Figure 2).

Though the between-group analysis is inconclusive, infants' failure to discriminate the test items in Experiment 3 is consistent with the hypothesis that infants were influenced by the presence of TP cues in Experiment 1. Without the low TPs at word boundaries to anchor the alternating /t/ syllables to segment onsets, infants seem unable to extract the novel pattern.

General Discussion

The results of these experiments indicate that infants are able to use a language-general regularity (dips in TPs at word boundaries) to discover a second, language-specific regularity (/t/-onsets). Moreover, infants generalized this newly learned cue to novel items, as demonstrated by their test performance. These findings suggest one possible class of solutions to the learning problem described earlier: How do infants discover relevant linguistic cues when there are many way to analyze speech and a single bit of information can be informative at multiple levels? Just as adults use correlations among cues to resolve ambiguities when using language, infants are able to use such correlations to acquire language, as suggested by the constraint satisfaction approach. Thus, infants' learning capacities, such as the ability to encode correlations across different types of information (Rose & Ruff, 1987), seem well matched to properties of natural language. What seems initially to be an insurmountable barrier to learning—the fact that elements of language contribute to multiple levels of structure simultaneously—actually helps solve the language acquisition problem (see Hirsh-Pasek, Golinkoff, Hennon, & Maguire, 2004, for a similar example in word learning).

Research over the past decade has shown that infants are sensitive to many different patterns that can be informative for language learning. It remains unclear, however, how infants find individual cues and combine different types of information to understand the complex structure of their language. Behavioral research on multiple cue usage in this domain has typically taken the form of cue-conflict studies, examining relative reliance on different types of information over time (e.g., Johnson & Jusczyk, 2001; Mattys, Jusczyk, Luce, & Morgan, 1999;

Thiessen & Saffran, 2003). Although studies using this approach have been quite revealing, they cannot address how infants may capitalize on the redundancies in natural speech or how cues are discovered. More recent research has focused on the use of multiple probabilistic patterns to categorize lexical items (Gerken et al., 2005; Gómez & Lakusta, 2004; Shi et al., 1999). Results from the present work demonstrate that the complexity of natural speech does not necessarily hinder language acquisition but in fact may facilitate learning. Paradoxically, complexity may help learning—as long as the complexity is consistent with the structure to be acquired (Morgan, Meier, & Newport, 1987, 1989).

The process observed in the present work is reminiscent of bootstrapping: Partial information about one element of language provides evidence about another element, which in turn provides further evidence for the first element (Gleitman & Wanner, 1982). On this view, the infant begins to pick up on TPs, facilitating discovery of the */t/*-onset cue, which in turn may further the consolidation of the TP cue. Both the TPs and the */t/*-onset cue provided evidence about the boundaries between words in the fluent speech stream. The */t/* cue is different, insofar as its discovery depended on some prior learning about TPs. We are not claiming that TPs or any specific regularity is necessary for this process to operate. Rather, any cues that infants can use to extract linguistic structure, and that overlap with other discoverable patterns, should be available for use in this fashion. This is an area where computational models of bootstrapping mechanisms would be informative. Existing models have typically built in different types of regularities, focusing on how combinations of given regularities can yield better learning outcomes than individual regularities (Christiansen et al., 1998; Shi, Morgan, & Allopenna, 1998). Models of how the cues themselves are identified, and the dependencies between them in learning, would be very timely.

This work shows that infants can use the overlapping nature of speech to isolate cues. Language-general regularities, such as TPs, may support the discovery of language-specific cues. Critically, the present research also expands the scope of statistical learning mechanisms. Not only can infants use such mechanisms to exploit the structure of their language, but they can also use statistical learning to discover the structure of their native language.

NICHD Early Child Care Research Network

Relations between nonrelative child care (birth to 4½ years) and functioning at age 15 were examined (N = 1,364). Both quality and quantity of child care were linked to adolescent functioning. Effects were similar in size as those observed at younger ages. Higher quality care predicted higher cognitive–academic achievement at age 15, with escalating positive effects at higher levels of quality. The association between quality and achievement was mediated, in part, by earlier child-care effects on achievement. High-quality early child care also predicted youth reports of less externalizing behavior. More hours of nonrelative care predicted greater risk taking and impulsivity at age 15, relations that were partially mediated by earlier child-care effects on externalizing behaviors.

The transition from childhood to adolescence involves substantial changes in multiple features of children's lives, which raises fundamental questions about the importance of early experience as an influence on adolescent development. Adolescence is defined by physical and cognitive changes (Kuhn, 2009; Susman & Dorn, 2009) as well as transformations in parent–child and peer

relationships (Collins & Steinberg, 2006) and schooling (Eccles & Roeser, 2009). With these myriad changes, there is reason to wonder whether effects of early child-care experiences persist into adolescence. This is the central issue addressed in this report. Specifically, we ask if nonrelative child care during the first 4½ years of life predicts academic achievement and behavioral adjustment at age 15. Then, we consider developmental processes that may mediate these associations. Finally, we ask if links between early child care and adolescent outcomes are moderated by child gender or familial risk.

The work to be reported is based on a large, nonexperimental field study—the National Institute of Child Health and Human Development Study of Early Child Care and Youth Development (NICHD SECCYD)—that affords estimation of statistical rather than causal effects. When causal language (e.g., effect, influence) is employed in this report, it is for heuristic purposes.

Child Care and Child Development

Two different perspectives have guided much of the research examining the effects of early child care. For at least 50 years, nursery schools and preschools have been viewed by parents and educators as a means to promote social and academic skills prior to entry to formal schooling (Lamb & Ahnert, 2006). In contrast, others, influenced in part by attachment theory, have expressed concerns that extensive nonmaternal care, especially beginning very early in life, could disrupt attachment bonds and result in problem behaviors (Belsky, 1986, 1988; Egeland & Hiester, 1995).

Research findings provide support for both views. Experimental studies of high-quality early intervention programs have demonstrated that these programs can enhance social, cognitive, and academic development of economically disadvantaged children (Campbell, Pungello, Miller-Johnson, Burchinal, & Ramey, 2001; Love et al., 2005; Reynolds, 2000; Schweinhart, Weikart, & Larner, 1986). Correlational studies of economically and ethnically diverse samples also have fairly consistently found higher quality child care to be associated with better cognitive and academic outcomes (Broberg, Wessels, Lamb, & Hwang, 1997; Burchinal et al., 2000; Cote et al., 2007; Gormley, Gayer, Phillips, & Dawson, 2005; Mashburn et al., 2008; Peisner-Feinberg & Burchinal, 1997). Evidence of social benefits of child care has been more mixed. Although some have found benefits of high-quality care for social development (Cote et al., 2007; Howes, Phillips, & Whitebook, 1992; Vandell, Henderson, & Wilson, 1988), other researchers have identified potentially adverse consequences of long hours of care, especially, though not exclusively, if initiated early in life (Bates et al., 1994; Belsky, 2001; Cote, Borge, Geoffroy, Rutter, & Tremblay, 2008; Haskins, 1985; Loeb, Bridges, Bassok, Fuller, & Rumberger, 2007; Nomaguchi, 2006; Vandell & Corasaniti, 1990). Time in center-type settings has been related to negative social behavioral outcomes but also positive academic outcomes (Huston et al., 2001; Loeb et al., 2007; Magnuson, Ruhm, & Waldfogel, 2007). Efforts to understand and integrate these disparate findings has led to a conceptualization of child care that differentiates quality of care, quantity of care, and types of care as potentially distinct influences on children's development.

The NICHD SECCYD was launched in the early 1990s to examine the effects of these three distinctive aspects of early child care. In previous reports of child functioning prior to school entry (NICHD Early Child Care Research Network [ECCRN], 2002), in the primary grades (NICHD ECCRN, 2005c), and later in elementary school (Belsky et al., 2007), child-care quality, quantity, and type were differentially linked to children's development. In general, higher quality of child care was related to higher cognitive–academic performance, whereas more hours of child care (especially by nonrelatives) was related to more problem behavior. More experience in center-type care was related to better cognitive skills but also more problem behavior. Although this general pattern of findings was detected at three time periods (preschool, early elementary, and later elementary), effects were small by traditional standards, and over time some previously detected child-care effects disappeared when evaluated at later ages, raising the core issue of the current inquiry, namely, whether effects of early child care are evident in adolescence.

Some have contended that child-care effects would fade away over time (Blau, 1999; Colwell, Pettit, Meece, Bates, & Dodge, 2001; Deater-Deckard, Pinkerton, & Scarr, 1996), especially by the time young people are in high school because subsequent life experiences likely override child-care experiences that occurred a decade or more earlier. At the same time, however, in view of the fact that development in adolescence builds on prior periods and that some effects of early experience may not manifest themselves until adolescence (so-called sleeper effects), some effects of early child care might remain even among teenagers.

To date, only a few early intervention studies have tracked effects of high-quality early child care and education into the high school years and beyond. Low-income children exposed to high-quality program care show better academic outcomes through high school and higher rates of employment and less criminal activity as young adults (Campbell et al., 2001; Lazar & Darlington, 1982; Schweinhart et al., 1986). Several large longitudinal studies that included middle- as well as low-income participants have documented quality effects in elementary school (Melhuish et al., 2008; Peisner-Feinberg et al., 2001), but none has considered child-care effects in adolescence.

This study extends previous research by examining the links between routine early child-care experience (i.e., not high-quality early intervention programs) and adolescent functioning at age 15 in a large and economically diverse sample. Three related issues are considered. The first concerns the specificity of child-care effects. Previous analyses of SECCYD data indicated that child-care quality positively predicts cognitive and academic functioning, more hours of care predicts more problem behavior, and more experience in center care predicts both better academic outcomes and more problem behavior at various times during the preschool and middle childhood years (Belsky et al., 2007; NICHD ECCRN, 1998, 2003, 2005c). Here, we examine whether such domain specificity is maintained at age 15.

A second issue involves possible pathways through which child care could affect adolescent development. The most simple and straightforward proposition is that differences in child functioning at entry to school that are linked to early care are carried forward to middle adolescence. We address this possibility by evaluating the extent to which observed effects of child care on adolescent functioning at age 15 are mediated by prior cognitive and social functioning in early and middle childhood.

A third issue that merits attention is whether associations between child care and adolescent functioning are moderated by child gender or familial risk. Hypotheses regarding differential gender effects have been in the literature for years (Belsky, 1988; Love et al., 2003; Maccoby & Lewis, 2003), with some evidence of these effects reported for child care and developmental outcomes in the preschool and early elementary years (Caughy, DiPietro, & Strobino, 1994; Crockenberg, 2003; Peisner-Feinberg et al., 2001). Additionally, some early studies of maternal employment highlighted negative effects for boys and positive effects for girls (Gottfried & Gottfried, 1988; Hoffman & Youngblade, 1999). A recent reanalysis of the Abecedarian, Perry Preschool, and the Early Training Projects found long-term educational benefits for girls, but not boys (Anderson, 2008), although a cost–benefit analysis of the Perry Preschool participants at the age of 40 indicated greater benefits for men than women, primarily because of economic savings associated with reductions in the men's incarcerations (Belfield, Nores, Barnett, & Schweinhart, 2006).

There also is some evidence that the effects of child care may vary as a function of familial risk. Quality of early child care has emerged as a protective factor of familial social risk (measured by maternal education, family income, household size, and maternal depression) in terms of academic achievement in elementary school (Burchinal, Vandergrift, & Pianta, 2009). A report based on a large national survey found that children of low-income families benefited more in terms of cognitive–academic performance when they experienced more hours of child care (labeled a compensatory effect), whereas children of middle-income households functioned more poorly when they experienced more hours of child care (labeled a lost-resources effect; Desai, Chase-Lansdale, & Michael, 1989). In other research, more time in center care predicted larger academic gains among low-income than middle-income children (Gormley et al., 2005; Magnuson et al., 2007). For the most part, however, previous analyses of the SECCYD have failed to detect familial risk- or gender-moderated child-care effects (NICHD ECCRN, 2002, 2005c). We examine whether such effects emerge in adolescence.

In all nonexperimental studies of child care, selection bias is a concern because family and child characteristics are related to quality, type, and hours of care as well as to children's functioning (Committee on Family and Work Policies, 2003). To reduce the likelihood of selection bias, extensive covariates measured in early childhood are used as control variables in all analyses, following the practice adopted in our previous reports. Primary analyses also include extensive covariates measured in middle childhood and adolescence, in line with our prior work and consistent with the standard adopted by developmental psychologists who have argued that controlling for subsequent family and school experiences provides a more conservative test of effects associated with early experience (Bradley, Caldwell, & Rock, 1988;

Kovan, Chung, & Sroufe, 2009; Lamb, Thompson, & Gardner, 1984). Failing to include such controls risks attributing effects to early experience that could just as well (and perhaps more parsimoniously) be a function of later experience. Nevertheless, we also test relations without the middle childhood and adolescent covariates because family factors in middle childhood and adolescence may have been influenced by child care. If early child care affected these covariates, then their inclusion might result in over- or underestimates of child-care effects.

In sum, this report provides new insights into potential long-term child-care effects by tracking a large sample of American children to 15 years of age to determine whether variations in early child-care quality, quantity, and type are related to cognitive development, academic achievement, and socioemotional functioning in adolescence.

Method

Participants

Hospital visits were conducted with mothers shortly after the birth of a child in 1991 in 10 locations in the United States. During selected 24-hr intervals, all women giving birth ($N = 8{,}986$) were screened for eligibility. Of those families, 3,142 were excluded owing to a priori criteria such as failure to speak English and plans to move within the next 3 years. At a follow-up telephone interview at 2 weeks, 1,353 could not be contacted or refused to participate. Families were randomly selected among the remaining pool of eligible participants. A total of 1,364 families were recruited, completed a home interview at 1 month, and became the study participants. Overall, this constituted a 52% response rate from the original approach to families in the hospital to successful recruitment in the study.

In terms of demographic characteristics, 26% of the mothers in the recruited sample had no more than a high school education at recruitment, 21% had incomes no greater than 200% of the poverty level, and 22% were minority (i.e., not non-Hispanic Euro-American). Details of the sampling plan can be found in NICHD ECCRN (2005b). It should be noted that the primary analyses to be presented estimate effects based on all 1,364 children originally recruited into the sample.

At age 15, measures of adolescent outcomes were obtained for 958 youth (70% of the original recruitment sample). Comparisons of the age 15 sample and the other 406 youth in the birth cohort sample revealed four significant differences on the 30 early and middle childhood variables listed in Tables 1 and 2. Nonparticipants were more likely to be boys (56% vs. 50%) and have lower scores at 4½ years on a test of math skills (97.8 vs. 102.5), and their mothers were less educated (13.4 years vs. 14.3 years) and provided lower quality parenting (−.25 standardized parenting score vs. −.02 standardized parenting score).

Measures

Children were studied from birth to age 15. Assessments occurred when the children were 1, 6, 15, 24, 36, and 54 months old; when they were in kindergarten and Grades 1, 2, 3, 4, 5, and 6; and at age 15. The following sections describe the specific measures used in the present analyses and the time points of administration. Additional details about all data collection procedures, psychometric properties of the instruments, and descriptions of how composites were derived and constructed can be found in the study's Manuals of Operation and Instrument Documentation (http://secc.rti.org).

Measurements are described in terms of their roles in the analyses. Measures reflecting the child's experiences in early child care are presented first, followed by the adolescent cognitive and social outcome measures. Variables used to control for family factors and schooling are then described. Finally, we describe measures of child functioning in early and middle childhood that are used in the mediation pathway analyses.

Child-Care Characteristics

Three aspects of child care were measured from birth through 4½ years: type of care, quantity of care, and quality of care (see Table 1).

Child-care type. During telephone and personal interviews conducted at 3-month intervals (or epochs) through 36 months and 4-month intervals (or epochs) to 4½ years of age, mothers reported types and hours of regularly used nonmaternal care. During each interview, mothers reported all of the care arrangements used since the previous interview. Arrangements were classified as center, child-care home (any home-based care outside the child's own home), in-home care (any caregiver in the child's own home), father care, and grandparent care. The proportion of epochs in which the child received care in a center for at least 10 hr/week was computed and used as variable to represent *type of care*.

[a] Reading measures were Woodcock–Johnson (WJ) Passage Comprehension at age 15, Broad Reading in Grades 3 and 5, and Letter-Word Identification at 4½ years and Grade 1.

[b] Math measures were WJ Applied Problems at 4½ years, Grade 1, and age 15, and Broad Math in Grades 3 and 5.

[c] Externalizing measure was Youth Self-Report at 15 years and Teacher Report at all other ages.

Child-care hours. The hours per week in all types of nonmaternal care excluding fathers and grandparents were tallied for each epoch, and then the mean of nonrelative care hours across epochs was computed.

Child-care quality. Observational assessments were conducted in the primary child-care arrangement at ages 6, 15, 24, 36, and 54 months. Quality was assessed during two half-day visits scheduled within a 2-week interval at 6–36 months and one half-day visit at 54 months. Observers completed four 44-min cycles of the Observational Record of the Caregiving Environment (ORCE) per child age through 36 months and two 44-min ORCE cycles at 54 months. Detailed descriptions of the ORCE assessments can be found in NICHD ECCRN (2002), including coding definitions, training procedures, and interobserver agreement. Reliability exceeded .90 at 6 months, .86 at 15 months, .81 at 24 months, .80 at 36 months, and .90 at 54 months.

A mean quality of nonrelative care score was computed for each child.

Adolescent Functioning at Age 15

Table 2 provides the descriptive statistics for the measures of adolescent functioning at age 15.

Cognitive–academic achievement. The Woodcock–Johnson Psycho-Educational Battery–Revised (WJ–R; Woodcock & Johnson, 1989) is a wide-range, comprehensive set of individually administered tests that consists of two major parts: the Tests of Cognitive Ability and the Tests of Achievement. At age 15, cognitive ability was assessed with two subscales, Picture Vocabulary and Verbal Analogies. Achievement was assessed using the Passage Comprehension and Applied Problems subscales. In this report, standard scores, which are based on a mean of 100 and a standard deviation of 15, and the equivalent percentile rank were used.

Risk taking. Adolescents reported *risk-taking* behaviors using an audio computer-assisted self-interview. Thirty-six risk-taking items were drawn from instruments used in prior studies of adolescents (Halpern-Felsher, Biehl, Kropp, & Rubinstein, 2004). Adolescents reported the extent to which, over the past year, they used alcohol, tobacco, or other drugs; behaved in ways that threatened their own safety (e.g., rode in a vehicle without the use of seatbelts); used or threatened to use a weapon; stole something; or harmed property. Responses were made on a 3-point scale (0 = *never,* 1 = *once or twice,* 2 = *more than twice*). Ratings were summed across component items and then subjected to square-root transformation to reduce skew and kurtosis (Cronbach alpha = .89).

Impulsivity. Adolescents completed an eight-item questionnaire to assess reactions to external constraints, taken from the Weinberger Adjustment Inventory (Weinberger & Schwartz, 1990). The measure asks participants to rate (1 = *false* to 5 = *true*) how closely their behavior matched a series of statements. Sample items include: "I'm the kind of person who will try anything once, even if it's not that safe," "I should try harder to control myself when I'm having fun," and "I do things without giving them enough thought." Seven items were used to create an impulsivity composite score (Cronbach alpha = .82).

Externalizing problems. Adolescents self-reported externalizing behaviors using the Youth Self-Report (YSR; Achenbach & Rescorla, 2001). The scale consists of 119 items that reflect a broad range of behavioral and emotional problems as well as 16 socially desirable items. For each item, the adolescent is asked to rate how well that item describes him or her currently or within the last 6 months: on a 3-point scale (0 = *not true,* 1 = *somewhat or sometimes true,* 2 = *very true or often true*). The format of the YSR is similar to that of the Child Behavior Checklist completed by parents (CBCL; Achenbach, 1991a) and the Teacher Report Form (TRF) completed by teachers (Achenbach, 1991b). The YSR, CBCL, and TRF have 89 problem items in common, but the YSR includes additional items that are specifically designed for adolescents. *Externalizing behaviors* are assessed by 30 items (Cronbach alpha = .86).

Maternal, Child, Family, and School Controls

Measures of maternal, child, and family characteristics during early childhood, middle childhood, and adolescence, and school quality were used as controls for possible selection bias. See Table 1 for the descriptive statistics.

The early childhood covariates are *maternal education* (in years); child *gender;* child *race and ethnicity;* the proportion of epochs through 4½ years in which the mother reported a *husband* or *partner* was present; family income through 4½ years calculated as the mean *income-to-needs ratio; maternal Peabody Picture Vocabulary Test–Revised* (PPVT–R; Dunn & Dunn, 1981) obtained when the study child was 3 years of age; *maternal psychological adjustment* measured when the study child was 6 months of age using three subscales (Neuroticism, Extraversion, and Agreeableness) of the NEO Personality Inventory (Costa & McCrae, 1985, 1989); the mean of *maternal depressive symptoms* assessed by the Center for Epidemiological Studies Depression Scale (CES–D; Radloff, 1977) reported by the mother at 6, 15, 24, 36, and 54 months; and an *early parenting quality* composite score created by averaging standardized ratings of observed maternal sensitivity and observed home environmental quality measured at 6, 15, 24, 36, and 54 months. These control variables are described in detail in NICHD ECCRN (2002) and the instrument documentation available at the project Web site (http://secc.rti.org).

The middle childhood covariates were measured when the study children were in Grades 1, 3, and 5. These family covariates paralleled those obtained in early childhood: the proportion of the middle childhood in which a *husband or partner* was present in the household, mean *income-to-needs ratio*, mean *maternal depressive symptoms*, and *mean observed parenting quality* (the average of standardized ratings of maternal sensitivity in a semistructured task and a home observation). In addition, the quality of school experiences in middle childhood was rated during two 44-min observations in Grade 1 and eight 44-min observations in Grades 3 and 5, and a *mean classroom quality score* was computed. For more details about the classroom observations and the classroom quality composites, see NICHD ECCRN (2004, 2005a).

The adolescent family covariates collected at age 15 corresponded to those used in early and middle childhood: *presence of a husband or partner* in the household, *income-to-needs ratio*, *maternal depressive symptoms*, and the *observed parenting quality composite*.

The age 15 parenting quality composite was based on ratings of maternal sensitivity made from a video-recorded 8-min discussion of areas of disagreement between the adolescent and mother (e.g., chores, homework, and money), selected by the adolescent (Allen et al., 2000), and a home observation combined with a semistructured interview (HOME; Bradley et al., 2000). The discussion task was coded using 7-point rating scales, with higher scores indicating higher levels of sensitivity based on adaptations of the more microanalytic coding systems of Allen et al. (2000, 2001) and coding systems used at earlier ages in the SECCYD (NICHD ECCRN, 2008). Maternal sensitivity was the sum of the 7-point ratings of supportive presence, respect for autonomy, and hostility (reversed). Cronbach alphas for the sensitivity composite scores ranged from .80 to .85 and interrater reliabilities determined from intraclass correlations based on a second coding of 19.5% (196/1004) to 27% (271/987) of the videotapes at different ages ranged from .84 to .91.

The adolescent version of the HOME scale consists of 44 items that assess five domains (Physical Elements, Learning Materials, Variety of Experiences, Acceptance and Responsiveness, and Regulatory Activities), which are combined to create a total score. The maternal sensitivity and HOME scores were standardized and averaged to create the parenting quality composite.

Child Functioning in Early and Middle Childhood

Measures of children's functioning in early and middle childhood included cognitive–academic achievement and behavior problems. Descriptive statistics for these measures can be found in Table 2.

For *cognitive–academic achievement*, children were administered subtests from the WJ–R: *Letter-Word Identification* (4½ years and first grade) and *Broad Reading* (third and fifth grades), which adds assessment of passage comprehension to the assessment of identification of words; *Applied Problems*, which measures skill in analyzing and solving practical problems in mathematics; and *Picture Vocabulary*, which measures children's ability to name objects depicted in a series of pictures.

The TRF (Achenbach, 1991b) was used to evaluate *Externalizing Problems* (e.g., ''hits others,'' ''disobedient at school,'' and ''argues a lot'') at 4½ years and in first, third, and fifth grades.

Results

Data analyses focus on whether early child-care quality, quantity, and type are associated with adolescent outcomes at 15 years of age, and if so, whether child functioning at entry to school mediates these subsequent associations. We also examine whether gender or family risk moderate associations between early child care and age 15 outcomes. Descriptive analyses are conducted and structural equation models (SEMs) test direct pathways, mediated pathways, and moderated relations between early child-care experiences and 15-year outcomes. The SEMs account for missing data through full-information maximum likelihood (FIML) based on the data for all 1,364 children originally recruited for the study. Alphas were set at .05, and thus all results reported are significant at $p < .05$ or better.

Preliminary Analyses

Descriptive statistics are presented in Tables 1–3. Table 1 describes the sample, presenting percentages, means, and standard deviations for the child-care variables and the selected covariates in the early childhood, middle childhood, and adolescent periods. Figure 1 shows the sample distributions for child-care quality, quantity, and type. Seventeen percent of the children experienced high-quality child care (ORCE scores of 3.30 or higher, on average), and 24% experienced moderately high-quality nonrelative care (ORCE scores of 3.0–3.29 on average). Less than one fourth of the children (21%) were in nonrelative care for more than 30 hr/week. Sixty-four percent of the children participated in center-type care for at least one epoch, with 24% experiencing more than 1 year of center care by 4½ years of age.

Table 2 provides descriptive statistics for the adolescent outcomes and for children's prior academic and behavioral functioning. The first column lists the means and standard deviations for cognitive–academic and behavioral outcomes at age 15. The next four columns show earlier assessments of cognitive–academic functioning and teacher-reported externalizing problems that are examined as potential pathways by which child-care experiences might be linked to age 15 outcomes. Table 3 presents correlations between child-care variables and all child outcomes. Because the analysis created a latent cognitive–academic achievement variable, a manifest composite was created for these correlations.

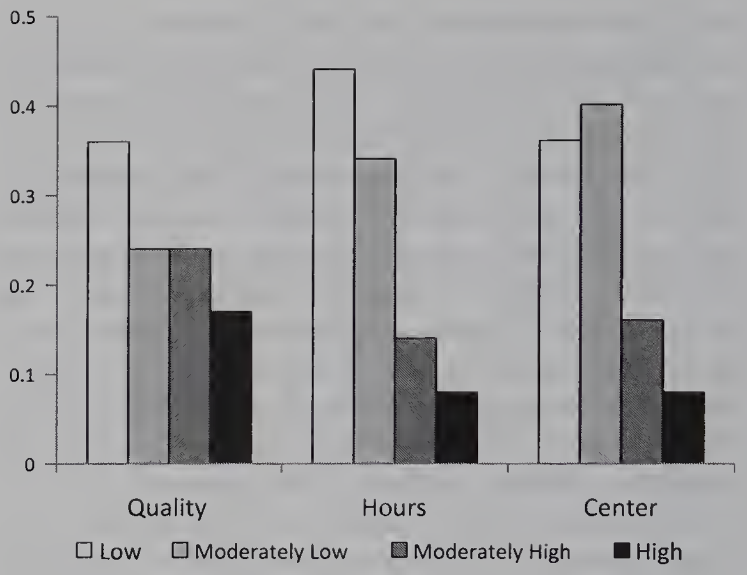

Figure 1. Distribution of quality, hours, and type of nonrelative child care.
Note. Quality categories: low: Observational Record of the Caregiving Environment (ORCE) ≤ 2.75; moderately low: ORCE = 2.75 to < 3.0; moderately high: ORCE = 3.00 to < 3.30; high: ORCE = 3.30–4.00. Hours categories: low: < 10 hr; moderately low: 10 to < 30 hr; moderately high: 30–40; high: > 40. Center categories: low: 0; moderately low: > 0 but less than 33%; moderately high: 33% to < 67%; high: 67%–100%.

Table 3
Correlations Among Child-Care Variables and Child Outcomes

Variable	Hours	Child-care quality	Center
Child care

Achievement G5	0.08	0.18	0.05
Externalizing 4½ years	0.20	−0.17	0.16
Externalizing G1	0.17	−0.11	0.11
Externalizing G3	0.10	−0.15	0.10
Externalizing G5	0.05	−0.11	0.04

Note. G1 = Grade 1; G3 = Grade 3; G5 = Grade 5.

Substantive Analyses

SEMs with FIML are used to test three sets of issues. The first examines direct associations between early child-care experiences and adolescent outcomes at age 15. The second adds potential mediators and the third tests potential moderators. The use of FIML allows the inclusion of the entire sample ($N = 1{,}364$) in these analyses. FIML has been shown to be as effective as multiple imputation in addressing problems associated with missing data (Schafer & Graham, 2002). When statistically significant associations are found, effect sizes are computed as the anticipated change in the outcome in standard deviation units when the predictor changes by a standard deviation or $d = B \times SD_{\text{predictor}}/SD_{\text{outcome}}$ (see NICHD ECCRN & Duncan, 2003).

Direct Associations Between Early Child Care and Age 15 Outcomes

The first set of analyses fit an SEM in which age 15 outcomes were predicted from early child-care hours, type, and quality, adjusting for family experiences in early and middle childhood and adolescence and school experiences in middle childhood (see Figure 2). The particular child-care variables of interest were child-care hours, proportion of time in center care, and child-care quality, computed from all care settings except those that involved fathers or grandparents. Preliminary analyses tested whether associations between the child-care variables and age 15 outcomes were linear or quadratic, indicating that only quality showed the quadratic association and that having the other quadratic terms did not increase fit, likelihood-ratio test $\chi^2(6) = 3.62$, $p = .27$. Accordingly, the quality-squared term was added to the model.

Academic achievement at age 15 was treated as a latent construct, with indicators of WJ–R Applied Problems, Picture Vocabulary, Passage Comprehension, and Verbal Analogies scores. Preliminary attempts to form a latent construct for problem behaviors suggested a poor fit, so adolescent self-reports of externalizing, risk taking, and impulsivity were analyzed as separate manifest variables. The model also included the following covariates: research site, child gender, child ethnicity, maternal education, maternal PPVT, maternal psychological adjustment, elementary school classroom quality, and repeated assessments from early childhood, middle childhood, and adolescence of family income, proportion time mother had a husband or partner, maternal depressive symptoms, and parenting quality. Including family covariates from the three developmental periods (early childhood, middle childhood, and adolescence) reduced the likelihood that observed associations between child outcomes and early child-care experience were because of family selection factors.

The SEM model fit the data well, $\chi^2 = 237.52(113)$; $\chi^2/df = 2.10$; comparative fit index (CFI) = .97; root mean square error of approximation (RMSEA) = .03. Generally, an RMSEA < .10 and a CFI ≥ .90 indicate good fit (Bollen, 1989). Table 4 shows the estimated coefficients and effect sizes for the paths from child-care quality variables to age 15 outcomes, and Figure 2 displays the statistically significant standardized coefficients. Results indicated that child-care quality showed significant linear ($B = 2.62$, $d = .09$) and quadratic ($B = 3.35$, $d = .07$) associations with children's

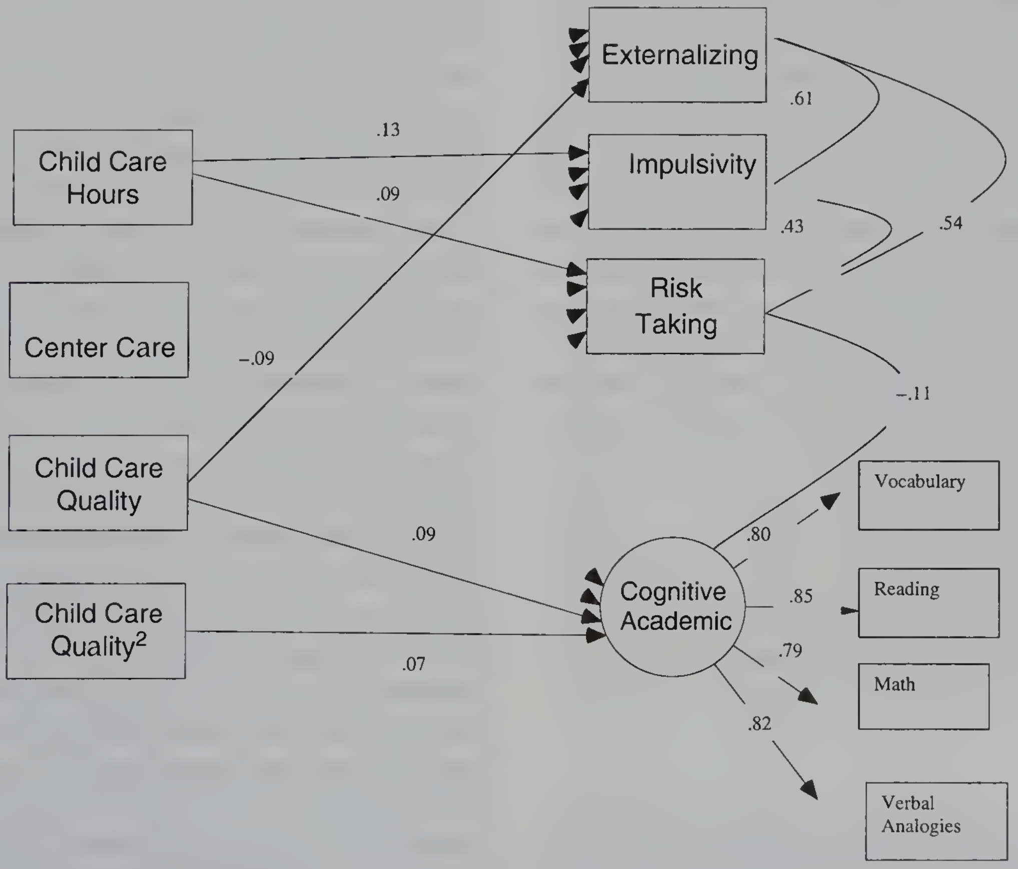

Figure 2. Standardized path coefficients in structural equation models relating child care experiences to 15-year outcomes.
Note. Only statistically significant paths are shown. Covariates include site, gender, ethnicity, maternal education, maternal Peabody Picture Vocabulary Test–Revised, maternal adjustment, elementary school classroom quality, and repeated assessments from early childhood, middle childhood, and adolescence of family income, proportion of time mother had a husband or partner, maternal depressive symptoms, and parenting quality.

Note. Model also includes as covariates site, gender, maternal education, maternal Peabody Picture Vocabulary Test–Revised, maternal adjustment, early childhood risk index, ethnicity, elementary school classroom quality and repeated assessments of family income, proportion time mother had husband/partner, maternal depressive symptoms, and parenting. A square-root transformation was applied to risk taking owing to its skewed distribution. *d* is analogous to the effect size measure Cohen's *d*, computed as $B \times SD_{\text{predictor}}/SD_{\text{outcomes}}$.
$^{*}p < .05.$ $^{**}p < .01.$ $^{***}p < .001.$

cognitive–academic achievement at age 15. The linear association suggested that children who experienced higher quality care had significantly higher levels of cognitive–academic achievement at age 15 whereas the quadratic association indicated that associations were stronger at moderately high levels of quality than at low or very low levels.

Figure 3 shows the estimated nonlinear association between child-care quality and achievement. Plotted are predicted values from −2.0 to +2.0 *SD* around the quality mean of 2.90. As shown, higher quality is associated with higher academic outcomes when ORCE scores are 2.75 or higher. In contrast, quality is nonsignificantly negatively related to academic outcomes when mean quality is in the very low range, averaging less than 2.5 on the ORCE over the first 4½ years. The turning point or minimum point of the quadratic function describing the association between quality and academic outcomes is computed by taking the derivative of the quadratic function. This value is −.39 on the mean-centered scale and 2.51 in the original ORCE scale. Thus, the turning point in this function is almost 1 *SD* (0.45) below the sample mean (2.90). The effect sizes for quality vary around this turning point. To illustrate, effect sizes were computed in terms of standard deviation units of child-care quality: *d* = .193 at +2 *SD* (ORCE = 3.8); *d* = .168 at +1.5 *SD* (ORCE = 3.58); *d* = .142 at +1 *SD* (ORCE = 3.35), *d* = .116 at +0.5 *SD* (ORCE = 3.13), *d* = .090 at the mean (ORCE = 2.90), *d* = .064 at −0.5 *SD* (ORCE = 2.67), *d* = .038 at −1 *SD* (ORCE = 2.45), and *d* = −.039 at −2 *SD* (ORCE = 2.00).

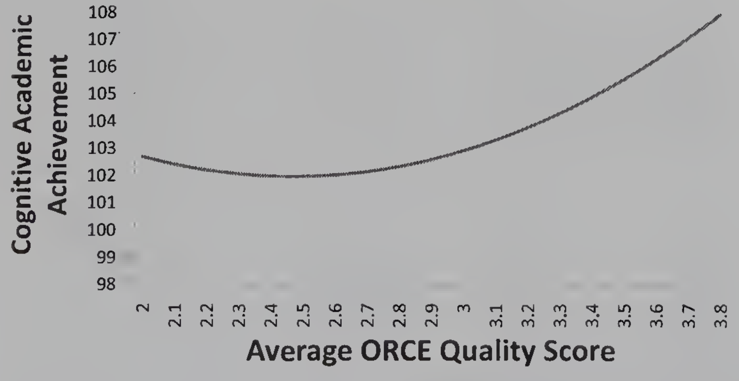

Figure 3. Predicting cognitive–academic achievement from child-care quality using quadratic regression.
Note. ORCE = Observational Record of the Caregiving Environment.

Table 4 and Figure 2 also show significant direct pathways between early child-care experience and problem behaviors. Adolescents who experienced more hours of nonrelative child care across their first 4½ years reported significantly more risk taking (*B* = 0.008, *d* = .09) and greater impulsivity (*B* = 0.08, *d* = .13) at age 15. In addition, children who experienced higher quality care had significantly lower externalizing scores (*B* = −1.89, *d* = .09).

Exposure to center care was not related to academic achievement or problem behaviors at age 15. Several analyses were conducted to examine the robustness of these findings. First, because child hours and proportion time in center care were correlated (*r* = .51), the SEM analysis was recalculated twice, first including quality and type and all covariates (but omitting hours of care) and, second, including quality and hours and all covariates (but omitting type of care). None of the paths involving type was significant in the first follow-up model. The findings associated with hours in these follow-up analyses remained the same as those reported in Table 4. Thus, more hours in nonrelative care, not proportion of measurement occasions spent in centers, predicted poorer social adjustment in adolescence.

Second, the basic SEM analysis examining quality, quality-squared, type, and hours was recalculated including the early childhood covariates and excluding the middle childhood and adolescent covariates. If early child care affects the middle childhood and adolescent covariates, then their inclusion might result in under- or overestimates of the child-care effects. For the most part, the same pattern of significant results was obtained when the middle childhood and adolescent covariates were removed from the model. Quality and quality-squared predicted higher academic outcomes ($B = 2.74$, $SE = 1.0$, $p < .05$, and $B = 3.63$, $SE = 1.51$, $p < .01$, respectively) and quality predicted less externalizing ($B = -1.96$, $SE = 0.87$, $p < .05$). Hours of care predicted more impulsivity ($B = 0.07$, $SE = 0.03$, $p < .001$).

Removing the middle childhood and adolescent covariates resulted in slightly different findings pertaining to adolescent reports of risk taking. More hours predicted more risk taking when all of the covariates were in the model ($p < .05$) but was only marginally significant when the middle childhood and adolescent covariates were excluded ($B = 0.007$, $SE = 0.003$, $p < .06$). Higher quality child care predicted less risk taking when the middle childhood and adolescent covariates were excluded ($B = -0.33$, $SE = 0.15$, $p < .05$) but was only marginally significant when these covariates were included ($B = -0.25$, $SE = 0.15$, $p < .10$).

Third, the quadratic association between child-care quality and cognitive–academic skills was examined in additional analyses to determine the robustness of these findings. A spline approach tested the extent that the association between child-care quality and cognitive–academic skills differed at varying levels of quality. The coefficient for quality as a continuous variable was estimated in models that included two, three, and four quality groups. These models did not provide a good fit to the data (CFI < .90) but did suggest that care quality was a nonsignificantly stronger predictor when quality was in the high range. A dummy variable approach estimated adjusted means for the outcome for the four quality groups. All these analyses suggested that children's cognitive–academic skills at 15 years were higher when they experienced higher quality care and that differences among the group means were larger at the higher end of quality than at the lower end. The two-group spline model with a knot at the mean, ORCE caregiving sensitivity = 2.90, indicated that quality was significantly related to achievement in the higher quality range ($B = 4.61$, $SE = 1.84$, $p = .01$, $d = .12$), was not significantly related in the lower quality range ($B = -0.22$, $SE = 1.60$, $p = .89$, $d = -.01$), and the difference in the magnitude of the association was "marginally" different ($B = 4.84$, $SE = 2.91$, $p = .097$, $d = .14$).

Other analyses that looked at other ORCE values between 2.5 and 3.1 to define higher or lower quality groups did not yield substantially different findings, suggesting that our data may not be able to identify a single cut-point for defining thresholds. These follow-up analyses indicate that the quadratic approach provided the most parsimonious description of the nonlinear association between child-care quality and cognitive–academic outcomes.

Because we had not detected the quadratic association between quality and cognitive–academic achievement at younger ages in our analyses that utilized somewhat different sets of covariates and analytic strategies, we reexamined possible links at these younger ages (54 months, Grades 1, 3, and 5) using the SEM approach and covariates that were used in the current analyses. No significant relations between quality-squared and cognitive–academic achievement were detected at the younger ages in these reanalyses.

Finally, the association between higher child-care quality and lower externalizing problems had not been detected in previous analyses at 54 months or elementary school (Belsky et al., 2007; NICHD ECCRN, 2002, 2003, 2005c), but those analyses also used somewhat different covariates and analytic methods. Therefore, follow-up analyses looked at externalizing ratings by the teacher at 4½ years, and in Grades 1, 3, and 5 using the SEM approach and covariates described earlier. The SEM reanalysis detected one significant relation: Quality of nonrelative care was a quadratic predictor of teacher reports of child externalizing behavior at Grade 1 ($B = -0.07$, $p = .02$). No other significant linear or quadratic associations between child-care quality and children's externalizing were detected between 4½ years and Grade 6.

Prior Functioning as Mediators

Next we sought to identify the pathways that might account for the associations between early child care and adolescent outcomes reported above. These analyses tested our hypothesis that observed associations between child-care experiences and adolescent outcomes are mediated by earlier child care effects. As a result of the complexity of the models, separate SEMs examined the pathways model for cognitive–academic achievement and the pathways model for the behavior outcomes. For these analyses, the initial SEM described in Figure 2 was modified to include child functioning at 4½ years, Grades 1, 3, and 5. Paths from the child-care variables to both the 4½- and 15-year outcomes were included as well as paths between repeated measures of the child functioning from 4½ years to Grade 5, allowing us to estimate a direct path from child-care experiences to age 15 outcomes and a mediated path through the repeated assessments of prior functioning in that outcome domain.

The first pathway model tested the extent to which child-care quality was related to age 15 academic achievement through the earlier associations between child-care quality and academic achievement beginning at 4½ years. Figure 4 displays the standardized paths involving child-care experiences and cognitive–academic achievement estimated by this model. The model fit these data adequately, $\chi^2 = 2447.1(645)$; $\chi^2/df = 3.70$; CFI = .88; RMSEA = .045. The indirect path between child-care quality and academic achievement at age 15 through academic achievement prior to and during elementary school was statistically significant for child-care quality ($B = 1.23$, $SE = 0.57$, $p < .05$, $d = .04$). In contrast, the corresponding direct pathways were statistically nonsignificant. This suggests that the observed association between child-care quality and age 15 cognitive–academic achievement can be explained at least partially by the association between child-care quality and academic skills at entry to school, which was then maintained into high school. This mediated pathway accounts for 47% of the total association between quality and age 15 cognitive–academic achievement and 29% of the total association between quality-squared and age 15 cognitive–academic achievement.

A second pathway model tested the extent to which child-care hours was related to youth reports of behavior problems, risk taking, and impulsivity at age 15 though the maintenance of earlier teacher-reported externalizing behaviors. The model fit these data adequately well despite the absence of latent variables in the model (RMSEA = .09). Results are shown in Figure 5.

Significant direct paths remained in these analyses from child-care hours to age 15 assessments of risk taking ($B = 0.007$, $SE = 0.003$, $p < .05$, $d = .08$)

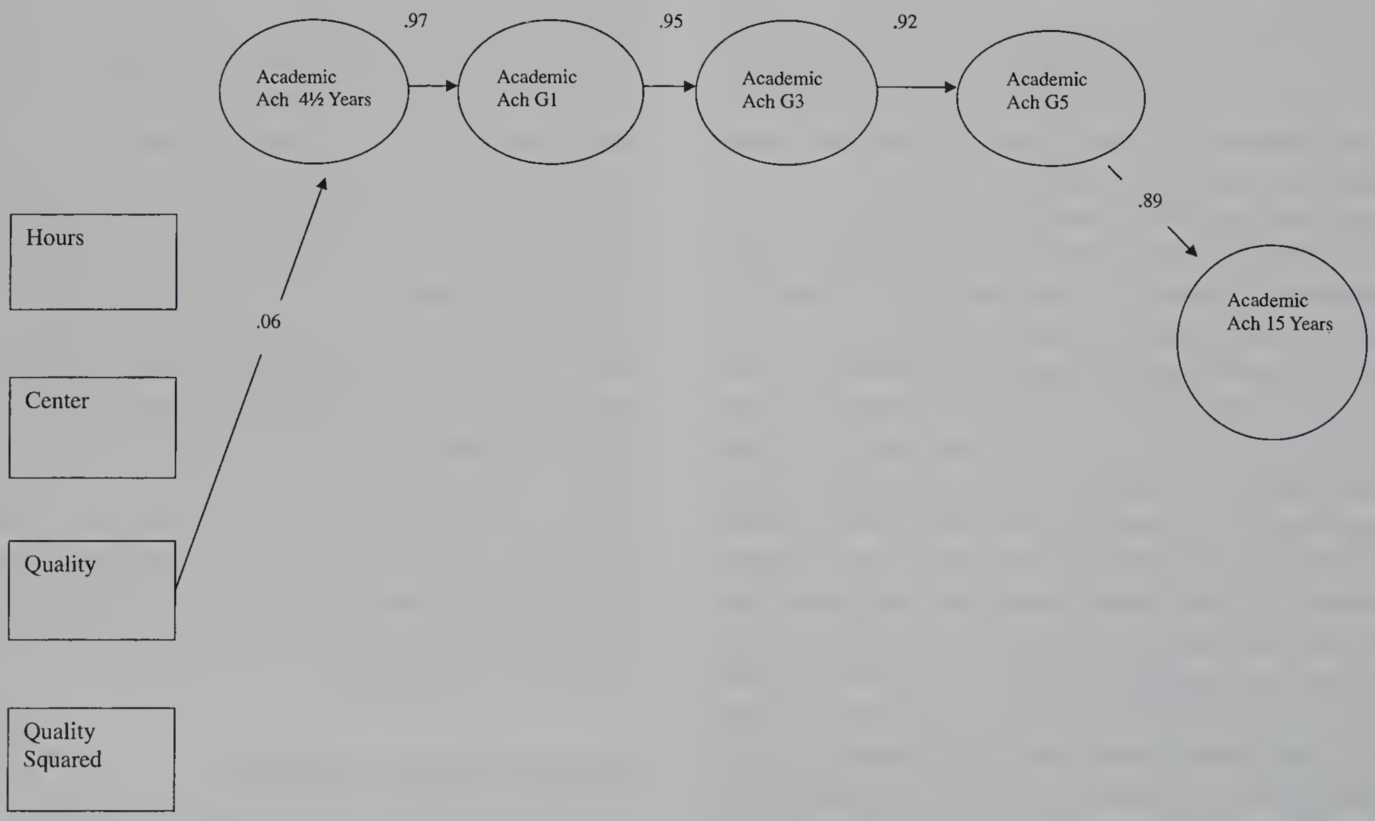

Figure 4. Pathway structural equation model testing of prior academic–cognitive achievement as a mediator of the link between child-care quality and age 15 academic–cognitive achievement.

Note. Only significant paths are depicted. Covariates were site, gender, ethnicity, maternal education, maternal psychological adjustment, maternal Peabody Picture Vocabulary Test–Revised, elementary school classroom quality and repeated assessments of family income, proportion time mother had a husband/partner, maternal depressive symptoms, and parenting. Ach = achievement; G1 = Grade 1; G3 = Grade 3; G5 = Grade 5.

and impulsivity ($B = 0.07$, $SE = 0.03$, $p < .001$, $d = .12$) and from child-care quality to externalizing ($B = -1.82$, $SE = 0.86$, $p < .05$, $d = -.08$), remained, suggesting that the hypothesized mediators—earlier caregiver- or teacher-reported externalizing problems—did not account for most of the observed effect of hours on these adolescent behavioral outcomes although the mediated paths from child-care hours through teacher ratings of externalizing behavior between preschool and Grade 5 were significant for both risk taking ($B = 0.001$, $SE = 0.001$, $p < .01$, $d = .003$) and impulsivity ($B = 0.002$, $SE = 0.001$, $p < .01$, $d = .003$). As a percentage of the total effect, these mediated effects were small: 4% of the total path to risk taking and 3% of total path to impulsivity.

Early Risk and Gender as Moderators

The final set of analyses addressed questions of moderation. One multiple group analysis tested familial risk and a second multiple group analysis tested gender as moderators of early child-care effects.

A cumulative familial risk index was created as the standardized mean of maternal education (reflected), mean income-to-needs ratio from 6 to 54 months (reflected), proportion time with single parent from 6 to 54 months, mean HOME total score from 6 to 54 months (reflected), and mean maternal sensitivity from 6 to 54 months (reflected). Families in the top quartile (high risk), middle 50%, and bottom quartile were compared with test hypotheses about compensatory effects and lost resources. Families in high-risk group had, on average, mothers with less than a high school education, an income-to-needs ratio of less than 1.3, CES–D depressive symptoms of 15.5, and a husband or partner less than 50% of the time. The low-risk group had, on average, mothers with a BA or more, income-to-needs ratio of 6.7, a husband or partner 99% of the time, and CED–D depressive symptom scores of 5.1.

A multigroup SEM allowed for different paths between child-care experiences and 15-year outcomes for the three risk groups. Due to the complexity of the multiple group SEMs for the three risk groups, separate models tested risk as a moderator for the behavioral outcomes and for the cognitive–achievement outcomes. The high correlation between hours of nonrelative care and time in center care prevented the multigroup

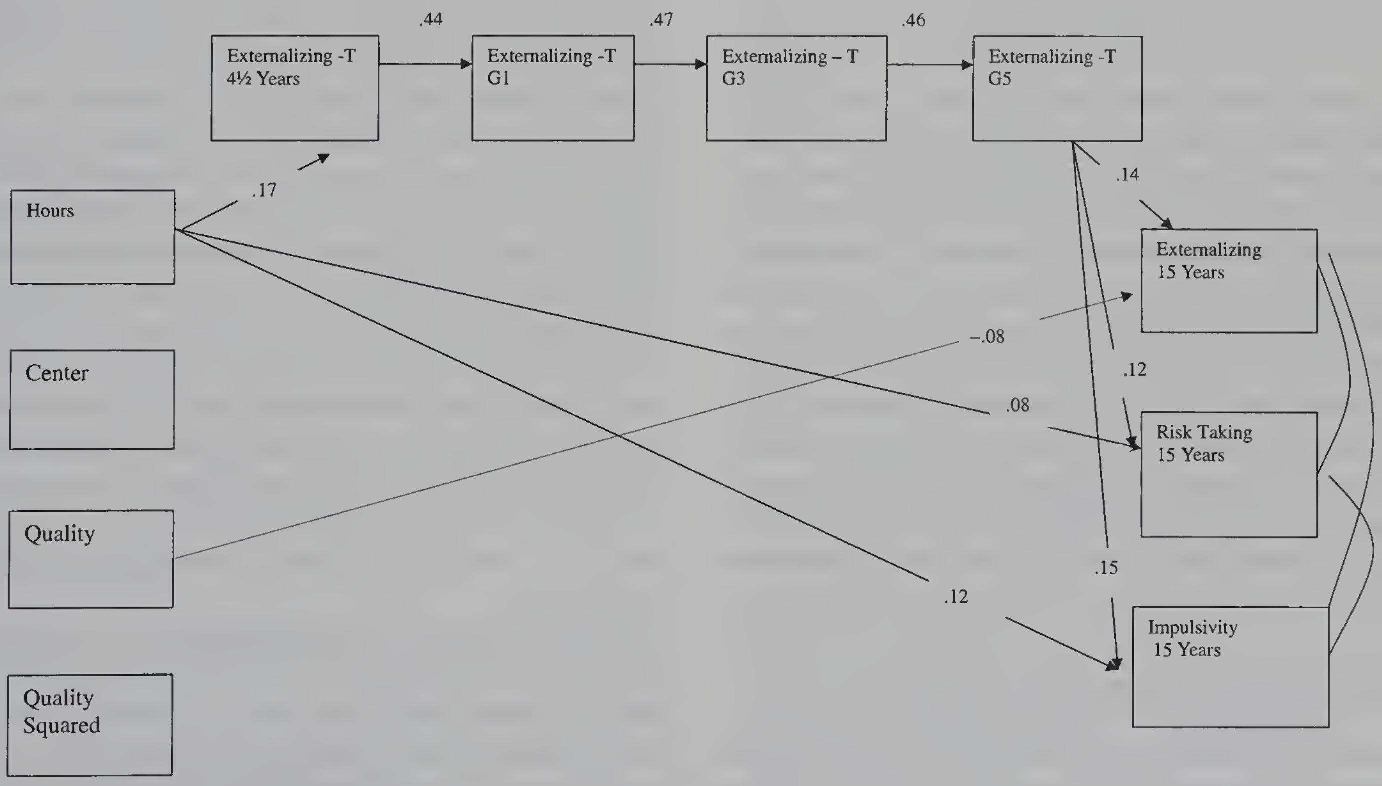

Figure 5. Pathway structural equation model testing teacher ratings of externalizing at earlier periods as a mediator of the link between child-care hours and quality and problem behaviors at age 15.

Note. Only significant paths are depicted. Covariates include site, gender, ethnicity, maternal education, maternal Peabody Picture Vocabulary Test–Revised, maternal psychological adjustment, elementary school classroom quality and repeated assessments of family income, proportion of time mother had a husband or partner, maternal depressive symptoms, and parenting quality. T = teacher report; G1 = Grade 1; G3 = Grade 3; G5 = Grade 5.

analyses from converging; hence, separate models were run to look at hours and center care as moderators.

The overall likelihood-ratio test between the model with and without separate paths from child-care experiences to behavioral outcomes was not reliably different among the three risk groups for the model that included hours and quality, $\chi^2(724) = 28.72$, $p = .99$, or for the model that included center care and quality, $\chi^2(838) = 58.26$, $p = .14$, suggesting no support for the compensatory hypothesis (i.e., stronger positive paths for high-risk children) or the lost resources hypothesis (i.e., stronger negative paths for low-risk children). Similarly, no evidence emerged in the analysis of the cognitive–academic achievement outcomes supporting either the compensatory or lost resources hypotheses.

A similar strategy was used to test whether gender moderated associations between the child-care variables and age 15 outcomes. Again, the likelihood-ratio test between the model with and without gender-specific paths from child-care experiences to child outcomes was nonsignificant, likelihood-ratio test $\chi^2(206) = 243.8$, $p = .13$, suggesting that gender did not moderate these associations.

Discussion

This latest installment in a 15-year longitudinal study of the effects of early child care on academic and behavioral development addressed three questions: (a) Are early child-care quality, quantity, and type related to adolescent functioning (cognitive–academic achievement and behavior problems) at age 15? (b) Are pathways from early child care to adolescent functioning mediated through prior functioning? and (c) Are relations between early child care and adolescent development moderated by either child gender or familial risk? Results pertaining to cognitive–academic achievement at age 15 are discussed first, followed by those pertaining to behavior problems.

Cognitive–Academic Achievement at Age 15

A relatively consistent finding across 40 years of child-care research is that quality and type of care are related to cognitive, academic, and language functioning in young children (Belsky & Steinberg, 1978; Lamb & Ahnert, 2006; Vandell, 2004). Previous findings from the NICHD SECCYD are consistent with this conclusion. At 4½ years, higher quality care predicted higher levels of preacademic skills ($d = .16$) and language ($d = .10$), whereas more exposure to center-type care predicted better language ($d = .11$) and memory ($d = .11$; NICHD ECCRN, 2002). In this report of adolescent functioning measured more than 10 years after the children had left child care, we find early child-care quality continues to predict cognitive–academic achievement. The size of the effect ($d = .09$) is similar in magnitude to that detected at 4½ years.

This evidence of long-term effects of early child-care quality is noteworthy because it occurred in a large economically and geographically diverse group of children who participated in routine non-relative child care in their communities. Previous long-term studies have focused on high-quality interventions aimed at children at risk because of poverty or low birth weight. The current findings suggest that the quality of early child-care experiences can have long-lasting (albeit small) effects on middle class and affluent children as well as those who are economically disadvantaged.

In addition to a linear relation between child-care quality and adolescent cognition, we detected a significant quadratic relation at age 15 (effect size = .07). This quadratic effect indicated that child-care quality was linked to academic outcomes for those adolescents whose care, on average was of moderate quality or better, with the magnitude of the quality effects being larger at higher levels of quality. Intriguingly, similar findings have been reported in an 11-state PreK evaluation that examined concurrent associations between child-care quality and academic outcomes (Burchinal et al., 2009). That study also reported escalating effect sizes linked to quality in the moderate to high quality range.

These two studies, taken together, underscore two points: that larger gains in cognitive–academic outcomes appear to accrue when children experience care of high quality, and that improvements in child-care quality in the moderate to high range may be needed to yield measurable long-term benefits.

This report is the first paper from the SECCYD data set to report this nonlinear quality effect, which raises the question of whether the effect was present at earlier ages but not detected because of different analytic strategies or whether this is a "new" finding (a sleeper effect). To address the first possibility, we examined relations between the quadratic term and earlier cognitive–academic functioning using the same models and operational variables as this study. We found no evidence of a quadratic relation at earlier ages. Therefore, the quadratic relation may be viewed as a sleeper effect. It remains to be seen whether this nonlinear effect carries forward to late adolescence and early adulthood or is found for other developmental domains.

Additional research is needed to better understand *why* the longer term effects in adolescence were evident only when early quality was in the moderate to high range. One possibility is that high school students bear much greater responsibility for their own academic progress whereas instruction for younger students is more closely monitored and supervised. Students who had attended higher quality programs (and who had excelled cognitively and academically) may be better positioned to oversee their own achievement in high school.

Mediated Pathways

An additional issue examined in this report was the mechanism or process that might mediate the long-term relation between early child care and age 15 functioning. It was anticipated that the cognitive–academic benefits of child-care quality observed at 4½ years would be carried forward to age 15 through functioning during middle childhood. As hypothesized, this mediated pathway was significant, accounting for 47% of the linear path and 29% of the quadratic path from child-care quality to adolescent cognitive functioning. These results are consistent with theory and empirical evidence that emphasize developmental continuities whereby competencies in one period set the stage for and are then carried forward to later periods (Bronfenbrenner & Morris, 2006; Burchinal, Peisner-Feinberg, Pianta, & Howes, 2002; Campbell et al., 2001). Because school achievement is largely cumulative, it is not a surprise to find that higher achievement in adolescence is linked to higher achievement in earlier periods.

Behavior Problems

Another consistent finding in the literature is that more hours in child care and more center-type care are related to higher levels of behavior problems in young children (Belsky, 2001; Lamb & Ahnert, 2006; Loeb et al., 2007). Previous findings from the SECCYD support this observation. At 4½ years of age, caregivers reported higher levels of externalizing behaviors for children who were in care for more hours ($d = .16$) and who had more center-type experience ($d = .11$; NICHD ECCRN, 2002). In this article, surprisingly similar relations were detected between child-care hours and problem behaviors at age 15. Higher hours predicted reports by the adolescents of more risk taking ($d = .09$) and greater impulsivity ($d = .13$). These effect sizes are similar in magnitude to the relation between hours and caregivers' reports of externalizing behavior problems originally detected at 4½ years.

We then sought to determine the extent to which associations between child-care hours and age 15 problem behaviors were mediated by behavior problems at 4½ years that were carried forward. Although we found statistically significant evidence of mediation, this mediated path accounted for only 3%–4% of the effect of child-care hours on adolescent problem behaviors. This modest level of mediation is likely because of two factors. The informant who reported the behavior problems changed from the caregivers in early childhood and teachers in middle childhood to the adolescent in this report. In addition, two of the three measures at 15 years assessed somewhat different aspects of behavior problems, ones that are particularly pertinent to adolescence: risk taking and impulsivity. Thus, although there is a large literature documenting continuity in behavior problems between childhood and adolescence (Farrington, 2004), we suspect that the very modest levels of mediation detected in this analysis are because of these changes in measurement.

Our age 15 analyses also revealed a relation between higher quality nonrelative child care and less externalizing behavior. This relation harkens back to findings detected when children were toddlers, when higher quality child care predicted fewer behavior problems at 2 and 3 years of age according to caregivers (NICHD ECCRN, 1998). We did not, however, find similar associations at 4½ years or middle childhood (Belsky et al., 2007; NICHD ECCRN, 2002, 2003, 2005c). Because the current analyses varied in a number of ways from those conducted at earlier ages, follow-up analyses examined externalizing at 4½ years of age and middle childhood using the same SEM models conducted for all analyses in this article. Some modest associations were found in these reanalyses, indicating that the link between higher quality of nonrelative care and fewer externalizing problems may not be as "new" as it might otherwise appear.

Small Enduring Effects

Although the obtained child-care effects on cognitive–academic outcomes and problem behaviors are small by conventional standards, we would argue that they should not be dismissed. First, they endured over a 10-year period at roughly the same size, suggesting a consistent pattern of relations. Second, as observed by McCartney and Rosenthal (2000), it is useful to benchmark effects against those reported in other studies that have been judged to be important or meaningful. A useful comparison to this study is the 18-year follow-up of the participants in the Infant Health and Development Program (IHDP; McCormick et al., 2006), an intensive early intervention program for low-birth-weight children that included home visits in the first 3 years and high-quality center care for 1–3 years. The IHDP reported significant effects for the heavier babies: effect sizes of .34 on math achievement and .27 for (reduced) risky behaviors at the 18-year follow-up, and no effects for the smallest of the low-birth-weight babies. The long-term effects associated with quality and quantity of child care in the SECCYD after 10 years are 29%–44%, respectively, as large as those found for the heavier infants in this *intensive* experimental intervention.

A third reason not to discount the findings is that child care, often full-time care beginning very early in life, has become a normative experience for American children, meaning that the number of children directly affected by child care is large. Small effects distributed over many people may have cumulative influences. Indeed, recent evidence suggests that children without child-care experience may be influenced by their classmates with early child care. Children in kindergarten classrooms in which there were higher proportions of children with child-care experience evinced better academic achievement but also more behavior problems than children in less child-care-saturated classrooms, even when the children themselves had not attended child care (Dmitrieva, Steinberg, & Belsky, 2007). Future research should more carefully examine such peer effects at older ages, especially as they may have implications for detecting child-care effects over the longer term (Belsky, 2009).

No Evidence of Moderation

Although two recent long-term follow-ups of early educational interventions have reported gender-moderated effects (Anderson, 2008; Belfield et al., 2006), we found no evidence of differential child-care effects as a function of child gender in either cognitive–academic performance or problem behaviors. This result is entirely consistent with findings discerned at earlier ages. Because our sample size is large and there is good variability in the measures of child-care experience and child functioning, it seems unlikely that the absence of significant gender-moderated child-care effects can be attributed to lack of statistical power. Perhaps secular changes in the 1990s, when maternal employment and nonmaternal child care became normative (i.e., characteristic of the majority of households in the United States), contributed to the similar developmental pathways among adolescent boys and girls observed in this study.

Evidence that high-quality care and/or center care are especially beneficial for economically disadvantaged children has emerged in a number of studies (Gormley et al., 2005; Loeb et al., 2007; Magnuson et al., 2007). We, however, did not detect any evidence that the effects of early child care (in quality, hours, type) on adolescent outcomes were moderated by familial risk, a pattern consistent with previous reports of the SECCYD (Belsky et al., 2007; NICHD ECRN, 2002, 2005c), although our high- and low-risk groups were decidedly different from one another. However, the exclusion of adolescent mothers and non-English speakers from the study may have limited our power to evaluate adequately this differential effect.

No Evidence of Long-Term Effects of Center Care

Robust center care effects have been chronicled in several large nationally representative surveys (Loeb et al., 2007; Magnuson et al., 2007), as well as evaluations of state prekindergarten initiatives (Gormley et al., 2005). Previous analyses of the SECCYD also have detected center care effects on both cognitive and social outcomes at every age through sixth grade. One of the most surprising findings of the current analyses was the failure to detect reliable associations between the proportion of time spent in center care and the age 15 outcomes explored in this report. One possible explanation is that children who experienced longer hours tended to have more center care ($r = .51$), thereby masking unique center care effects. However, this explanation was ruled out when follow-up analyses failed to discern center care effects even when hours were excluded from the model. Interestingly, another recent analysis based on the SECCYD did detect relations between center-type care and other age 15 outcomes—more center-type care experience was linked to blunted awakening cortisol levels (Roisman et al., 2009)—so it would seem misguided to conclude broadly that by mid-adolescence type of care no longer predicts children's development. As we continue to follow the sample, it will be important to determine if center care effects on cognitive and social functioning reemerge in late adolescence or early adulthood.

Finally, there are limitations to the study that should be noted. First, the study design is correlational, not experimental. So, analyses were tests of associations, not causation. Although extensive covariates were included in the analyses, omitted variables may account for the obtained effects. Second, although the sample was diverse economically and geographically, the study sample was not constructed to be nationally representative.

Conclusion

Perhaps the most important findings of this report from the SECCYD is that the effects of early child-care quality on cognitive–academic achievement and early child-care hours on problem behaviors were evident in mid-adolescence, more than a decade after the children had transitioned from child care to elementary school. Effect sizes were small but comparable in size with those detected at earlier ages. These findings extend research from other projects that documented the impact of high-quality child-care interventions for economically disadvantaged children into adolescence and adulthood. This study is the first to document relations between routine nonrelative child care and adolescent functioning for children from economically diverse families.

It remains to be determined whether, as individuals develop from adolescence into adulthood, the apparent consequences of child care are sustained, dissipate, or increase. To the extent that early child-care quality increases cognitive–academic skills, it will be important to learn whether subsequent educational attainment in high school and beyond is related to early child-care experience. To the extent that early child care increases adolescent impulsivity and risk taking, it is important to follow individuals into late adolescence, when opportunities for engaging in risky behavior increase and the capacity for self-regulation is still not fully mature.

The Development of Social Essentialism: The Case of Israeli Children's Inferences About Jews and Arabs

Dana Birnbaum, Inas Deeb, and Gili Segall
Bar-Ilan University

Adar Ben-Eliyahu
Duke University

Gil Diesendruck
Bar-Ilan University

Two studies examined the inductive potential of various social categories among 144 kindergarten, 2nd-, and 6th-grade Israeli children from 3 sectors: secular Jews, religious Jews, and Muslim Arabs. Study 1—wherein social categories were labeled—found that ethnic categories were the most inductively powerful, especially for religious Jewish children. Study 2—wherein no social category labels were provided—found no differences across sectors either in the inductive potential of ethnic categories or in children's capacity to visually recognize social categories. These results stress the importance of labels and cultural background in children's beliefs about social categories. The implications of these findings for accounts of the development of social essentialism are discussed.

For the past few years, a growing body of literature suggests that people across the world conceive of social categories in a way akin to how they conceive of living kinds. Specifically, people believe that, like categories of animals (Gelman, 2003), human categories (Gil-White, 2001) have unique properties that are innate and causal and that membership in these categories is absolute, permanent, and inductively powerful—a belief Medin and Ortony (1989) termed ''psychological essentialism.'' In pioneering work among North American children, Hirschfeld (1996) found that kindergarteners believe racial identity to be absolute, established at birth, and thus independent of upbringing environment (see also Taylor, 1996, on gender). Analogous findings have been reported on other cultures. For instance, Mahalingam (2003) showed that Indian Brahmin adults believe that a person's caste is inherited from birth parents, rather than acquired from adoptive parents, and Gil-White (2001) found a similar nativist construal of ethnic differences among Mongolian Torguuds (see also Astuti, Solomon, & Carey, 2004).

This cross-cultural and developmental consistency in children and adults' tendency to essentialize human kinds on the one hand, and the cultural specificity of the particular categories essentialized on the other, has led researchers to ponder about the *origins* of such beliefs (see, e.g., Atran, 1990; Hirschfeld, 1996; Sperber, 1996). Manifest in these accounts is the need to understand how social essentialism emerges and to what extent it is susceptible to cultural and linguistic variations. The present studies attempt to do exactly that. In particular, we investigate how *one* component of essentialism is manifested in children from various *subcultural* groups, toward the *same* social categories. As briefly reviewed above, the cross-cultural developmental literature on social essentialism consists of studies assessing different components of essentialism (e.g., induction vs. innateness), conducted on different cultural groups (e.g., the Vezo

of Madagascar vs. North Americans), and targeting different social categories (e.g., ethnicity vs. race). One of the main goals of the present studies was to attempt to minimize variance in these three dimensions, so as to more decisively assess the potential effect of cultural input on children's beliefs.

The component we chose to focus on is the inductive power of social categories, that is, the extent to which knowledge of the category to which an object belongs allows one to infer properties of the object. Gelman and colleagues have documented how from a young age children are sensitive to the unique inductive power of animal categories (see Gelman, 2003, for a review). In the domain of human categories, Heyman and Gelman (2000) found that children draw inferences based on characters' personality traits rather than their physical appearance, and Diesendruck and haLevi (2006) found that for Jewish Israeli adults and kindergarteners, ethnicity is the most inductively powerful social category. The present studies follow up on these latter findings.

For historical and political reasons, the category "Arab" for Jewish Israelis and the category "Jew" for Arab Israelis are extremely salient and important. Studies reveal that even 3-year-old Israeli Jewish children are somewhat familiar with the category "Arab" and that negative stereotypes regarding Arabs grow stronger from kindergarten to high school (Bar-Tal, 1996; Pitner, Astor, Benbenishty, Haj-Yahia, & Zeira, 2003; Slone, Tarrasch, & Hallis, 2000; Teichman, 2001). Bar-Tal and Teichman (2005) argue that a potential source for the development of negative stereotypes is the portrayal of Arabs and Jews in the media in general, and school books in particular (see also Al-Haj, 2002; Soen, 2002).

Taking into account the cultural and ideological heterogeneity of Israeli society, particularly with respect to issues pertaining to ethnicity, in the present studies we tested children from three different subcultural "sectors" within the Israeli society: secular Jews, modern religious (Zionist) Jews, and Muslim Arabs. Our selection of the three subgroups was motivated both by the diversity of ideological commitments vis-à-vis ethnicity typified by these groups, and by attention to the representativeness of these groups within the Israeli society. Specifically, secular Jews represent the majority group in Israel, modern religious Jews manifest different values for religious and often political reasons, and Muslim Arabs constitute the minority about whom the focal majority stereotypes are held (see the Participants section for further details). Evidence for cross-group differences would reinforce the notion that social essentialism is influenced by the type of input children are exposed to.

In order to trace the development of these potential cultural differences, we tested children from three age groups: kindergarteners, second graders, and sixth graders. Studies in North America found that these developmental points capture the transition from intuitive to more adult-like beliefs about human kinds (Hirschfeld, 1996; Taylor, 1996). Thus, in contrast to previous cross-cultural studies on social essentialism (Astuti et al., 2004; Gil-White, 2001; Mahalingam, 2003), the present design allowed us to assess how children's concepts change as they immerse into the institutionalized views exposed in schools.

Study 1 employed a methodology similar to the one used by Diesendruck and haLevi (2006). The experimenter presented children with pictures of two test characters, told children the category membership of these characters vis-à-vis two social categories (e.g., their ethnicity and gender), and informed children about a novel psychological property each test character had (e.g., their game preferences). The experimenter then presented to children a target character that resembled one of the test characters on one of the categories but resembled the other test character on the other category. Children were asked which of the two properties attributed to the test characters the target character possessed. The rationale was that children's pattern of responses across a number of trials would be indicative of the inductive power of the different social categories tested. To the extent that children's essentialist beliefs about certain social categories—especially ethnicity—is indeed susceptible to cultural input, we should find differences in the inductive power of these social categories across children from the different sectors. The age factor would allow us to assess how early these potential cultural differences appear.

A second major goal of the present studies was to continue investigating systematically the factors contributing to the inductive power of social categories, and their potential interaction with children's cultural group. A number of studies found that language (Bigler & Liben, 2007; Gelman, Taylor, & Nguyen, 2004; Heyman & Diesendruck, 2002), and perhaps especially labels (Cimpian, Arce, Markman, & Dweck, 2007; Gelman & Heyman, 1999; Patterson & Bigler, 2006), might be implicated in the development of social essentialism. The present studies investigate the role of language in children's essentialist reasoning by comparing children's pattern of induction when provided with category labels versus when only provided with physical appearance information about category membership. This comparison allowed us to verify to what extent appearance information about social category membership is sufficient to bring about potential differences among social categories. This examination is relevant to the broader question regarding whether children's essentialization of human kinds is a ''bottom-up'' process by which children simply represent categories they perceive in the world, or a ''top-down'' process by which the categories are first in the child's mind and then looked for in the world. The comparison is also relevant for understanding potential differences between cultural groups. Specifically, if a particular cultural group essentializes a certain social category, then will this bias be manifested only when labeling is present? In order to address these two related questions, Study 2 replicated part of Study 1, but whereas in Study 1 all the social categories were verbally labeled, in Study 2 none were.

Study 1

The goal of Study 1 was to assess the inductive power of various social categories across children from different cultural and age groups. For this purpose, we designed the induction task so as to both maximize the salience of social categories and allow a comprehensive assessment of their inductive potential. To these ends, the induction task included two parts. In the first—so-called relative power part—the two dimensions children had to decide between were both social categories. For instance, children had to decide whether to draw inferences based on the ethnic similarity between two characters, or their gender similarity. The maximization of the salience of social categories was operationalized by having all social categories represented by stereotypical visual markers associated with each social category, as well as their familiar category labels. The second—so-called absolute power part–was a direct replication of Diesendruck and haLevi (2006), and in it the two dimensions children had to decide between were personality traits (e.g., niceness) and social categories (e.g., ethnicity). This design feature augmented the comprehensiveness of our assessment, by widening the range of inferential contexts presented to children, including conflicts between different types of human categories. Moreover, Diesendruck and haLevi found that while kindergarteners had a preference for drawing inferences based on social categories, adults had a preference for drawing inferences based on personality traits. Thus, the inclusion of the absolute power part in the current study also allowed us to track in more detail the developmental changes in children's reliance on social categories versus personality traits as bases for inferences.

Method

Participants

A total of 144 children participated in this study. The sample consisted of 16 children from each of three sectors (secular Jews, religious Jews, and Muslim Arabs), and each of three age groups (kindergarten, second grade, and sixth grade). Only children with signed parental permission participated in the study. Table 1 presents age and gender information about the participants. The secular and religious Jewish children were recruited from secular and religious schools and kindergartens in the same cities surrounding the university. These cities have mixed populations of secular and religious Jews, though few Orthodox Jews, and practically no Arabs. The Arab children were recruited from an Arab and primarily Muslim city (Baka al Garbiah) within Israel. No Jews live in this city.

In general, the Israeli Jewish population is composed of three main religiosity subgroups: secular Jews (71%), religious Jews (21%), and Orthodox religious Jews (8%; Central Bureau of Statistics, 2006). We targeted secular and religious Jews for a variety of reasons. First, they represent the majority of the Jewish population. Second, both groups are socially, economically, and politically involved in Israeli life to similar extents, and to a greater extent than the Orthodox Jewish population. Third, despite these similarities, these two groups are denominationally distinguished, have substantially different belief systems and norms of behavior in everyday life, and are differentially distributed across the political spectrum (Sikron, 2004). Denominationally, Hebrew has two separate words, which are frequently used either as adjectives or count nouns, to refer to secular (*chiloni*) and religious (*dati*) Jews. Secular and religious groups diverge substantially in beliefs regarding God, the Jewish commandments, and afterlife, and in their practices, such as keeping the Sabbath and its commandments, eating Kosher food, celebrating the Jewish religious holidays, praying, and attending synagogues (Levy, Levinson, & Katz, 2002). Reflecting this divide, while most children from these two

Table 1

sectors attend the national public school system, they each attend the administratively and pedagogically separate branch that caters to each sector. In other words, the vast majority of students who attend secular schools come from secular families, and the vast majority of students who attend religious schools come from religious or traditional families. All major cities in Israel have public schools from each kind, and they are identifiable by their official names. One example of a major distinction between the two systems has to do with the extent of and approach toward teaching the Old Testament. In the secular system, the Old Testament is taught as a text recounting the *myths* and traditions of ancient Jews. In the religious system, the Old Testament is taught as a *veridical* account of the history of the world and the Jewish people, and the traditions are presented as normative rules to be followed presently as well. Lastly, these two sectors are characterized by distinct political orientations, especially toward the Israeli–Arab conflict. Namely, while the secular population endorses a variety of political opinions vis-à-vis the conflict, modern religious Zionist Jews tend toward opposing or stalling the creation of a Palestinian state in the West Bank and Gaza.

The Arab population in Israel is primarily Muslim (about 90%; Central Bureau of Statistics, 2006). In contrast to Hebrew, Palestinian Arabic does not have separate count nouns for ''religious'' and ''secular'' Muslims—all are referred to simply as ''Muslims.'' While there is variation in the degree of observance of religious practices, the majority (approximately 70%) of the Muslim population identifies itself as ''religious'' and rigorously observes the basic Islamic commandments, such as the belief in Allah and the prophet Mohamed, providing for the needy, praying five times a day, and fasting during the month of Ramadan. Moreover, less observant Arab Muslims nonetheless respect and attempt to incorporate some of these traditions into their daily lives (Stendel, 1996). Smooha (1989) observes that while since the establishment of the State of Israel in 1948, Arab Muslims have been undergoing a process of ''westernization,'' they still maintain their traditions and values, especially in cities and villages populated exclusively by Arab Muslims. The children recruited for the present study reside in such a city. Baka al Garbiah is located in an area of Israel referred to as the ''Triangle,'' is one of the largest Arab cities in Israel (over 30,000 inhabitants), and is almost exclusively Muslim. Over 90% of the children in this city attend public schools, which in contrast to the Jewish sector, all belong to the same pedagogical branch. These schools are administered by the Israeli

Ministry of Education, and they incorporate Islamic studies in their curricula. For instance, the schools celebrate all Muslim holidays, and there are at least 2 hr a week of classes on Islamic religion and history. Even though there are different Arab groups in Israel (e.g., Christians), for the sake of brevity, we refer to our Muslim Arab sample as "Arabs." In fact, while young Jewish Israeli children may be familiar with the term "Arab," it is unclear to what extent they differentiate between Muslims, Christians, Bedouins, or Druze.

Design

Study 1 consisted of two parts. In the first—"relative power"—part, children had to complete a series of 12 trials in which they had to draw inferences based on one of two possible social categories. This was named the relative power part because it assessed the inductive power of each social category relative to the other social categories. In the second—"absolute power"—part, children had to complete a series of 8 trials in which they had to draw inferences based either on a social category or a personality trait. This was named the absolute power part because in it, children did not have to choose between competing social categories but rather between each social category and a personality trait. The relative power part was always presented first, so as to allow an unbiased comparison between children's responses to this part across the two studies (to be described later).

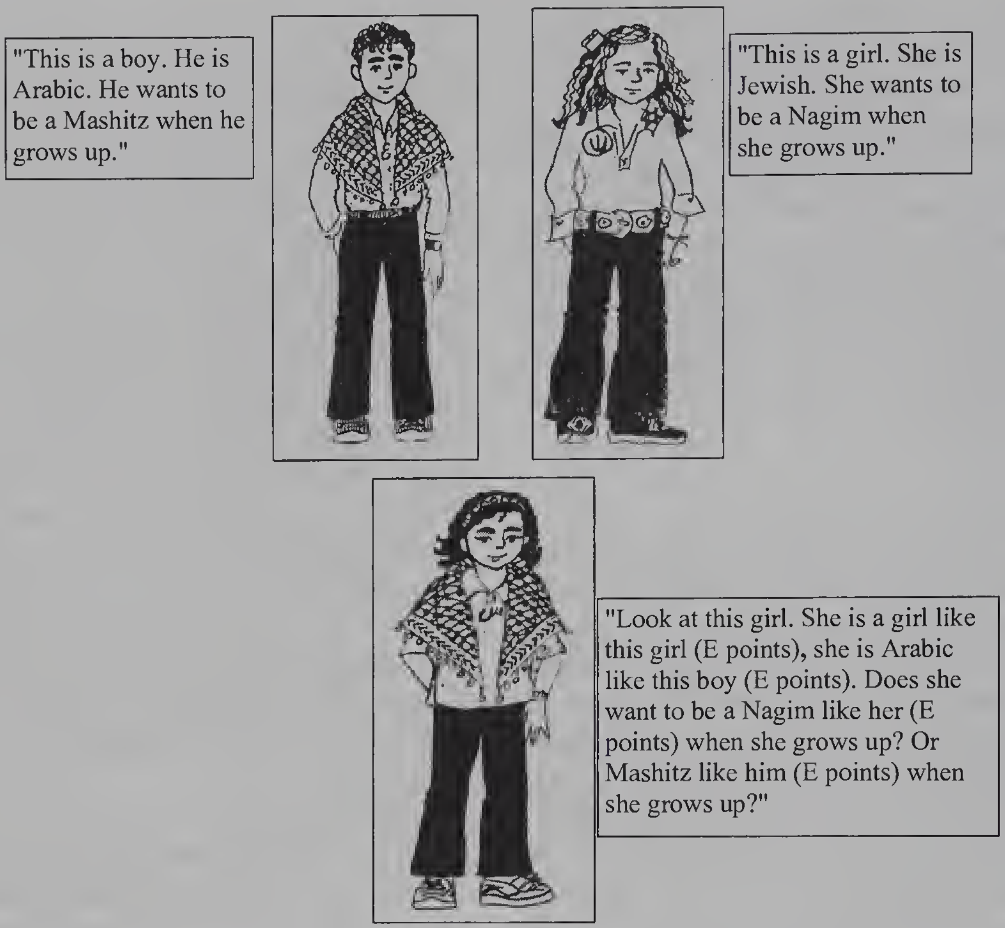
The social categories used in both parts were: ethnicity (Jew/Arab), gender (boy/girl), social status (rich/poor), and religiosity (religious/secular). The four personality traits used in the absolute power part were "niceness" (nice/not nice), "shyness" (shy/friendly), "creativeness" (creative/not creative), and "activeness" (active/quiet). These categories and traits are salient in the Israeli society, and have been found to be familiar to Israeli kindergarten children (Diesendruck & haLevi, 2006).

Materials

In each trial, children were shown a triad of line-drawn black and white human characters: a target character and two test characters. Each character was professionally drawn with physical markers that are typical of specific social categories. In the relative power part, all three characters within a triad belonged to the same two social categories, but each was assigned a specific value of these categories (e.g., Arab or Jew for the category ethnicity). All possible combinations of social categories were presented to children, resulting in six types of triads: ethnicity/gender, ethnicity/social status, ethnicity/religiosity, gender/social status, gender/religiosity, and social status/religiosity. In each triad, each of the test characters resembled the target character on one of the social categories but was different from the target character on the other social category. For example, in a triad contrasting the social categories ethnicity and gender (as in Figure 1), one of the test characters was drawn as an Arabic boy, the other test character as a Jewish girl, and the target character as an Arabic girl. In this example, the test character "Arabic boy" resembled the target character ("Arabic girl") with regard to ethnicity (i.e., it was an "ethnicity match") but differed from her with regard to gender. In turn, the test character "Jewish girl" resembled the target character with regard to gender, but differed from her with regard to ethnicity (i.e., it was a "gender-match").

The visual cues consisted primarily of dressing attire and accessories typical of the social category. All Jewish characters had on their shirt or as a necklace the Star of David sign and a letter in Hebrew. Secular Arab characters wore on their shoulders Kaffiyah (a Palestinian scarf) and had a letter in Arabic on their shirt. Although there are no consistent visual cues that differentiate secular Arabs from secular Jews within Israeli society, the visual cues described above are typical markers of each ethnicity. In turn, there are distinct markers for both religious/practicing Jews and Muslims, and these were represented in the pictures. Specifically, male religious Jewish characters wore a yarmulke, fringes that come out of the shirt (*tzitziot*), and sidelocks (*peyot*). Female religious Jewish characters wore long dresses and had a head cover. Male religious Muslims wore a long robe and a skullcap. Female religious Muslims wore a head cover (*hijab*) and a long dress (*jilbab*). Rich characters wore fancy clothes and jewelry, and held expensive accessories. Poor characters wore ragged clothes and torn shoes or sandals. When the character was "religious" without a specific ethnicity, for example, a "religious boy" or "religious rich," it was depicted as a religious Jew for participants in the Jewish sector and as a religious Muslim for participants in the Arab sector. Figure 2 provides examples of the pictures used here.

In order to emphasize the relevant social categories in each triad in either part of the study, the physical characteristics of the characters not indicative of their social category membership were made



"This is a boy. He is Arabic. He wants to be a Mashitz when he grows up."
"This is a girl. She is Jewish. She wants to be a Nagim when she grows up."
"Look at this girl. She is a girl like this girl (E points), she is Arabic like this boy (E points). Does she want to be a Nagim like her (E points) when she grows up? Or Mashitz like him (E points) when she grows up?"

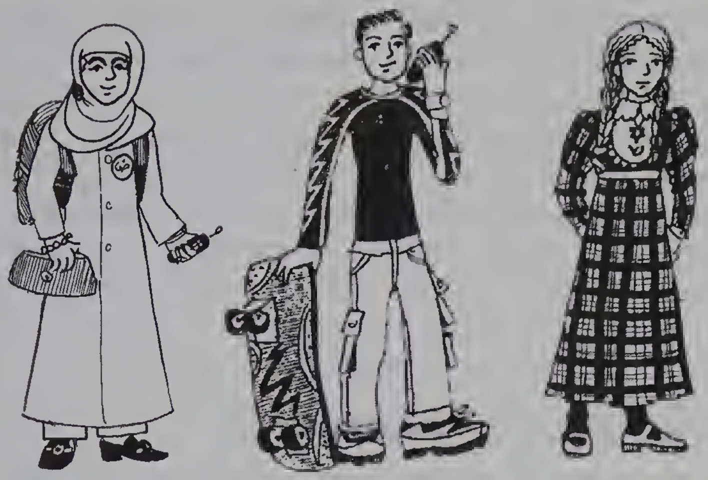
Note. The character on the bottom is the target character. The character on the top left is the ethnicity match. The character on the top right is the gender match.

irrelevant, either by equating them (e.g., height) or by randomizing them across all characters (e.g., hair color). Moreover, in all triads in which gender was not a target social category, the gender of all characters was the same.

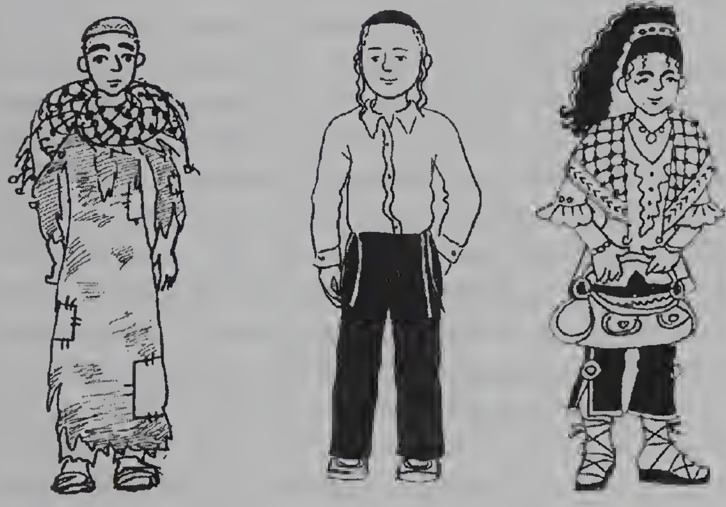
Each triad (e.g., ethnicity/gender) was presented to each participant on two separate trials. Each time, the target character was of a different value (e.g., for one child, on one of the two trials with this triad, the target character was an Arabic/girl, and on the other trial, the target character was a Jewish/boy). All possible target characters composed of the crossing of all social categories were presented an equal number of times across children (e.g., another child would get the target characters Arabic/boy and Jewish/girl, for the ethnicity/gender triad). The pairings of characters were randomly assigned to participants, and they appeared the same number of times across children.

The absolute power part of the study resembled the relative power part, except that each character was described by a social category and a personality trait rather than by two social categories. One of the test characters was presented to children as being of the same social category as the target but as having a different personality trait (*social category match*), while the other test character was described as having the same personality trait as the target character but as belonging to a different social category (*personality trait match*). Given that personality traits cannot be depicted visually in a conventional and exclusive manner, they were presented only via verbal labels. The visual cues indicating the social categories were the same as in the relative power part. All possible pairings of social category and personality trait were used for each child. In other words, for each child, each social category (e.g., social status) was paired with two different personality traits, such that each social category value (e.g., rich and poor) was paired with a different personality trait. The pairings were randomly assigned to participants, and they appeared the same number of times across children.

For both parts, all the properties attributed to the characters were novel, so that children could not base their answers on stigmas tying particular properties to categories. The properties had to do with preferences, patterns of behaviors, aspirations,



Rich Religious (for Arab sector) **Rich Boy** **Religious Jew**



Poor Religious (for Arab sector) **Religious Boy** (for Jewish sector) **Rich Arab**

Figure 2. Sample of pictures used in the studies.

and physiological properties, and were framed within sentences that allowed children to understand their general meaning. There were 20 different novel properties (12 for the relative power part of the study and 8 for the absolute power part), so that on each trial children were asked to draw inferences about a different property. The novel words were Hebrew-sounding words for the Jewish children (see the list below) and Arabic-sounding words for the Arab children. The full list of properties was: eats Dabo/Fifo for lunch, plays Zigo/Zabo at the school yard, pretends that s/he is a Talan/Falkan, listens a lot to Rendit/Mishnit music, in her/his school s/he is best in Salmon/Takton, wants to be a Mashitz/Nagim when s/he grows up, believes that in the moon there is Tugit/Pushrit, thinks it is important to be Manil/Gakish, thinks that Vitot/Bidot are the nicest animals on earth, believes that Dushon/Pitzug is the most beautiful place on earth, enjoys to read books about Tushib/Masrib, loves to watch TV programs about Dulon/Sulon, feels happy when s/he is in Nunga/Smuda, is afraid of Namtagim/Natgarim, gets angry when someone says s/he is Taluf/Mitlon, has blood type Papuch/Tirel, has Lidon/Kiron in her/his stomach, feels bad when s/her eats Hamgal/Lamdash, the smell of Miker/Lakanf makes her/him sneeze, has too little Vitamin G/R in her/his body.

Procedure

A female experimenter tested participants individually in a quiet area of their kindergarten or school. All Jewish children were tested in Hebrew by Jewish research assistants, and all Arab children were tested in Arabic by Muslim Arab research assistants from the same area that children were from. The relative and absolute power parts were conducted one after the other, with a brief intermission between them when testing kindergarteners. The procedure lasted between 15 and 20 min.

Relative power part. The procedure started with the experimenter placing one of the test pictures of the first trial in front and to the right of the child, telling the child the character's two social categories, and then informing the child about a novel property this test character had. In the same manner, the experimenter placed the second test character to the left of the child, assigning to this character his or her corresponding social categories and a different value for the novel property. The experimenter then placed the target character in between the two test characters, and slightly closer to the child. The experimenter told the child the target character's two social categories, explicitly noting the similarities to each of the test characters. Finally, the experimenter asked the child to infer whether the target character had the same property as the first test character or as the second test character. Figure 1 depicts a schematic example of the procedure. Once children responded by pointing to one of the test characters, the experimenter removed all the pictures, and brought out the next set of pictures. The experimenter avoided giving any feedback to the child that could be interpreted in terms of accuracy in their performance.

There were 12 trials in this part: 2 trials with each triad type. The order of presentation of the triads for each participant was random and was counterbalanced across participants within a sample (i.e., there were 16 different presentation orders). The right–left placement of the test characters, and consequently the order of presentation of the test characters, was also counterbalanced within and between subjects. For instance, for the ethnicity/gender triad, on one trial the gender match was presented first and was placed to the right of the child, and on the other trial, the gender match was presented second and placed to the left of the child. Finally, the order in which the social category labels were applied to each character was also counterbalanced within and between subjects. For instance, on one trial of the ethnicity/gender triad, the experimenter first noted the ethnic membership of the character and then the gender, and on the other trial she did the opposite (e.g., ''He is a boy, he is Jewish'' vs. ''He is Jewish, he is a boy''). It is important to note that in the sentences we used in Hebrew and Arabic, all the social category labels were morphologically and syntactically ambiguous as to whether they were adjectives or nouns—a fact that is representative of Hebrew and Arabic in general. Here, we translated the labels into the form that seemed most appropriate for the English construction.

Participants' responses in the first part were scored according to the number of trials in which children drew inferences based on a particular social category. Given that each triad of social categories appeared twice for each participant, scores for each triad could vary from 0 to 2 (e.g., on ethnicity/gender triads, children could select the ethnicity match on 0, 1, or both of the trials). These Triad Relative Inference Scores were used in the analyses of children's preferences for specific social categories. In order to evaluate potential differences across sectors and age groups, we summed all such scores for any given social category, creating Total Relative Inference Scores. Given that each social category appeared on three triads, with each triad appearing twice, the Total Relative Inference Score for each category could range from 0 (*no inferences based on this category*) to 6 (*inferences based on this category in all trials involving this category*).

Absolute power part. The procedure in the absolute power part was similar to the procedure in the relative power part, except that here each character was described by a social category and a personality trait (e.g., ''nice Arab,'' ''shy Jew''), and there were only eight trials. The same counterbalancing precautions described above with regard to the relative power part were also obeyed in this part. Children's responses in this part were scored according to the number of trials in which children drew inferences based on a social category or a personality trait. We refer to these scores as the Absolute Inference Scores. Given that each social category appeared on two trials in this part, the Absolute Inference Score for each category could range from 0 (*no inferences based on this category*) to 2 (*inferences based on this category in both trials involving this category*).

Results

Comparisons Across Social Categories

In order to compare the inductive power of social categories, we compared the frequency of children's selections of the different social categories to chance, conducting separate analyses for each of the two parts of the study.

On the relative power part, to avoid violating an assumption of independence of measurements, and given that the Triad Relative Inference Scores ranged from 0 to 2, we conducted nonparametric tests assessing the distribution of children on each triad type. For instance, we counted the number of children, out of the total 144, who on the two ethnicity/gender triads picked the ethnicity match on both, only one, or none of the trials. The expected (chance) distribution was 25% (36 children), 50% (72 children), and 25% (36 children), respectively. These analyses revealed that the only triad types in which the distribution significantly deviated from chance were ones involving ethnicity. In particular, on the ethnicity/gender triads, significantly more children than were expected by chance selected ethnicity on both trials (distribution for both, one, and none, was 57, 62, and 25, respectively), $\chi^2(2, N = 144) = 17.00$, $p < .001$. A similar pattern was found on ethnicity/religiosity triads (distribution for both, one, and none, was 48, 75, and 21, respectively), $\chi^2(2, N = 144) = 10.38$, $p < .01$. On ethnicity/social status triads the pattern was in a similar direction, but not significantly different from chance (distribution for both, one, and none, was 46, 68, and 30, respectively), $\chi^2(2, N = 144) = 4.00$, $p = .13$. On all other triad types the distributions did not differ from chance, $ps > .2$.

Similar tests were conducted on the absolute power part, in which each social category appeared twice, each time paired against a different personality trait. The analyses showed that only ethnicity was selected more often than expected by chance (distribution for both, one, and none, was 37, 84, and 23, respectively), $\chi^2(2, N = 144) = 6.72$, $p < .05$.

Altogether, these findings reveal that across all sectors and ages, ethnicity trumped alternative social categories and personality traits as the strongest basis for induction.

Comparisons Across Sectors and Age Groups

The second main goal of Study 1 was to compare the inductive power of various social categories across Israeli children from different ages and sectors. In order to maximize the representativeness of this assessment, we calculated a Total Inference Score for each category by adding each category's Total Relative Inference Score (0–6) and Absolute Inference Score (0–2). These scores could thus range from 0 (*no inferences based on the category*) to 8 (*all inferences based on the category*).

We entered the Total Inference Scores for each social category into a multivariate analysis of variance (MANOVA), with age (kindergarten, second grade, and sixth grade) and sector (Arabs, secular Jews, and religious Jews) as between-subjects factors (see Figure 3 for means). The overall MANOVA revealed a significant effect of sector, $F(8, 266) = 2.19$, $p < .05$, $\eta^2 = .06$, but neither the effect of age nor the interaction between sector and age were significant, *p*s > .09. Looking at each social category separately, we found that sector had a significant effect on ethnicity, $F(2, 135) = 4.21$, $p < .05$, $\eta^2 = .06$. Tukey's honestly significant difference (HSD) post hoc tests revealed that religious Jews made ethnicity-based inferences more than Arabs, $p < .05$. Sector also had a significant effect on social status, $F(2, 135) = 3.39$, $p < .05$, $\eta^2 = .05$, with Arab children drawing the most inferences based on social status and secular Jewish children the least (Tukey's HSD, $p < .05$). We also found that age had a significant effect on gender, $F(2, 135) = 3.97$, $p < .05$, $\eta^2 = .05$, with kindergarteners drawing the most inferences based on gender, and sixth graders the least (Tukey's HSD, $p < .05$).

In order to further evaluate children's inferential tendencies, we compared the Total Inference Score of each social category, for each age group and sector, against chance (chance = 4). As can be seen in Figure 3, these analyses revealed distinct sectorial and developmental patterns of responses. Among Arab children, the only significant finding was that sixth graders drew fewer inferences based on gender than would be expected by chance. Among secular Jews, none of the Total Inference Scores, at any age, were significantly different from chance. Finally, among religious Jews, the pattern was quite different, as children at all ages made ethnicity-based inferences—and only ethnicity-based inferences—significantly more than would be expected by chance.

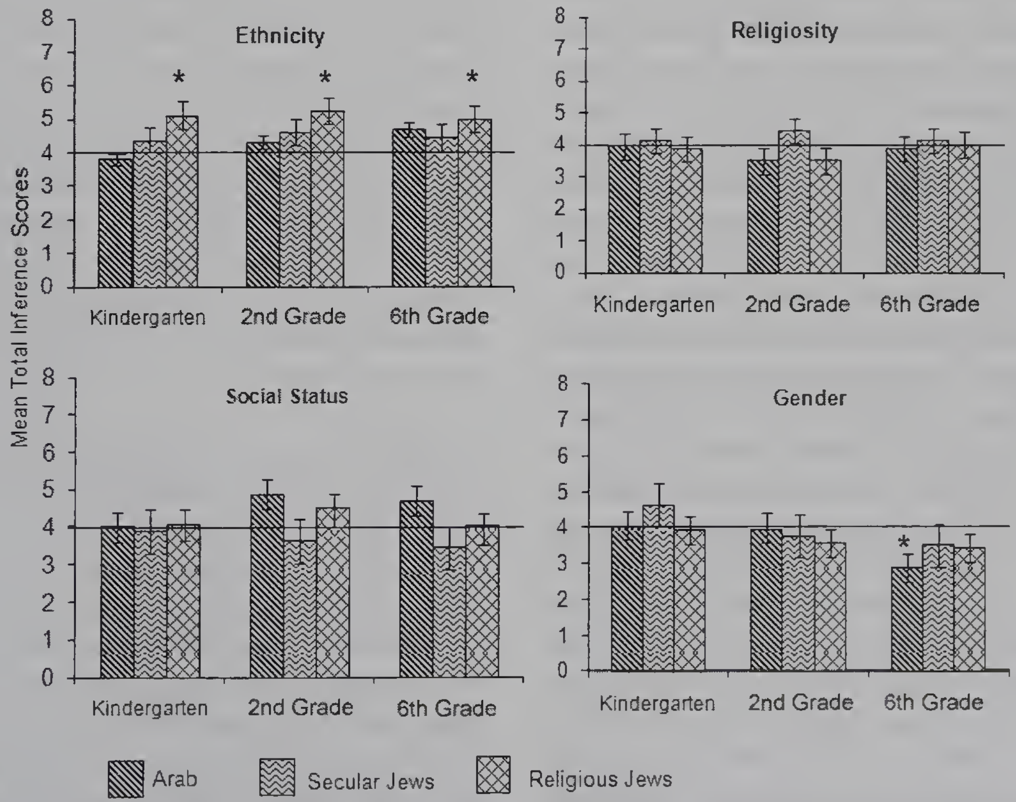


Figure 3. Mean Total Inference Scores for each social category, age group, and sector, in Study 1.
Note. The horizontal bold line indicates chance value (4). Asterisks denote difference from chance, on *t* tests (15), $p < .05$.

Analyses of Group Membership

Given the structure of the stimulus set, the study also allowed us to explore an additional set of issues having to do with group membership. In particular, we analyzed whether there were differences in the pattern of participants' inferences, based on whether the target of the inferences belonged to the same group as the participant. For this purpose, we conducted two sets of analyses, one looking at the ethnic membership of the participants (Jew or Arab), and another looking at the gender membership (boy or girl).

For the analyses on ethnicity, we created two new variables: (a) the number of trials in which children drew inferences based on ethnicity when the target character was a Jew and (b) the number of trials in which children drew inferences based on ethnicity when the target character was an Arab. Given the counterbalancing precautions noted before, for each participant, half of all eight trials involving ethnicity across the two parts of the study had a Jewish character as target, and half had an Arab character as target. Thus, these scores ranged from 0 to 4. For the analyses, we divided the participants into two sectors according to their ethnicity: Arabs and Jews (including both secular and religious). (Separate analyses on religious and secular participants generated the same results as the ones reported below.)

The above scores were entered into a repeated measures analysis of variance (ANOVA) in which target type (Jew, Arab) constituted a within-subjects factor, and ethnic sector (Jews, Arabs) a between-subjects factor. This analysis revealed only a significant interaction between target type and ethnic sector, $F(2, 138) = 5.27$, $p < .05$, $\eta^2 = .04$. To uncover the source of this interaction, we conducted separate paired t tests within each ethnic sector, comparing between the inference scores for each target type. These analyses revealed that while among Jewish participants, there was no difference between their tendency to draw inferences based on ethnicity when the target character was a Jew ($M = 2.49$, $SD = 1.19$) versus when the target character was an Arab ($M = 2.32$, $SD = 1.14$), $p > .3$, Arab participants were less likely to draw inferences based on ethnicity when the target character was a Jew ($M = 1.89$, $SD = 0.95$) than when the target character was an Arab ($M = 2.35$, $SD = 0.93$), $t(47) = 2.44$, $p < .05$. As can be seen by the means, the exceptional pattern of inferences stemmed from the Arab participants' responses to Jewish target characters.

Analogous analyses were conducted with regard to gender. For these analyses, we created two new scores: (a) the number of trials in which children drew inferences based on gender when the target character was a boy (out of 4) and (b) the number of trials in which children drew inferences based on gender when the target character was a girl (out of 4).

These scores were entered into a repeated measures ANOVA in which target type (Boy, Girl) constituted a within-subjects factor, and participants' gender (boys, girls) a between-subjects factor. This analysis revealed a significant effect of target type, $F(1, 138) = 8.88$, $p < .005$, $\eta^2 = .06$, such that children were overall more likely to draw inferences based on gender when the target character was a girl ($M = 2.11$, $SD = 1.19$), than when the target character was a boy ($M = 1.67$, $SD = 1.15$). This main effect was subsumed by a close to significant interaction between target type and participants' gender, $F(1, 138) = 3.14$, $p = .079$, $\eta^2 = .02$. Given the exploratory nature of this analysis, and the analogy with the results on ethnicity, we followed up this analysis by again conducting separate paired t tests within each participants' gender group, comparing between the inference scores for each target type. These analyses revealed that while among male participants, there was no difference between their tendency to draw inferences based on gender when the target character was a boy ($M = 1.89$, $SD = 1.15$) versus when the target character was a girl ($M = 2.00$, $SD = 1.25$), $p > .6$, female participants were less likely to draw inferences based on gender when the target character was a boy ($M = 1.53$, $SD = 1.9135$) than when the target character was a girl ($M = 2.18$, $SD = 1.16$), $t(47) = 3.93$, $p < .001$. As can be seen by the means, the exceptional pattern of inferences stemmed from the female participants' responses to male target characters.

Comparison of Social Categories Against Personality Traits

A minor goal of Study 1 was to assess the development of children's overall social category-based induction. Earlier studies conducted among secular Jews in Israel had found that while kindergarteners were more likely to draw inferences based on social category membership than based on personality traits, adults showed the reverse pattern (Diesendruck & haLevi, 2006). The absolute power part of Study 1 allowed us to assess this developmental trend in more detail. For this purpose, we computed a Social Categories Inference Score by simply adding the Absolute Inference Scores across the four social categories. This score could range from 0 (*all inferences based on personality traits*) to 8 (*all inferences based on social categories*). We then conducted an ANOVA on these Social Categories Inference Scores, with age and sector as between-subjects factors. The only close to significant effect was of age, $F(2, 135) = 2.81$, $p = .06$, $\eta^2 = .04$. Given our interest in the development of this tendency, we compared the Social Categories Inference Score for each age group separately to chance (chance = 4). These analyses revealed that both kindergarteners ($M = 4.67$, $SD = 1.50$), $t(47) = 3.07$, $p < .005$, and second graders ($M = 4.67$, $SD = 1.62$), $t(47) = 2.86$, $p < .01$, drew inferences based on social categories significantly more than would be expected by chance. In turn, sixth graders did so at a level no different than chance ($M = 4.02$, $SD = 1.56$), $p = .9$. In other words, it seems that by sixth grade, children are midway toward the adult pattern of reliance on personality traits.

Discussion

The results of Study 1 reveal that, overall, ethnicity was the most powerful source of induction. Importantly, it appears that ethnicity was especially salient for religious Jewish children, and it became a powerful source of induction earlier for them than for children from the other two sectors. In other words, while there are some indications that by sixth grade, children from other sectors (e.g., Arabs) start construing ethnicity as the most powerful source of induction among a variety of human categories, religious Jewish children manifest this bias already by kindergarten.

The above conclusions raise questions about why is it that ethnicity is such a powerful source of induction for children in Israel, and why is it especially important for religious Jewish children. Some of the plausible responses to these questions are beyond the scope of the present studies, and will be raised in the General Discussion. Nonetheless, a direct question has to do with whether ethnicity's inductive power derived from the salience of its visual markers. That is, was the presence of the unique attire and visual symbols associated with the Jewish and Arab characters in our materials, a more visually compelling cue to children than the other social category markers, making that dimension of similarity stand out above all others? Were these cues especially salient for religious Jewish children? Or did the inductive power of ethnic categories derive from their linguistic markers (i.e., labels), and thus exerted their effect independently of children's capacity to visually recognize the categories? Study 2 addressed these alternatives.

Study 2

In order to assess the relative contributions of visual versus linguistic markers to the effects found in Study 1, Study 2 adopted the same procedure as in the relative power part of Study 1, except that the experimenter did not provide children any social category labels. Thus, in Study 2, the only information available to children about the social category membership of the characters displayed was their physical markers. The rationale was that if the inductive power of ethnicity—or any other social category—derives from bottom-up perceptual processes, then sheer exposure to stereotypical visual markers of ethnic categories should lead children to draw inferences based on them. Moreover, we should find that religious Jewish children will show the same higher sensitivity to ethnicity as found in Study 1. Alternatively, if the inductive power of ethnicity—as revealed in Study 1—is attributable primarily to the presence of cultural markers such as labels, then children in Study 2—including religious Jewish children—should not draw inferences based on ethnicity when only physical information about category membership is available. A comparison between children's responses in the two studies would allow us to estimate directly the impact of labeling on children's inferences.

In a sense, this comparison complements one reported in Diesendruck and haLevi (2006). In that study, children were tested in one of two conditions: a category labels + visual markers condition—similar to the present Study 1—and a category labels, no visual markers condition. That study thus assessed the relative contribution of *visual markers* to the inductive potential of various social categories. In fact, Diesendruck and haLevi found that visual markers did not contribute significantly to the inductive power of social categories. The present Study 2 assessed the complementary effect by adding the missing cell, that is, a visual markers-only condition. It thus allowed us to evaluate how much *labels* contribute to the inductive potential of social categories.

In Study 2, we did not replicate the absolute power part of Study 1, because that part contrasted social categories with personality traits. While one can visually hint at the personality trait of a person by, for instance, illustrating his or her behavior, we believe these visual cues differ from those associated with most of the social categories examined here insofar as they are not conventional and stereotypical physical markers that exclusively identify the category membership of an individual.

In addition, in order to estimate potential differences in the salience or recognizability of the social categories, we conducted a ''category recognition'' task at the end of the triad induction task. Children's accuracy would allow us to evaluate to what extent differences in the inductive power of social categories and across sectors could be attributed to the ease of category recognition.

Method

Participants

A total of 144 children participated in this study (see Table 1 for details). The samples and recruitment methods were identical to those in Study 1. None of the children had participated in Study 1.

Design

Study 2 consisted of two parts: an induction part and a category recognition part. The induction part was nearly identical to the relative power part of Study 1, except that the experimenter did not provide category labels for any of the characters. The same 12 trials presented in Study 1 were presented in this part of Study 2. In the category recognition part, children were shown a series of six triads that had appeared in the induction part and, on separate trials, were asked to describe and identify the characters corresponding to the different social category labels mentioned by the experimenter.

Materials

The materials were the same as those of the relative power part of Study 1.

Procedure

The procedure was identical to the one in Study 1. The category recognition part followed the induction part after a short intermission between them.

Induction part. The procedure in the induction part was identical to the procedure in the relative power part of Study 1, except that the experimenter did not mention the social categories of each character. Children's responses were scored in the same way as in Study 1: namely, according to the number of trials (0–2) within each triad type in which they selected a particular social category (Triad Relative Inference Scores) and according to the total number of trials (0–6) across triad types in which children drew inferences based on a particular social category (Total Relative Inference Scores).

Category recognition part. Category recognition was assessed in both an unprompted and a prompted manner. For the two unprompted trials, the experimenter showed children the six pictures from the first two trials of characters that children had seen in the induction part. Children were simply asked to describe each character in their own words, and the experimenter wrote down these descriptions. After these two unprompted trials, the experimenter moved on to the prompted trials, which tested children's capacity to recognize the characters as exemplars of the target categories. For this purpose, the experimenter laid down the three pictures of the third trial each child had seen in the induction part and asked the child to identify the referent characters of the different social categories depicted in those pictures. For example, regarding the triad displayed in Figure 1, the experimenter asked: ''Is there an Arab among these characters? Who is an Arab?'' The experimenter wrote which characters the child recognized as Arabs and then asked about the next categories depicted (e.g., ''Is there a Jew among these pictures? Is there a girl? A boy?''). The same procedure was repeated for the next three triads in the child's set, thus resulting in the presentation of a total of 12 pictures.

Children's responses in the unprompted trials were scored according to the number of times in which children explicitly mentioned the target category value when describing the character (e.g., said ''Jew'' of a Jewish character). We refer to these as the Unprompted Category-Recognition Scores. Children's responses in the prompted trials were scored according to the number of characters identified correctly for each social category. Given that in this part, each social category appeared on six pictures, children's Prompted Category-Recognition Scores for each social category varied from 0 (*no category exemplar correctly identified*) to 6 (*all category exemplars correctly identified*).

Results

Induction Part

As in Study 1, we first compared the inductive power of the various social categories and then analyzed the effects of sector and age group on children's choices.

Comparisons across social categories. As in Study 1, in order to evaluate the inductive power of each social category, we analyzed the distribution of children according to their Triad Relative Inference Scores on each triad type, comparing it against the expected chance distribution (36, 72, and 36, respectively, for selecting a particular dimension on both, one, or none of the trials of a given type). These analyses revealed a pattern of results different from the one found in Study 1. In particular, on ethnicity/gender triads, again significantly more children than were expected by chance selected ethnicity on both trials (distribution for both, one, and none, was 53, 58, and 33, respectively), $\chi^2(2, N = 144) = 11.00$, $p < .005$. However, on ethnicity/social status triads, the pattern was the reverse. Namely, significantly more children selected ethnicity on *neither one* of the two trials (i.e., selected social status on both) than what was expected by chance (distribution for both, one, and none, was 22, 70, and 52, respectively), $\chi^2(2, N = 144) = 12.61$, $p < .005$. Social status was also frequently selected on both trials in social status/gender triads (distribution for both social status, one, and none, was 65, 46, and 33, respectively), $\chi^2(2, N = 144) = 33.00$, $p < .001$. On all other triad types the distributions did not differ from chance, *ps* > .2. In sum, when no labels were offered, children did not consistently privilege ethnicity over all other social categories and, in fact, seemed to privilege another social category—social status—instead.

Comparisons across sectors and age groups. In order to evaluate the effects of sector and age group on children's choices, we entered the Total Relative Inference Score for each social category into a MANOVA, with age (kindergarten, second grade, and sixth grade) and sector (Arabs, secular Jews, and religious Jews) as between-subjects factors (see Figure 4 for means). The overall MANOVA revealed only a significant effect of age, $F(8, 266) = 4.33$, $p < .001$, $\eta^2 = .12$. Neither the effect of sector nor the interaction between sector and age was significant, *ps* > .4. Looking at each social category separately, we found that age had a significant effect on ethnicity, $F(2, 135) = 4.56$, $p < .05$, $\eta^2 = .06$, with children making more ethnicity-based inferences as they grew older (difference between sixth and second graders, $p < .05$, Tukey's HSD). Age also had a significant effect on social status, $F(2, 135) = 3.33$, $p < .05$, $\eta^2 = .05$, again with children making more social-status-based inferences as they matured (difference between sixth graders and kindergarteners, $p < .05$, Tukey's HSD). Finally, age also had an effect on gender, $F(2, 135) = 12.36$, $p < .001$, $\eta^2 = .16$, with sixth graders being less likely to make gender-based inferences than both second graders and kindergarteners (Tukey's HSD, *ps* < .001). Neither sector nor the interaction between sector and age had significant effects on any of the individual social categories' Total Relative Inference Scores.

In order to further evaluate children's inferential tendencies, we compared the Total Relative Inference Score of each social category, for each age group and sector, against chance (chance = 3). As can be seen in Figure 4, these analyses revealed sectorial and developmental patterns of responses that were quite different from the ones found in Study 1 (compare asterisks in Figures 3 and 4). Among Arab children, in kindergarten, none of the scores were significantly different from chance; in second grade, religiosity was selected significantly less often than expected by chance, and in sixth grade, ethnicity was selected significantly more than expected by chance, and gender significantly less than expected by chance. Among secular Jews, the only score that differed significantly from chance was for gender in sixth grade, with children drawing gender-based inferences less often than expected by chance. Finally, among religious Jewish children, only by sixth grade, children were more likely to draw inferences based on social status than would be expected by chance and were less likely to draw inferences based on gender than would be expected by chance.

Comparisons Between Studies 1 and 2

In order to assess the effect of labels on children's responses, we conducted a MANOVA on the Total Relative Inference Scores of each social category in Study 2 (no labels) and Study 1 (with labels). Recall that the relative power part was identical in the two studies, with the only difference being the presence of category labels in Study 1. In this analysis, we entered study, age, and sector as between-subjects variables. Here we report only on the effects involving Study.

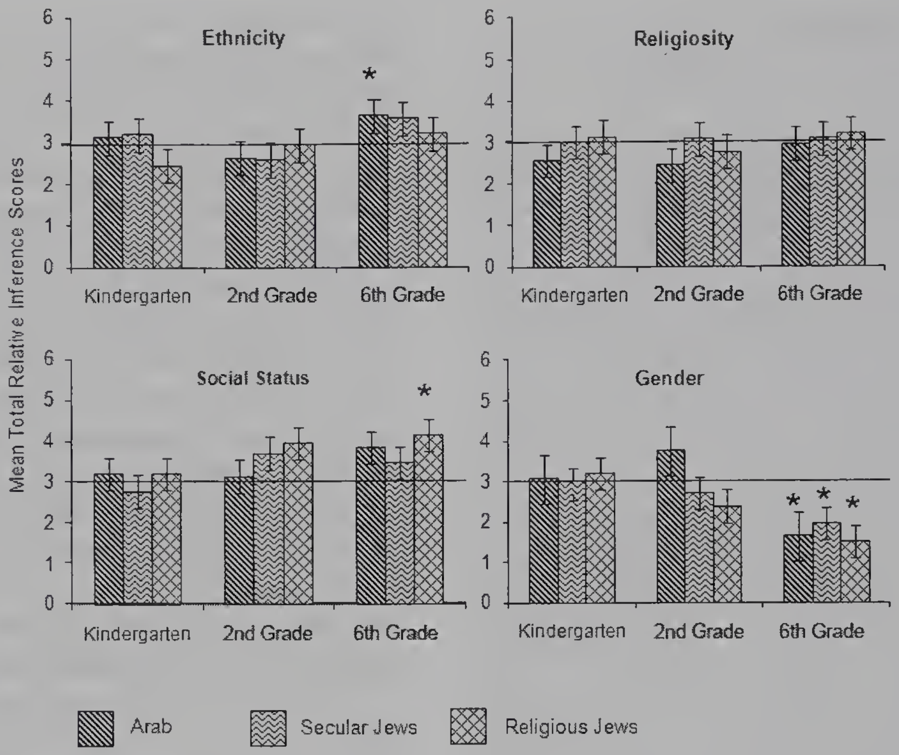

Figure 4. Mean Total Relative Inference Scores for each social category, age group, and sector, in Study 2.
Note. The horizontal bold line indicates chance value (4). Asterisks denote difference from chance, on *t* tests (15), $p < .05$.

The overall MANOVA revealed a main effect of study, $F(4, 267) = 3.85$, $p < .01$, $\eta^2 = .06$ (see Figure 5). The separate ANOVAs showed that this effect was significant for ethnicity, $F(1, 270) = 10.03$, $p < .005$, $\eta^2 = .04$, with children *more* likely to draw ethnicity-based inferences in Study 1 ($M = 3.52$, $SD = 1.39$) than in Study 2 ($M = 3.03$, $SD = 1.28$). The effect of study was also significant with regard to social status, $F(1, 270) = 8.11$, $p < .01$, $\eta^2 = .03$, with children *less* likely to draw social-status-based inferences in Study 1 ($M = 2.99$, $SD = 1.43$) than in Study 2 ($M = 3.47$, $SD = 1.49$). Finally, the interaction between age and study was significant with regard to gender, $F(2, 270) = 3.40$, $p < .05$, $\eta^2 = .03$, and the interaction between sector and study was significant with respect to ethnicity, $F(2, 270) = 3.18$, $p < .05$, $\eta^2 = .02$.

In order to identify the source of the theoretically central Sector × Study interaction on ethnicity, we conducted separate ANOVAs on each of the three sectors. In these analyses, the Total Relative Inference Scores for ethnicity was used as the dependent measure, and study as a between-subjects factor. These ANOVAs revealed that while study did not have a significant effect on either Arab or secular Jewish children's tendency to draw inferences based on ethnicity (*ps* > .3), study did have a significant effect on religious Jewish children's tendency to do so, $F(1, 94) = 14.19$, $p < .001$, $\eta^2 = .13$. In particular, these children were more likely to rely on ethnicity when it was labeled (Study 1, $M = 3.90$, $SD = 1.48$) than when it was not (Study 2, $M = 2.85$, $SD = 1.22$).

Category Recognition Part

The main goals of the category recognition part of Study 2 were to estimate potential differences in the visual salience of the different social categories, and to evaluate whether there are differences in this respect between ages and sectors.

Preliminary analyses of the unprompted trials revealed no significant differences between the values within each category (e.g., no differences between children's spontaneous recognition of Jews vs. Arabs). We thus analyzed the data using as the dependent measures children's Unprompted Category-Recognition Scores for each of the three social categories. Given that gender is pervasively marked in both Hebrew and Arabic, it would have been pragmatically odd for children to mention a character's gender category. For this reason, we excluded the category gender from the analyses.

We entered these scores into a MANOVA with age and sector as between-subjects variables. This analysis revealed only a significant effect of age, $F(6, 244) = 11.89$, $p < .001$, $\eta^2 = .23$. Neither the effect of sector nor the interaction between age and sector was significant (*ps* > .2). The individual ANOVAs on each category revealed that age had a

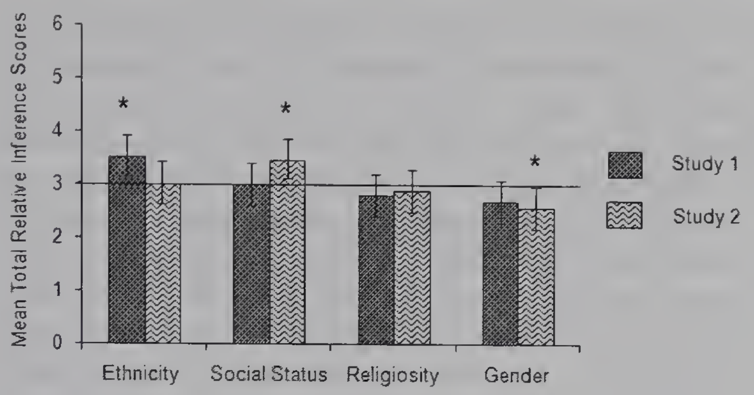

Figure 5. Comparison of mean Total Relative Inference Scores between studies, for each social category.
Note. The horizontal bold line indicates chance value (3). Asterisks denote difference from chance.

significant effect on all categories ($ps < .001$), with sixth graders more likely to mention the category labels than children from the other two age groups (Tukey's HSD, $ps < .001$). Additionally, we conducted paired t tests comparing the frequency with which children mentioned the category labels across the different categories. These tests revealed that the proportion of trials in which children mentioned the social status label of the characters ($M = 0.27$, $SD = 0.38$) was significantly higher than the proportion of trials in which children mentioned either a religiosity label ($M = 0.16$, $SD = 0.26$), $t(134) = 3.76$, $p < .001$, or an ethnicity label ($M = 0.18$, $SD = 0.34$), $t(132) = 2.90$, $p < .005$.

For the analyses of the prompted trials, we compared the Prompted Category-Recognition Score for each social category (range = 0–6), and in each age group and sector, against chance (chance = 3 pictures recognized correctly). The Gender Recognition Scores were close to ceiling (above 5) in all ages and sectors, and were therefore omitted from the analyses. As depicted in Figure 6, these analyses showed that in kindergarten, Arab children identified ethnicity at a rate significantly lower than expected by chance, and religiosity and social status at chance. Secular Jewish children identified religiosity at a rate lower than expected by chance, and ethnicity and social status at chance. Finally, religious Jewish children identified all categories at chance. By second grade, and even more so at sixth grade, all children identified all categories at a rate better than expected by chance.

Last, to directly address potential associations between children's capacity to recognize members of a social category, and children's tendency to draw inferences based on a social category, we assessed the correlations between children's Prompted Category-Recognition Score on any given social category, and their Total Relative Inference Score on these same categories. None of these correlations was significant ($ps > .16$).

Discussion

One of the main goals of Study 2 was to assess whether the presence of visual markers of social category membership was sufficient to generate the

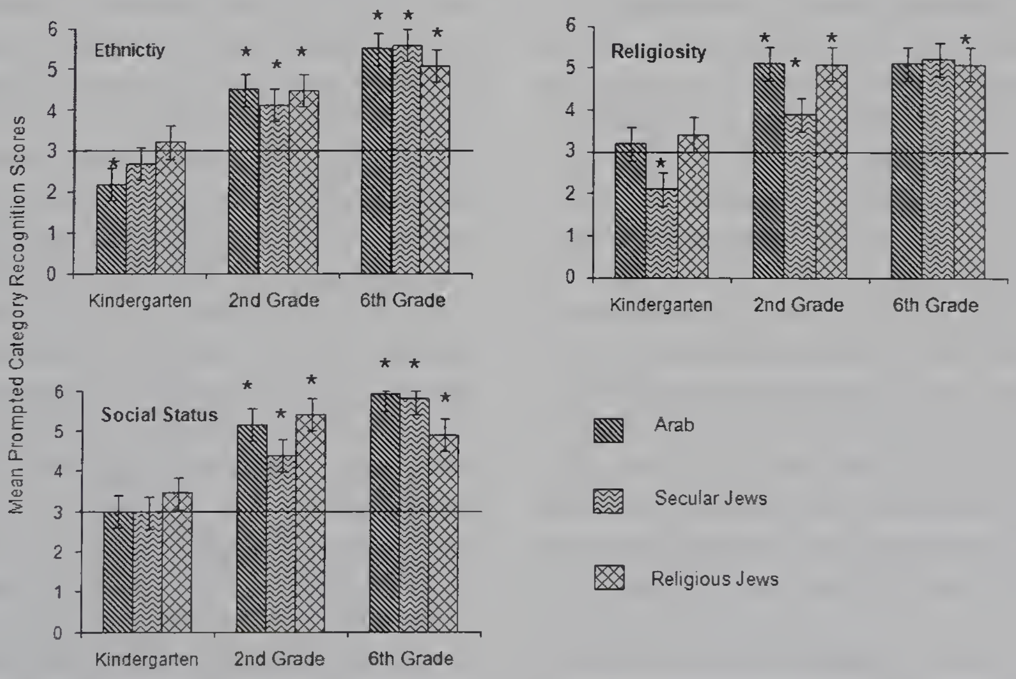

Figure 6. Mean Prompted Category Recognition scores for each social category, age group, and sector, in Study 2.
Note. The horizontal bold line indicates chance value (4). Asterisks denote difference from chance, on t tests (15).
$p < .05$.

pattern of induction observed in Study 1. The simple answer is "no." The most consistent findings from Study 2 were that with development, children's tendency to draw inferences based on social status and ethnicity increased, and their tendency to draw inferences based on gender decreased. Crucially for the present purposes, however, Study 2 revealed neither a consistent effect of sector on children's inferences nor a distinctive sensitivity to ethnic categories. In particular, there was no evidence that religious Jewish children were more likely to draw ethnicity-based inferences than children from the other sectors.

The comparison between the two studies revealed a number of important patterns. First, they confirmed that with development, children's reliance on gender as a source for induction declines, but their reliance on ethnicity rises. These results on gender are consistent with Taylor's (1996) finding of a decrease, from kindergarten to fifth grade, in children's beliefs about the innateness of gender-typical behavior. Second, the analyses showed that labeling has a distinctive effect on children's ethnicity-based inferences. In particular, labeling significantly increased the frequency of ethnicity-based inferences but had no effect on either religiosity- or gender-based inferences. There was an effect of labeling on social-status-based inferences but in a negative direction; that is, labeling decreased social status-based inferences. Given that the task required children to choose between social categories, it is possible that the decrease in social-status-based inferences in Study 1 was partly on account of the increase in ethnicity-based inferences. It is nonetheless revealing that the increase was only in terms of ethnicity. Third and finally, the analyses by sector showed that labeling had a significant effect only among religious Jewish children. In other words, labeling in itself does not seem to create an inferential bias in a vacuum. Rather, it is only within a population already disposed toward such a bias that labeling carries an effect. We will return to these issues in the General Discussion.

The findings from the category recognition part of Study 2 further confirmed the overall conclusions noted above. In particular, first, we found that there were no differences across children from the different sectors in their capacity to recognize social category members in the pictures we used as stimuli. In other words, any differences that exist between children from the different sectors in terms of the inductive power of a given social category—especially ethnicity—do not seem to reflect differences across sectors in the ability to recognize the visual cues associated with a category, or in the visual salience of a category to a particular sector. This was further confirmed at an individual child level, by the lack of significant correlations between children's recognition and induction scores. Second, we did find a consistent increase with age in children's capacity to recognize social category members, but again, this developmental effect held across all three sectors. Thus, even though in Study 1, religious Jewish children—and only them—favored ethnicity as a source of induction already by kindergarten and second grade, it does not seem that this pattern derived from the stronger perceptual salience of ethnicity to children in this sector at those ages. In fact, by second grade, children from all sectors recognized ethnic categories in the prompted trials at above chance rates, and yet this increased recognition capacity was not accompanied by an increase in the rate of ethnicity-based inferences.

General Discussion

A number of studies conducted with both children and adults have found that in different societies, different social categories seem to be essentialized (e.g., Astuti et al., 2004; Hirschfeld, 1996; Mahalingam, 2003). One of the main goals of the present studies was to assess potential differences among sectors within a given society in their tendency to essentialize the same social categories and to examine this matter from a developmental perspective. The three sectors of the Israeli society evaluated here—secular Jews, Zionist modern religious Jews, and Muslim Arabs—were selected for the presumed diversity in their perspectives regarding ethnicity. The hypotheses were that to the extent that essentialist beliefs about a given social category are influenced by the cultural input to which children are exposed, we should find differences in a measure of essentialism among children from these three sectors. Moreover, to the extent that essentialism is a bias available to children from early on, then we should find evidence for these hypothesized differences among sectors from the earliest age assessed.

The findings from Study 1 were consistent with the above sectorial and developmental hypotheses. In that study, we found that across all ages and sectors, children were most likely to draw inferences based on ethnicity. That is, overall, when characters were described as Jews or Arabs, children were more likely to focus on that categorical similarity when drawing novel inferences about these characters than on any dimension of similarity between the characters, be the dimension another social category (e.g., gender) or a personality trait (e.g., niceness). This privileged status of ethnicity seems to reflect the salience of this category in public discourse in Israel (Bar-Tal & Teichman, 2005) and is generally consistent with previous findings among Jewish secular kindergarten children (Diesendruck & haLevi, 2006). In fact, this focus on ethnicity has been found in other societies as well (see, e.g., Astuti et al., 2004; Gil-White, 2001; Kanovsky, 2007).

A further important finding from Study 1 is that there were nonetheless differences in the emphasis on ethnicity among sectors. In particular, compared to secular Jews and Muslim Arabs, we found that religious Jewish children were the most likely to draw inferences based on ethnicity. In fact, among kindergarteners and second graders, only the religious Jewish children drew inferences based on ethnicity significantly more than would be expected by chance. This differs from the findings of Diesendruck and haLevi (2006) who found distinctive attention to ethnicity also among secular Jewish kindergarteners. One possible explanation for this apparent disparity in the responses of secular children regarding ethnicity is that while in Diesendruck & haLevi, ethnicity was contrasted exclusively against personality traits, in the present study ethnicity was first contrasted against other social categories. This exposure to other social categories may have weakened the "appeal" of ethnicity to secular Jewish kindergarten children in the present study. In other words, it is possible that for secular Jewish children, ethnicity is a powerful enough category that it trumps personality traits, but it is not powerful enough to trump other social categories. Ethnicity does have this latter kind of power for religious Jewish children, intimating that this group may be the most essentialist about ethnicity among the three sectors who participated in these studies.

The above conclusion raises the question of what might give rise to these differences among the sociocultural sectors in Israeli society, or more generally, what causes differential essentialist beliefs toward a particular social category to emerge? There are a number of possibilities raised in the literature. One possibility derived from the social psychological literature (Allport, 1954) is that the degree of contact among members of different social categories may be inversely related to the degree to which the social categories are essentialized. It seems to us, however, that this factor cannot fully account for the differences we found in the present study. For instance, the religious and secular Jewish samples were recruited from the same cities, and so it does not seem to be the case that the religious Jewish children would have less contact with Arabs than the secular Jewish children. A second possibility is that essentialism may be particularly enforced within groups that wish to maintain a power differential toward a separate group. Mahalingam (2003) raised this possibility as an account of the essentialist beliefs of Brahmin Indian adults toward other castes. While this notion may indeed be applicable to the context of Israeli society, it is unlikely that already by kindergarten, religious Jewish children are aware of this ideology of power. In other words, this ideology would have to be somehow transmitted to children by means they could understand and enforce.

A third possibility that addresses this latter matter is that due to ideological values, religious Jewish adults may emphasize distinctions between ethnic groups, which children may then pick up and reproduce (see Bigler & Liben, 2007, for a discussion of such processes). One way in which adults might emphasize ethnicity is via linguistic markers, such as chronic labeling of ethnic categories, or use of generics to describe ethnic categories. Gelman and colleagues found that such cues may be related to essentialist beliefs about gender (Gelman et al., 2004), and thus a similar process may occur in the context of ethnic categories. We are currently examining this possibility. A final possibility we would like to raise is that religious beliefs per se may endorse essentialist beliefs. In fact, in a recent study among secular and religious Jewish children, Diesendruck and Haber (2009) found that children's beliefs about God as the creator of social categories was positively related to children's essentialist construal of the social categories.

Clearly, there are a number of research routes to undertake in order to uncover why a particular group within a society comes to essentialize a particular social category. The present findings not only establish the need to pursue these routes but also provide some initial guidelines for doing so. One such guideline mentioned above that carries important theoretical implications has to do with the age at which differences across sectors start emerging. In Study 1, we found that the differences between religious Jewish children and the other two groups of children in terms of privileging ethnicity as a basis for induction were evident already in the youngest age group tested, that is, kindergarteners. This finding suggests that whatever effect cultural input might have on children's essentialist beliefs, it takes place early on in development and prior to children's intensive immersion into their sector's unique educational institutions. In fact, recent studies reveal that even under conditions of arbitrary social classification, preschoolers manifest ingroup favoritism, thus corroborating the notion that processes of social categorization have significant implications very early on in development (Patterson & Bigler, 2006). This conclusion seems most consistent with the claim that rather than having to acquire essentialist beliefs per se (Fodor, 1998), children might start off with an intuitive essentialist bias, and cultural input orients this bias to specific social categories (Hirschfeld, 1996).

One important general caveat with regard to the above conclusions is that, while we have been discussing the sectorial and developmental findings in terms of ''essentialism,'' all the results come from induction tasks. Although these tasks have been used in the past as one of the components of essentialist reasoning, it is possible that not all components of essentialism pattern in the same way; that is, that they do not form a coherent construct (Gelman, Heyman, & Legare, 2007). In fact, comparing the same populations as the ones included here but on different components of essentialism, Birnbaum (2009) found that Muslim Arab children, rather than religious Jewish children, manifested the most essentialist-like response patterns. At a minimum, nonetheless, the present findings on induction invite the same kinds of questions about the origins of the status of ethnicity as the ones raised above about essentialism in general.

The second major goal of the present studies was to evaluate the contribution of labeling to the inductive potential of social categories. This was accomplished by comparing children's responses in a task where all categories were labeled (Study 1) to a task where categories were not labeled (Study 2). There have been claims about the importance of language in the generation of essentialism in general (Carey, 1995), and social essentialism in particular (Sperber, 1996). In fact, a number of studies highlight the importance of labeling to the inductive potential of categories in general (Gelman & Markman, 1987; Sloutsky, Lo, & Fisher, 2001), and social categories in particular (Diesendruck & haLevi, 2006; Gelman & Heyman, 1999).

The findings from these two studies converged onto the same conclusion regarding this issue. Namely, that labeling plays an important role in the inductive power of social categories, and that visual cues—or perceptual similarity—are not sufficient to account for the inductive potential of social categories. First, we found that different from Study 1, in Study 2 ethnicity was not the most powerful source of induction. Second, in Study 2 we found that religious Jewish children were no more likely than secular Jewish children or Muslim Arab children to rely on ethnicity for drawing inferences. Third and finally, we found that there were no systematic differences across sectors in children's capacity to recognize the social categories depicted in the stimuli, and there were no significant correlations between children's capacity to recognize a social category and children's tendency to rely on that category as a basis for induction. In fact, the finding that religious Jewish kindergarteners privileged ethnicity as a basis for induction when ethnicity was labeled, even though they were incapable of systematically recognizing Jews and Arabs in pictures, suggests that children's concept of ethnicity predates their perceptual classification. Altogether, social categories—in the present case, ethnicity—earn their inductive potential not from their visual distinctiveness, bur rather from their labels (see also Hirschfeld, 1993).

There is considerable debate regarding the mechanisms by which labeling affects induction and essentialism. Some researchers argue that young children rely on labels for induction because of the privileged status of the auditory modality (Sloutsky et al., 2001). Others claim that labels invite children to search for the commonalities among instances of a category, thus fostering the acquisition of a notion of kind (Waxman, 1999; Xu, 2002). Finally, there are suggestions about the possibility of labels causing children to believe that deep commonalities between category members exist (Carey, 1995; Gelman & Heyman, 1999). The comparison between Studies 1 and 2 provides important new insights regarding this issue. That comparison revealed that labeling significantly increased the inductive potential only of ethnic categories, and only for religious Jewish children.

The category specificity of the effect of labeling is inconsistent with any generalist account of such an effect, perhaps especially one based exclusively on low-level perceptual capacities. This specificity intimates that children are relying on more than what is made available to them in the task; that is, children seem to be relying also on their underlying concepts about the categories. As a consequence, not all *categories* are equally susceptible to this effect. The sector specificity of the effect of labeling reinforces the above conclusion, by emphasizing that not all *children* are equally susceptible to such an effect. Labeling does not seem to create essentialism out of vacuous concepts but rather from already fertile ones. The fact that this was true for the religious Jewish children across all ages also undermines the argument that labeling effects in young children are due to the early maturation of the auditory system (Sloutsky et al., 2001).

These findings about the specificity of labeling are also relevant to a recent theory expounded by Bigler and Liben (2007) about the development of intergroup concepts. According to Bigler and Liben, the psychological salience of a particular category derives primarily from four factors: perceptual discriminability, labeling, differential distribution, and implicit use. We would add that prior concepts about real-life categories may modulate the weighting of these factors. Using the effect of labeling as an example, it is only within a particular population that a certain labeled category stood out. One caveat to this conclusion is that it is possible that while we have manipulated—and thus equated—children's exposure to social category labels *in the task,* children from different sectors may nonetheless be differentially exposed to social category labels *in their daily lives.* In other words, consistent with Bigler and Liben, ethnicity may be salient to religious Jewish children because this category is more frequently labeled in their regular input. As mentioned earlier, we are currently examining this possibility.

The conclusion that seems most consistent with all these findings is that labels are particularly effective triggers of an essentialist bias that, while intuitive to all children, may be differentially latent with regard to particular social categories depending on a child's sociocultural background. In other words, the argument is that religious Jewish children in Israel may have a stronger essentialist belief about ethnicity than children from the other two sectors tested here. This belief does not derive from children's perception of the categories or from their experiences with members of the categories. Rather, as discussed earlier, aspects of these children's sociocultural input may endorse this belief. Interestingly, it is only by sixth grade that children have sufficiently fine-tuned visual schemas for the different categories, that they do not "need" labels to activate their rich concepts about the categories. Up until then, labels are one of the primary means by which this function is achieved. In other words, rather than construing ethnic categories "from the bottom up," children are doing so by first associating abstract conceptual richness with labels, and only then recognizing the referents of these labels in their social environment.

One final finding that may have important implications for the development of social essentialism came from our analyses of the effect of group membership on children's inferences. In Study 1 we found that the experimental context least conducive to ethnicity-based inferences was one in which the participant was an Arab and the target of the inference was described as a Jew. Similarly, the context least conducive to gender-based inferences was one in which the participant was a girl and the target of the inference a boy.

A line of research that may aid in the interpretation of the above pattern of results are adult social psychological studies on intergroup perceptions. Following this literature, we may describe the present pattern of findings regarding category-based inferences in terms of the perceived homogeneity of categories. The more one relies on a particular category as the basis for inference, the more one can be said to conceive of the members of the category as being similar. Thus, for instance, the asymmetry summarized above can be described as Arab children viewing "Jewishness" as more heterogeneous than "Arabness." The casting of the findings in this light makes them directly relevant to a well-documented phenomenon on adults' intergroup perceptions—the so-called outgroup homogeneity effect. The effect refers to the finding that adults tend to perceive members of an outgroup as more homogenous than members of their ingroup (see Ostrom & Sedikides, 1992, for a review). At face value, if children were susceptible to this effect, then we would have expected the exact opposite pattern of findings from the one reported here; for example, Arab children should have perceived Jewishness as more *homogeneous* than Arabness. Interestingly, nonetheless, studies in the adult social psychological literature report that under certain circumstances, there may occur a reversal of the outgroup homogeneity effect, analogous to the one found in the present study. In particular, the effect has been found to reverse when the participants belong to a minority group with whom they identify highly, and whom they positively value (Doosje, Ellemers, & Spears, 1995). To the extent that Arab children (and girls) correspond to these characteristics, the present findings may be taken as evidence for the early manifestation of this adult social psychological phenomenon. In general, these findings invite the incorporation of assessments of self-identification with groups, to the study of the development of social essentialism.

To conclude, the present studies shed light on a number of aspects regarding social essentialism. First, at a descriptive level, the studies confirm that within the Israeli society, ethnicity stands out as the most inductively powerful human category, above a number of other social categories or personality traits. Second, the studies reveal that ethnicity has a privileged status particularly within a sector of that society, namely, modern religious Zionist Jewish children. This finding underscores the role of cultural input in the emergence of social essentialism. Third, the early emergence of these sectorial differences intimates that cultural input is of a form capable of affecting children's concepts from early on. Fourth, it becomes evident that the distinctive status of ethnicity is only manifest when labels are used, but again this effect is both category and sector specific. Finally, the results implicate the role of self-identification in children's concepts of social categories.

Gender, Values, and Occupational Interests Among Children, Adolescents, and Adults

Lynn S. Liben
The Pennsylvania State University

Work fulfills personal values, perhaps differently for males and females. Explored here was the role values play in shaping occupational interests. Study 1 examined children's, adolescents', and adults' ($N = 313$) occupational values (regarding money, power, family, altruism), occupational interests, and perceptions of values afforded by traditionally masculine and feminine occupations. Results revealed sex differences in occupational values and interests. Furthermore, participants' values predicted their own interests in culturally masculine and feminine occupations. Study 2 used novel jobs and experimentally manipulated prototypical sex of worker and value affordances to disentangle their effects on occupational interests. At all ages, participants' ($N = 240$) occupational interests were affected by the depicted sex of the workers and by the stated value affordances of the jobs.

The distinction between male and female is perhaps the most visible and dramatic subdivision within our species. Within developmental psychology, empirical and theoretical literatures document sex differences in behavioral realms such as play, cognitive skills, peer relations, and educational pathways (Blakemore, Berenbaum, & Liben, 2009; Ruble, Martin, & Berenbaum, 2006). From a lifespan developmental perspective, one of the most striking domains of gender differentiation occurs in the world of work: Substantial sex differences in career interests are evident in preschoolers, elementary-school-age children, adolescents, and adults (Erb, 1983; Herzog, 1982; Schulenberg, Goldstein, & Vondracek, 1991). Although the workforce is, overall, roughly evenly divided by sex, specific jobs remain differentiated. Illustratively, the 2000 U.S. Census (U.S. Department of Commerce, 2005) shows that women hold most jobs in nursing, education, and child care (88%, 81%, and 95%, respectively) whereas men hold most jobs in engineering, computer programming, and physical science (90%, 88%, and 78%, respectively).

The etiology of occupational sex differences has been studied within the fields of psychology, vocational guidance, and counseling psychology for decades, although relatively little work has addressed children's career interests. In a special issue of the *Career Development Quarterly*, McMahon and Watson (2008) called for additional theoretically derived, programmatic research on occupational interests across the lifespan. The work we describe here responds to this call by examining the role of sex-typed occupational values in shaping children's, adolescents', and adults' career

---

This work is based, in part, on the first author's dissertation, which was completed under the direction of the second author and submitted to the University of Texas at Austin. The authors thank the members of the dissertation committee, Jacqueline Woolley, Judith Langlois, William Swann Jr., and Tasha Beretvas, for their insights and suggestions. Many thanks are also extended to Steven Witt, Jamie Garcia, Ellen Hope, Susan Owen, and Amy Weisgram Engstrom for their willingness to invite students to participate in these studies, and to the participants who took part in these studies. We are also appreciative of the undergraduate students in the Gender and Racial Attitudes Lab who assisted in data collection, data entry, and recruitment of subjects, especially Lindsey Fivecoat, Ashley Smith, Masha Sharf, Fran Aucna-Neely, Desiree Sorenson, Marissa Contreras, Lisa Newhouse, John Goosey, and Camille Garvin. Lastly, thanks to Theresa Lesperance for editorial assistance. Portions of this work were presented at the Gender Development Research Conference, April 2006, San Francisco, CA, and at the biennial conference of the Society for Research in Child Development, March 2007, Boston, MA.

Correspondence concerning this article should be addressed to Erica S. Weisgram, University of Wisconsin–Stevens Point, Department of Psychology, 2100 Main Street, Stevens Point, WI 54481. Electronic mail may be sent to eweisgra@uwsp.edu.

interests. Specifically, we tested the hypothesis that some occupational values are endorsed differentially by males and females, and that these differing values contribute to the gender differentiation of occupational interests. In Study 1, we tested the hypothesis that children's, adolescents', and adults' own occupational interests would be related to their career values and of the values afforded by specific occupations. In Study 2, we tested whether children's, adolescents', and adults' occupational interests would be affected by experimental manipulations of jobs' value affordances.

Practical and Theoretical Motivations for Examining the Role of Values in Occupational Goals

The world of work is of practical importance both because it encompasses a large portion of life and because it predicts life quality (e.g., income, mental health, and social relationships; see Crouter, Bumpus, Maguire, & McHale, 1999; Thomas, Benzeval, & Stansfeld, 2007). It is also of theoretical interest for the study of gender differentiation because it involves not only individual development but also societal policies and cultural stereotypes. A recent and highly publicized demonstration of the importance of multiple levels of influence on occupational outcomes comes from an address given by Larry Summers (2005) during his presidency of Harvard University. In his speech, he suggested that the relative dearth of women faculty in engineering and science at prestigious institutions might, in part, be attributed to biological gender differences in cognitive aptitude. This part of his argument became national headline news, contributing to his removal from the Harvard presidency. Although it received far less national attention, Summers also mentioned that another potential explanation for gender differentiation in the work force might lie in sex differences in men's and women's attempts to satisfy life values (e.g., work and family).

Indeed, research has shown that values affect individuals' behaviors and mental processes in various domains, including political beliefs, moral behaviors, and educational attainment (Simpkins, Davis-Kean, & Eccles, 2006). Within the vocational psychology literature, studies have consistently demonstrated that occupational values, typically defined as desires one most wants to be fulfilled within a career (Singer & Stefflre, 1954; Zytowski, 1970), are associated with occupational preferences (Judge & Bretz, 1992; Lindsay & Knox, 1984). Importantly, there is also extensive research demonstrating that some career values are endorsed differentially by males and females (e.g., see Konrad, Ritchie, Lieb, & Corrigall, 2000), although when in the life course such gender differentiation occurs is unknown.

Developmental and Sex Differences in Work Values

Past work has documented that occupational values are under active development during early adolescence. Young adolescents have been found to endorse many values simultaneously (Johnson, 2001; Schulenberg, Vondracek, & Kim, 1993; Weisgram & Bigler, 2006). For example, young adolescents want a job that simultaneously helps people, allows spending time with family, makes a lot of money, and holds influence over others. This set of desires is unrealistic given the values afforded by most occupations. In a longitudinal study, Johnson (2001) found that the proportion of individuals rating multiple values as ''very important'' declined with age; by late adolescence, individuals highly endorsed only a select subset of occupational values. Once adolescents become selective, they generally value money, security, and family time more highly than power and responsibility (Lee, 1984; Thomas, 1986). Little is known, however, about occupational values among children younger than adolescents, despite calls for life-span approaches to understanding career development (Hartung, Porfeli, & Vondracek, 2008).

Although some occupational values are not differentially endorsed by males and females (Rowe & Snizek, 1995), other occupational values are valued more strongly by one gender than the other (Herzog, 1982; Konrad et al., 2000; Schulenberg et al., 1993). Among older adolescents and adults, males typically prefer jobs characterized by high salaries, power or influence over others, opportunities for advancement or achievement, risk taking, challenging tasks, a high level of responsibility, and a high level of prestige (Eccles, 1994; Konrad et al., 2000; Post-Kammer, 1987). Females, in contrast, typically prefer jobs that allow them to work with or help others, develop their knowledge or skills, and spend time with family (Cinamon & Rich, 2002; Eccles, 1994; Konrad et al., 2000; Post-Kammer, 1987). Indeed, Marini, Fan, Finley, and Beutel (1996) reported that gender explained more of the variance in occupational values than race, parental education, maternal employment, community of origin, or religion. The developmental origins of such differences are not, however, well understood.

Effects of Gender-Differentiated Values on Occupational Interests

Based on previous theoretical and empirical work (Eccles, 1994; Eccles et al., 1983; Judge & Bretz, 1992), we hypothesized that sex differences in occupational values may be a driving force in sex differences in occupational interests. Within developmental psychology, Eccles and her colleagues are leading proponents of the notion that values shape individuals' academic and vocational achievement (Eccles, 1987, 1994; Eccles et al., 1983). In their expectancy values model, Eccles and colleagues have conceptualized values in a variety of ways, including the perceived importance or utility of careers, interest or enjoyment of careers, and the cost of choosing one career over another. We focus here on the notion of occupational values as the rewards that are desired from and experienced in work (e.g., money, power; Brown, 2002; Knoop, 1991; Schulenberg et al., 1993), and hypothesize that males and females—at the group level—may seek occupations that fulfill different values. Thus, to the extent that a particular job affords the values prized by one gender more than the other, one would expect to see gender segregation within that particular occupation.

Suggestive evidence for this process has been reported in longitudinal work by Vida and Eccles (2003). They found that females endorse altruistic values to a greater extent than males and that endorsing these values negatively predicts to majoring in math and science at age 20, as well as to having a career in those fields at age 25. Similarly, Weisgram and Bigler (2006) reported that girls who viewed science as affording altruistic values showed greater interest in scientific jobs than girls who did not share this view. Thus, individuals' values and the perceived value affordances of occupations may combine to produce gender differentiation in occupational selections. Furthermore, it seems possible that this effect emerges in childhood (rather than adolescence or adulthood) as a result of children's attention to gender as a social category and their learning of the correlates of maleness and femaleness in the culture (Blakemore et al., 2009; Ruble et al., 2006).

But which jobs afford typically ''masculine'' and typically ''feminine'' values? The answer is unknown. There has been almost no systematic study of the extent to which specific occupations are perceived to afford the satisfaction of various values, or whether children, adolescents, and adults endorse the view that traditionally masculine and feminine occupations—at the group level—afford the fulfillment of different values. One reason for the gap in the literature is the common practice in the career development field of collapsing *across* traditionally masculine and feminine occupations to form career interest subscales (Ji, Lapan, & Tate, 2004; Schulenberg et al., 1991). For example, Holland's (1997) widely used model posits that individuals' occupational interests can be described with reference to six subtypes of occupations (realistic, investigative, artistic, social, enterprising, and conventional). Each subtype includes masculine as well as feminine sex-typed occupation (e.g., ''realistic'' jobs include engineer and dietician). Thus, the question of whether traditionally masculine and feminine jobs are perceived as affording different occupational values is unanswered. It is clear, however, that sex differences characterize adolescents' and adults' interest in many, if not most, of the career subtypes on Holland's and other scales. For example, males score higher on the realistic and investigative Holland subscales, whereas females score higher on the artistic, social, and enterprising subscales (Tracey & Ward, 1998). The issues reviewed above make it apparent that additional research is needed to understand the contributions of both sex typing and values to the development of occupational interests.

A first step in studying the role of values in the gender differentiation of occupational interest is, therefore, documenting children's, adolescents', and adults' views of the values afforded by jobs that are traditionally viewed as masculine versus feminine, and then examining whether individuals' occupational values predict differential levels of interest in these two broad classes of occupations. In addition, research must examine whether the endorsement of occupational values predicts interest in occupations perceived to afford these particular values (e.g., money, power, family, and altruism). Study 1 was designed to fulfill these research goals.

Imagine, however, that—as predicted—masculine versus feminine jobs are found to be perceived by children, adolescents, and adults as affording different values. Why might this be true? It is possible that masculine jobs are characterized by duties and perks that objectively enhance job holders in ways that feminine jobs do not (e.g., the activities engaged in by workers who hold jobs that are culturally viewed as masculine jobs may carry more power). It is also possible, however, that it is not the characteristics of the job itself—but rather the sex of workers who typically hold that job—that shape such perceptions. For example, the mere fact of associating business executives with males may mean that the job of business executive is seen as powerful (because men are seen as powerful). If business executives were instead usually female, the job—even if it had the identical job responsibilities—might then be perceived as being a job that affords family values but *not* be perceived as offering substantial power. Such a process would be consistent with Eagly's (1987) social role theory that posits that gender segregation shapes perceptions of the traits required for occupational roles and, consequently, individuals' occupational interests. Studies that include only measures of participants' interest in existing jobs, although useful for establishing patterns of evidence that are consistent with theoretically derived hypotheses about influence of sex of worker and values on career interests, are unhelpful in disentangling the independent causal effects of these variables. Study 2 was designed to examine this relation by using an experimental methodology to examine the independent roles of (a) perceived value affordances and (b) perceived gender segregation of occupations (i.e., sex of prototypical workers) in occupational interests.

Study 1

In Study 1 we examined children's, adolescents', and adults' self-endorsement of job values (i.e., what values they consider to be important for themselves) and job interests, and whether values and interests differ by participant sex. We focused on four values widely reported in the adult literature to show sex differences: money (sometimes called *salary*, *compensation*, or *economic return*), power (*management* or *authority*), family time, and altruistic values (see Eccles, 1994; Eccles et al., 1983; Post-Kammer, 1987; Weisgram & Bigler, 2006).

Based on past work, we expected females to endorse altruistic and family values more strongly than males and, in contrast, males to endorse money and power values more strongly than females. We expected this pattern would be strongest among adults because children and adolescents were expected to endorse all four values at a generally high rate due to their unrealistic belief that jobs can afford all positive values simultaneously (Johnson, 2001). We also expected to replicate findings from prior studies (Gregg & Dobson, 1980; Liben & Bigler, 2002) that participants would show greater interest in jobs culturally associated with their own sex.

We also examined participants' perceptions of values afforded by a diverse sample of occupations to test our hypothesis that culturally masculine jobs would be rated as higher for fulfilling money and power values than culturally feminine jobs and, conversely, that culturally feminine jobs would be rated higher for fulfilling family and altruistic values than culturally masculine jobs.

Finally, we examined whether individuals' self-endorsements of job values would predict their interests in particular kinds of jobs. To this end, we examined whether individuals' values predicted their relative degree of interest in culturally feminine versus culturally masculine jobs, over and above the variance explained by individuals' biological sex. We expected that participants' personal endorsement of money and power values would predict their interest in masculine occupations, whereas personal endorsement of family and altruistic values would predict their interest in feminine occupations.

Method

Participants

In all, 313 participants were tested. Children (36 boys and 44 girls) ranged from 5 to 10 years ($M = 7.62$, $SD = 1.67$) and included 10 African Americans, 18 Latinos, 50 European Americans, 1 Asian American, and 1 child whose race was unreported. Adolescents (54 boys and 43 girls) ranged from 11 to 17 years ($M = 15.14$, $SD = 1.61$) and included 1 African American, 4 Latinos, 88 European Americans, 2 Asian Americans, and 2 youth whose race was unreported. Children and adolescents were recruited from after-school programs and private schools in the Southwest and Midwest. Adults (73 men and 63 women) ranged from 18 to 23 years ($M = 18.81$, $SD = 1.07$) and included 8 African Americans, 39 Latinos, 61 European Americans, 24 Asian Americans, and 4 individuals whose race was unreported. Adults were recruited from an introductory psychology course at a major university in the Southwest.

Overview of the Procedure

Children were tested individually by the first author or a research assistant, adolescents completed written measures in class, and adults completed measures in small groups. Participants reported their (a) perceptions of the degree to which various occupations afford money, power, family, and altruistic values; (b) occupational values; (c) occupational interests; and (d) demographic characteristics (age, sex, race/ethnicity).

Measures

Perceived value affordances of occupations. To assess beliefs about affordances, children were asked to rate the degree to which each of 40 occupations (drawn from the Occupation, Activity, and Trait scale [OAT]; Liben & Bigler, 2002; described below) "is a job that makes a lot of money/lets people make the rules for others/lets people spend a lot of time with their family/helps people" using a scale ranging from 1 (*not at all*) to 4 (*very much*). Adolescents and adults rated the degree to which each job "provides someone with the opportunity to have a high income/allows someone to be in a position of power/gives someone plenty of time to spend with their family/helps people." Money, power, altruism, and family scores were averaged separately for culturally masculine jobs and for feminine jobs, allowing us to examine whether ratings varied across age groups and allowing us to identify jobs that were viewed as affording money, power, family, or altruism values, and then to examine whether individuals' values predicted to their interest in such occupations. Reliability was acceptable for all subscales within each age group (Cronbach's alphas ranged from .66 to .88, with only two falling below .70). Item analyses revealed similar but not identical factor structures among each age group, with most (but not all) items loading onto the identical factors across age groups.

Endorsement of occupational values. Adolescents' and adults' occupational values were assessed by the 16-item Occupational Values Scale, an instrument developed for young adolescents by Weisgram and Bigler (2006). Children's occupational values were assessed by the Occupational Values Scale for Children, a measure created specifically for this study structured similarly but with developmentally appropriate items (see the Appendix). Participants were asked to indicate how much they would like to have job that incorporates aspects of each of four values (money, power, family, altruism) on a 4-point scale from 1 (*not at all*) to 4 (*very much*).

Cronbach's alphas for the four subscales ranged from .66 to .75 for children, .71 to .91 for adolescents, and .74 to .92 for adults. Item analyses resulted in four factors (money, power, family, and altruism) among adults and adolescents and five factors among children. When a four-factor solution was forced for the children, the same four factors emerged as in the older samples, with items loading identically with an exception of a single item. Responses within each subscale were averaged to create the dependent variables.

Personal occupational interests. Participants were asked to indicate their interest in 40 items drawn from the 80-item long version of the OAT–Personal Measure (Liben & Bigler, 2002). To select the 40 items, we asked an independent sample of adults ($n = 100$; recruited from the undergraduate psychology research pool at a major public university) to rate all 80 items on the four target values and then selected a group of culturally masculine and feminine jobs that would offer as diverse a range of values as possible. For each of the 40 occupations, participants indicated their interest on a scale of 1 (*not at all*) to 4 (*very much*). Cronbach's alphas for the masculine and feminine occupation subscales within each of the age groups ranged between .79 and .94. Item analyses indicated similar but not identical factor structures across age groups. Most (but not all) items loaded on the identical factors across age groups. Summary scores of participants' interest in culturally masculine and feminine occupations were computed by averaging responses to items of each type.

Results

Overview of Analyses

First, we examined participants' perceptions of the values afforded by the target occupations with the goal of determining (a) whether views are shared (or diverge) across age groups, (b) whether culturally masculine and feminine jobs are perceived as affording different values, and (c) whether participants' age and sex were associated with perceptions of the values collectively afforded by culturally masculine versus feminine target occupations. Second, we tested for age and sex differences in participants' personal occupational values and occupational interests. Third, we used hierarchical multiple regression analyses to examine predictors of participants' interest in masculine and feminine occupations. Separate regression analyses were conducted for each sample to examine patterns within each age group.

Perceived Value Affordances of Occupations

To evaluate consistencies across age concerning jobs' value affordances, zero-order correlations were computed for value ratings of each of the 40 occupations, separately for each of the four value categories (money, power, family, and altruism). Agreement was high across age groups, with correlations between children's and adolescents' average value ratings ranging from $r = .79$ to $r = .88$, those between children and adults ranging from $r = .77$ to $r = .90$, and those between adolescents and adults ranging from $r = .95$ to $r = .99$. Given the similar patterns of ratings across age groups, we provide only adults' ratings in Table 1.

To examine possible age or gender differences in perceptions of values afforded by masculine and feminine occupations, each of the four value ratings (i.e., money, power, family, altruism) was analyzed by a separate 2 (participant sex: male, female) × 3 (participant age: children, adolescents, adults) × 2 (sex-type of job: masculine, feminine) mixed-effects-analysis of variance (ANOVA) in which sex-type of job was a within-subjects variable. Means and standard deviations are presented in Table 2. In each case, significant interactions were followed by simple effects analyses (with Bonferonni correction). Results reported as significant here and elsewhere in this article were $p < .05$ or better unless otherwise noted.

Money ratings. The two-way interaction of participant age and sex-type of job was significant, $F(2, 306) = 80.49$. As expected, masculine jobs received higher money ratings than did feminine jobs among all three age groups. The significant interaction stemmed from the fact that the difference between the ratings of masculine and feminine jobs was greater in adults than in either adolescents or children, and greater in adolescents than in children.

Power ratings. The two-way interaction of participant age and sex-type of job was significant, $F(2, 305) = 57.21$. As expected, masculine jobs received higher power ratings than did feminine jobs among all three age groups. Again, the significant interaction stemmed from the fact that the difference between masculine and feminine job ratings was greater in adults than in either adolescents or children, and greater in adolescents than in children.

Family ratings. The two-way interaction of participant sex and sex-type of job was significant, $F(1, 307) = 6.12$. As expected, feminine jobs received higher family values ratings than masculine jobs in both males and females. The significant interaction stemmed from the fact that the difference between ratings of masculine and feminine jobs was greater in females than in males. Also significant was the interaction between participant age and sex-type of job, $F(2, 307) = 26.34$. Feminine jobs were rated as affording family values significantly more than masculine jobs in all three age groups, but the difference was larger in adults than in adolescents or children, and larger in adolescents than in children.

Altruism ratings. The two-way interaction between participant age and sex-type of job was significant, $F(2, 307) = 8.32$. Contrary to expectations, masculine jobs were rated as affording altruistic values significantly more than feminine jobs in all age groups. The significant interaction revealed that the difference between ratings of masculine and feminine jobs was greater in adults than in either adolescents or children, and greater in adolescents than in children.

Occupational Values

Group differences in personal endorsement of occupational values were examined with a 2 (participant sex: male, female) × 3 (participant age: children, adolescents, adults) × 4 (value: money, power, family, altruism) mixed-effects ANOVA with value as a repeated measures factor. Significant interactions were followed by simple effects analyses (with Bonferonni correction). Means and standard deviations are presented in Table 3.

The three-way interaction of participant sex, participant age, and value was significant, $F(6, 918) = 4.12$. Among children, follow-up analyses indicated no significant effects or interactions. Among adolescents, there was a significant Participant Sex × Value interaction, with females endorsing altruistic values significantly more than males. Among adults, the same finding held, and in addition, females endorsed family values significantly more than did males.

Occupational Interests

Group differences in occupational interests were examined by a 2 (participant sex: males, females) × 3 (participant age: children, adolescents, adults) × 2 (sex-type of job: masculine, feminine) mixed-effects ANOVA. Means and standard deviations are presented in Table 3. The three-way interaction of participant sex, participant age, and sex-type of job was significant, $F(2, 307) = 4.13$. Simple effects analyses showed a significant interaction between participant sex and sex-type of job among all three age groups. Among children, girls

were significantly more interested in culturally feminine occupations than were boys; among adolescents, males were significantly more interested in culturally masculine occupations than were females; and among adults, males were significantly more interested in culturally masculine occupations—and less interested in culturally feminine occupations—than were females.

Predictors of Interest in Culturally Masculine and Feminine Occupations

To examine the predictors of individuals' interests in culturally masculine and feminine occupations, hierarchical multiple regression analyses were conducted in which participant age, participant sex, endorsement of each of the four

Note. Value scales for all samples range from 1 to 4, with higher scores indicating stronger endorsement of the value. Interest scales range from 1 to 4, with higher scores indicating greater personal interest in the occupation.

occupational values, and the various interactions between age, sex, and the endorsement of occupational values served as predictors of participants' interest in masculine and feminine occupations separately. For interest in masculine occupations, this model was found to be significant, $F(28, 280) = 5.18$, $R^2 = .34$. Importantly, age produced interaction terms with each of the values. For interest in feminine occupations, this model was also significant, $F(28, 280) = 8.53$, $R^2 = .46$. Again, age was involved in significant interactions with each of the values. To clarify these age interactions, hierarchical multiple regression analyses were conducted within each of the age groups (i.e., children, adolescents, and adults). In each model, predictor variables included participant sex, participant age in years, and participants' endorsement of each of the four occupational values. Results of these regressions are summarized below and detailed in Table 4.

For each regression, participant sex and age were entered at the first step of the model for all three age groups. At Step 2, endorsement of each occupational value was entered. Tests of multicollinearity (i.e., tests of minimum tolerance) among constructs indicated that collinearity was at an acceptable level for each analysis. Table 4 presents beta values, standard errors, and standardized betas for regressions predicting interest in masculine and feminine occupations.

Children. For masculine occupations, the overall model was significant in predicting children's

interest, $F(6, 72) = 6.65$, $R^2 = .34$, adjusted $R^2 = .28$. Age was a negative predictor of interest in masculine occupations. In addition, the endorsement of power values positively predicted interest in masculine occupations, after accounting for participant sex and age. For feminine occupations, the overall model was significant in predicting children's interest, $F(6, 72) = 15.27$, $R^2 = .56$, adjusted $R^2 = .52$. Sex of participant was a significant predictor of interest in feminine occupations, with girls showing greater interest than boys. Age was a negative predictor of interest in feminine occupations. After accounting for the effects of participant sex and age, altruistic values positively predicted interest in feminine occupations.

Adolescents. For masculine occupations, the overall model was significant in predicting adolescents' interest, $F(6, 90) = 5.53$, $R^2 = .27$, adjusted $R^2 = .22$. Sex of participant was the only significant predictor of interest in masculine occupations, with males showing greater interest than females. For feminine occupations, the overall model was significant in predicting adolescents' interest, $F(6, 90) = 2.20$, $R^2 = .13$, adjusted $R^2 = .08$. Age was a negative predictor of interest in feminine occupations. After accounting for participant sex and age, the endorsement of power values negatively predicted interest in feminine occupations.

Adults. For masculine occupations, the overall model was significant in predicting adults' interest,

$F(6, 130) = 12.88$, $R^2 = .37$, adjusted $R^2 = .34$. Sex of participant was a significant predictor of interest in masculine occupations, with men showing greater interest than women. In addition, the endorsement of altruistic and power values positively predicted interest in masculine occupations. For feminine occupations, the overall model was significant in predicting adults' interest, $F(6, 130) = 11.56$, $R^2 = .35$, adjusted $R^2 = .32$. Participant sex predicted interest in feminine occupations, with women showing greater interest than men. In addition, the endorsement of altruistic and family values positively predicted interest. The endorsement of power values negatively predicted interest in feminine occupations.

Discussion

The primary purpose of Study 1 was to examine individuals' occupational interests in relation to sex, age, and own occupational values. Participants rated first, how much they believed various occupations satisfy money, power, family, and altruistic values; and second, their own occupational values and occupational interests.

Interestingly, the data indicate a very high degree of agreement among the three age samples concerning values afforded by specific jobs. Individuals' perceptions of the values collectively afforded by culturally masculine and feminine occupations were also informative. As hypothesized, masculine jobs were perceived as affording money and power values more than feminine jobs. Feminine jobs, in contrast, were perceived as affording family values to a greater extent than masculine jobs. Interestingly, and contrary to expectations, masculine occupations were perceived by all groups as affording altruistic values to a greater extent than feminine occupations. Although children perceived masculine occupations as affording altruistic values more than feminine occupations, the altruism ratings of feminine occupations were elevated relative to the money, power, and family ratings of these same occupations. In other words, traditionally feminine occupations were perceived as less useful than traditionally masculine jobs for fulfilling most values and were best at fulfilling altruistic values (albeit still less useful for this purpose than masculine jobs).

Consistent with prior research, participants' own occupational values showed significant sex differences. As predicted, in both adolescent and adult groups, altruistic and family values were rated more highly by females than males. In these age groups, ratings for power and money were also in the predicted direction (i.e., males showing greater endorsement than females for money and power values), but these differences were not significant. This pattern—females endorsing traditionally masculine as well as feminine traits and interests, and men avoiding traditionally feminine traits and interests—characterizes much of the literature on sex differences (Konrad et al., 2000; Ryckman & Houston, 2003). Among children, however, there were no sex differences in occupational values. Instead, children strongly endorsed all four values (money, power, family, and altruism). Perhaps it is during middle childhood that children become aware that a single occupation cannot realistically afford all positive values simultaneously, and this realization, in turn, prompts the development of a more strongly prioritized (and sex-differentiated) set of occupational values.

With respect to occupational interests, predicted sex differences in masculine and feminine occupations occurred. Specifically, among children and adults (but not adolescents), females were significantly more interested in feminine occupations than were males. Among adolescents and adults (but not children), males were more interested in masculine occupations than were females. These data are thus highly consistent with past work on occupational interests in indicating that, with the exception of a brief period in late childhood and early adolescence, females are more interested in feminine occupations than males despite the fact that females themselves rate feminine jobs as lower in salary, power, and altruism (Liben, Bigler, & Krogh, 2001). This finding is intriguing and unexplained in the literature. Low self-esteem, academic competence, and self-efficacy have been reported among girls, especially within the domain of mathematics, and could potentially explain their low aspirations (Watt & Eccles, 2008). The data are, however, not entirely consistent with the idea that a lack of confidence within traditionally masculine domains lowers girls' occupational aspirations. Girls receive better grades in all academic subjects than boys and sometimes report high levels of academic competence, self-efficacy, and aspirations within masculine domains such as science (Blakemore et al., 2009; Schulenberg et al., 1991). Furthermore, it is difficult, if not impossible, on the basis of existing data to establish the direction of causal relations (if present) among interest, self-efficacy, and expectations. Such findings leave open the possibility that girls prefer feminine occupations—perhaps because such jobs afford the fulfillment of their values—rather than expect to be unqualified for masculine occupations.

Our primary interest—the role of occupational values in shaping individuals' occupational interest—was examined using regression models. Individuals' endorsement of values was a significant predictor of their occupational interests in several cases. The endorsement of power values positively predicted interest in masculine occupations among children and adults, and negatively predicted interest in feminine occupations among all three samples (children, adolescents, and adults). Thus, the desire for a job that affords power was a clear factor in differentiating interest in masculine versus feminine occupations. In addition, the endorsement of altruistic values positively predicted interest in masculine occupations among adults. Given that masculine occupations included in this research were rated as high on the altruism scale, this finding is not entirely surprising. This same finding did not hold true, however, within our younger samples and, indeed, the reverse held among children. That is, children who endorsed altruistic values were more (rather than less) interested in feminine occupations than children who did not endorse altruistic values. These data are interesting in that they suggest that the sex typing of occupations, gender, and altruistic values may be conceived of, and related to each other, in ways that differ over the life course.

Overall, results show sex differences in occupational values in adults and adolescents, and sex differences in occupational interests at all three ages. Data also suggest that values (especially power and altruism) are connected to occupational interests at all ages.

Although the findings discussed above are generally consistent with the hypotheses we derived from earlier literature, the relevant data are limited in a number of important ways. One important limitation—which the data from Study 1 themselves confirm—is that sex typing of occupations is, overall, confounded with the values associated with occupations. Thus, the data in Study 1 do not allow us to discern, for example, whether males are more interested than females in masculine occupations because these "masculine" occupations afford male-typed values (e.g., money, power) or instead because these occupations are dominated by male workers. Indeed, it is impossible to disentangle the effects of these two factors (sex typing and values) by collecting data concerning actual occupations because these two qualities are confounded in the job structure of our culture. A second limitation is that the correlational nature of Study 1 does not allow us to disentangle the effects of the values afforded by an occupation from other qualities of the job (e.g., sex of workers, specific duties). Thus, experimental research is necessary to determine whether occupational values can have a casual effect on individuals' occupational interests. Because we deemed it unethical to experimentally manipulate individuals' values, we sought to examine the effects of manipulating the value affordances of particular jobs. To do so, we introduced participants to novel occupations whose characteristics would therefore be unknown and whose critical qualities (i.e., the values the jobs afford, the prototypical sex of workers in those jobs) could be experimentally manipulated.

Study 2

In Study 2 we conducted an experimental test of individuals' occupational interests as a function of the separate contributions of value affordances (i.e., the values afforded by a given job) and sex of worker (i.e., the percentage of males and females workers in a given job). Previous research has documented that individuals show higher levels of interest in occupations that are performed by same-sex than other-sex individuals (Heilman, 1979; Touhey, 1974). Thus, it was important to manipulate the role of values independently of sex of worker. To do so, we used an adaptation and extension of Liben et al.'s (2001) novel job paradigm. Participants were introduced to eight novel jobs whose value affordances were manipulated between subjects. That is, each job was described as satisfying one of four values: money, power, family, and altruism. We predicted that males would be more interested in jobs that were depicted as affording money and power than would females, whereas females would be more interested in jobs that were depicted as affording family and altruistic values than would males. We expected such effects to emerge by adolescence, and possibly by late childhood.

To disentangle the effect of value affordances from the effect of sex typing of occupations, we also manipulated the sex of workers depicted in each novel occupation: Half the novel jobs were depicted with female workers and half were depicted with male workers. Based on previous research (Plost & Rosen, 1974), we expected males to be significantly more interested in jobs depicted with male than female workers and, in contrast, females to be more interested in jobs depicted with female than male workers. Each of the novel jobs appeared in each combination of depicted sex of worker and value (i.e., stimuli were completely counterbalanced). Thus, the effect of sex of worker, value affordance, and their interaction could be determined independent of the specific job portrayed.

Method

Participants

Participants included 240 individuals. Children (40 boys and 40 girls; all European Americans) between 5 and 10 years ($M = 7.53$, $SD = 1.53$) were recruited from after school programs in a mid-sized city in the Southwest. Adolescents (40 boys and 40 girls: 1 African American, 1 Hispanic American, 1 Asian American, 77 European Americans) between 11 and 17 years ($M = 14.06$, $SD = 1.13$) were recruited from summer programs and a private school in the Midwest. Adults (40 men and 40 women: 2 African Americans, 6 Hispanic Americans, 4 Asian Americans, 68 European Americans) were undergraduates attending a large university in the Southwest (ages 18–25; $M = 18.81$, $SD = 1.28$) who participated in exchange for course credit.

Overview of Procedure

Participants received a brief introduction to eight novel occupations. They then heard a detailed description of each job and completed measures of their perception of values represented by, perception of sex of workers in, their own interest in, and stereotyping of the job. Participants had visual access to depictions of the novel jobs while completing these measures.

Experimental Manipulation

As described above, Study 2 used 8 of the 12 novel occupations developed by Liben et al. (2001), selected on the basis of pilot data showing that these job descriptions could be modified to convey different value affordances. For example, the job of benster was first described as ''a person who studies deer. They collect information about where deer live, how much food they need, how to keep them off the highways, and how pollution might be hurting them.'' The four value affordances were presented by continuing the job description in one of the following four ways: ''Bensters make a lot of money studying deer. Because they get special training to become experts on deer, they then get paid a lot of money to do their job'' (money); ''Bensters have a lot of power because they train other deer specialists and tell them what to do. Bensters also make very important decisions and have a lot of responsibility'' (power); ''Bensters only work when deer are out so they have lots of time to spend with their children'' (family); or ''Bensters help deer by keeping them healthy and keeping them safe. Bensters also help deer by feeding them and taking care of them'' (altruism).

During training, participants were told they would learn about eight new occupations. For each occupation, a job description was provided, accompanied by a poster showing either six men or six women performing the occupation. Specific jobs were counterbalanced across gender and value condition to ensure that posttest responses reflected only the experimental manipulations and not effects of specific jobs. Posters remained in view while the four measures were given.

Measures

First, to examine whether participants had attended to the sex of worker manipulation, for each job, participants were asked: ''Who is usually a _____ [e.g., benster]?'' Response options included: ''men,'' ''women,'' or ''both men and women.'' Second, to test whether participants had attended to the values manipulation, participants were asked to how much each occupation afforded money, power, family, and altruistic values. For example, participants were asked: ''How much money do bensters make?'' Response options included: ''none,'' ''a little,'' ''some,'' and ''a lot.'' Third, to assess stereotyping of novel occupations, participants were asked: ''Who should be a(n) __________?'' Following Liben and Bigler (2002), response options included ''only women,'' ''only men,'' or ''both men and women.'' Finally, to assess interest in the novel occupations, participants were asked: ''How much would you like to be a(n) ________?'' Participants responded using a 4-point scale ranging from *not at all* to *very much*.

Results

Knowledge of Sex of Worker

To evaluate participants' awareness of the depicted sex of worker, we tallied the number of correct responses to the question: ''Who usually is a

_____?'' Participants correctly identified the workers' gender at a high rate (98%, 86%, and 91% for children, adolescents, and adults, respectively). Participants who answered incorrectly never reversed the depicted sex of worker but instead responded that ''both men and women'' usually perform the occupation.

Perceptions of Values Afforded by Occupations

To ascertain if we successfully manipulated participants' perceptions of the values afforded by the novel occupations, a 3 (age of participant: child, adolescent, adult) × 2 (sex of worker: male, female) × 4 (manipulated value: money, power, family, altruism) ANOVA was conducted using each of the four value ratings of each job (i.e., money, power, family, altruism) as a dependent variable. Significant main effects were followed by simple contrasts among means; means and standard deviations are presented in Table 5.

Money. For money ratings, a significant interaction between age group and manipulated value was found, $F(6, 708) = 11.69$. Within each age a significant effect of manipulated value was evident: children, $F(3, 237) = 64.64$; adolescents, $F(3, 237) = 237.47$; and adults, $F(3, 237) = 368.54$. Within age, follow-up tests revealed participants' money ratings of jobs depicted as high in salary were—as expected—significantly greater than money ratings of jobs depicted with other values (i.e., power, family, altruism). Other patterns differed by age: In adolescents and adults (but not children) jobs depicted as high in power were rated as significantly higher in affording money values than were jobs depicted as high in family or altruism.

Power. For power ratings, a significant interaction between age group and manipulated value was found, $F(6, 711) = 8.31$. Within age groups, a significant effect of manipulated value was found: children, $F(3, 237) = 64.21$; adolescents, $F(3, 237) = 155.21$; and adults, $F(3, 237) = 275.43$. Follow-up tests revealed that—as expected—participants' ratings of power were higher for jobs depicted as high in power than for jobs depicting other values (i.e., money, family, altruism). Other contrasts, however, differed by age: Among adolescents and adults (but not children), jobs depicted as high in money were rated as significantly higher in affording power values than were jobs depicted as high in family or altruism.

Family. For family ratings, a significant interaction between age group and manipulated value was found, $F(6, 708) = 4.13$. Within age, a significant effect of manipulated value was evident: children, $F(3, 237) = 117.85$; adolescents, $F(3, 237) = 307.75$; and adults, $F(3, 237) = 334.10$. Within age, follow-up tests showed that family ratings of jobs depicted as allowing time with family were —as expected—significantly greater than family ratings of jobs depicted with other values. Other

Table 5
Mean Value Ratings (and Standard Deviations) by Manipulated Value and Sex of Worker in Study 2

	Manipulated value				Sex of worker	
	Money	Power	Family	Altruism	Males	Females
Children's value ratings						
Money	3.98 (.12)	3.13 (.78)	3.01 (.76)	3.06 (.80)	3.29 (.54)	3.29 (.54)
Power	2.99 (.88)	3.98 (.14)	2.82 (.89)	2.91 (.99)	3.17 (.62)	3.18 (.64)
Family	2.63 (.78)	2.59 (.78)	3.93 (.20)	2.63 (.81)	2.98 (.54)	2.91 (.54)
Altruism	3.36 (.67)	3.25 (.88)	3.26 (.78)	3.91 (.23)	3.44 (.60)	3.45 (.49)
Adolescents' value ratings						
Money	3.93 (.33)	2.86 (.53)	2.46 (.60)	2.53 (.46)	2.96 (.35)	2.93 (.44)
Power	2.47 (.71)	3.81 (.41)	2.17 (.65)	2.27 (.75)	2.67 (.46)	2.68 (.50)
Family	2.34 (.56)	2.29 (.50)	3.93 (.25)	2.66 (.50)	2.77 (.39)	2.84 (.33)
Altruism	2.64 (.84)	2.76 (.81)	2.64 (.71)	3.67 (.52)	2.94 (.52)	2.92 (.58)
Adults' value ratings						
Money	3.97 (.15)	2.74 (.44)	2.35 (.45)	2.36 (.48)	2.88 (.30)	2.83 (.31)
Power	2.28 (.64)	3.86 (.44)	1.99 (.58)	2.03 (.60)	2.56 (.45)	2.55 (.45)
Family	2.39 (.60)	2.46 (.45)	3.98 (.16)	2.70 (.48)	2.82 (.34)	2.95 (.37)
Altruism	2.33 (.57)	2.36 (.67)	2.43 (.63)	3.73 (.48)	2.73 (.38)	2.69 (.47)

Note. Value ratings range from 1 (*low*) to 4 (*high*).

patterns differed by age: For adolescents and adults (but not children) jobs depicted as high in altruism were rated as significantly higher in affording family values than jobs depicted as high in money or power.

A significant interaction between age group and sex of worker was also found, $F(2, 236) = 7.97$. Within age, a significant effect of sex of worker was present in adolescents $F(1, 79) = 5.01$, and adults, $F(1, 79) = 16.94$, but not children, $F(1, 79) = 3.05$, $p = .09$. Among adolescents and adults (but not children), jobs depicted with female workers were perceived as affording family values significantly more than jobs depicted with male workers.

Altruism. For altruism ratings, a significant interaction of age group and manipulated value was found, $F(6, 708) = 9.36$. Within age, a significant effect of manipulated value was found: children, $F(3, 237) = 27.08$; adolescents, $F(3, 237) = 49.77$; adults, $F(3, 237) = 115.62$. Within age, altruism ratings of jobs depicted as helping others were—as expected—significantly greater than altruism ratings of jobs depicting other values.

Egalitarian Attitudes Toward Novel Occupations

A mixed-effects ANOVA was performed on participants' egalitarian attitudes toward novel occupations. Between-subject variables were sex of participant (male, female) and age group (children, adolescents, adults). Within-subject variables were sex of depicted workers (male, female) and manipulated value (money, power, family, altruism). Dependent measures were proportions of egalitarian responses (i.e., "both men and women" should do the job).

Results indicated a significant three-way interaction of age group, sex of depicted worker, and manipulated value, $F(6, 699) = 2.40$. Simple effects analyses indicated a marginally significant interaction between sex of depicted worker and manipulated value for children, $F(3, 237) = 2.61$, $p = .06$, but not for adolescents or adults. Follow-up tests indicated that children held more egalitarian attitudes toward jobs depicted as high in salary when male workers were depicted ($M = .59$, $SD = .50$) than when female workers were depicted ($M = .38$, $SD = .49$). This trend was not found in jobs depicted as high in power, family, or altruism. Among adolescents and adults, however, a significant main effect of sex of depicted worker was present: for adolescents, $F(1, 78) = 11.20$, and for adults, $F(1, 79) = 12.70$. Across all manipulated values, adolescents and adults held more egalitarian attitudes toward jobs depicted with male workers ($M = .92$, $SD = .18$ and $M = .96$, $SD = .15$, respectively) than with female workers ($M = .84$, $SD = .25$ and $M = .88$, $SD = .24$, respectively).

Interest in Novel Occupations

A mixed-effects ANOVA was performed with between-subjects variables of sex of participant (male, female) and age (children, adolescents, adults) and within-subjects variables of sex of depicted workers (males, females) and manipulated value (money, power, family, altruism). Following interactions, simple effects analyses were performed to explore group differences on the dependent variable. Means and standard deviations are presented in Table 6.

Results indicated a significant three-way interaction of age group, sex of participant, and sex of workers, $F(2, 233) = 9.92$. To explore this interaction, separate mixed-effects ANOVAs were performed for each age group with sex of participant (male, female) as the between-subjects variable and sex of depicted workers (males, females) as the within-subjects variable. Within each age group, a significant interaction between sex of depicted worker and sex of participant was found: children, $F(1, 78) = 57.04$; adolescents, $F(1, 78) = 16.34$; and adults, $F(1, 78) = 13.43$. Among children and adolescents, participants showed greater interest in jobs depicted with members of their own sex. Among adults, jobs depicted with male workers were significantly more attractive to men than women; jobs depicted with female workers were not differentially attractive in relation to participant sex.

A significant interaction between sex of participant and manipulated value was also found, $F(3, 699) = 2.90$. Follow-up analyses indicated that males, across all ages, were significantly more interested in jobs when they were depicted as high in money than when the identical jobs were depicted as high in power, family, or altruism. Like males, females were significantly more interested in jobs depicted as high in money than in the identical jobs depicted as high in power and family; unlike males, however, their interest did not differ between jobs depicted as high in money and those depicted as high in altruism. In addition, males (but not females) were significantly more interested in jobs that were depicted as high in power and family than in identical jobs that were depicted as high in altruism.

Table 6
Means (and Standard Deviations) for Interest in Novel Occupations Manipulated Value and Sex of Worker in Study 2

	Manipulated value				Sex of worker	
	Money	Power	Family	Altruism	Males	Females
Children						
Boys	2.29 (.87)	2.08 (.92)	2.24 (.97)	2.01 (.86)	2.51 (.78)	1.79 (.73)
Girls	2.41 (.98)	2.13 (.77)	2.24 (.84)	2.34 (.75)	2.06 (.63)	2.50 (.79)
Combined	2.35 (.92)	2.10 (.84)	2.24 (.90)	2.18 (.82)	2.28 (.74)	2.15 (.84)
Adolescents						
Boys	1.90 (.66)	1.76 (.58)	1.61 (.58)	1.61 (.58)	1.90 (.52)	1.54 (.46)
Girls	1.96 (.88)	1.80 (.81)	1.71 (.75)	1.90 (.82)	1.78 (.66)	1.91 (.71)
Combined	1.93 (.77)	1.78 (.70)	1.66 (.67)	1.76 (.72)	1.84 (.59)	1.73 (.62)
Adults						
Men	2.21 (.75)	1.78 (.81)	1.81 (.81)	1.59 (.66)	2.04 (.63)	1.66 (.67)
Women	1.93 (.66)	1.70 (.77)	1.69 (.72)	1.71 (.60)	1.74 (.53)	1.78 (.57)
Combined	2.10 (.71)	1.74 (.79)	1.75 (.77)	1.65 (.63)	1.89 (.60)	1.72 (.62)

Note. Scores range from 1 to 4, with higher scores indicting greater personal interest in performing the occupation.

Discussion

The primary purpose of Study 2 was to determine whether children's, adolescents', and adults' interests in occupations are affected, independently, by (a) the values afforded by occupations and (b) the sex of workers employed within occupations, apart from whatever links exist between these two factors. To accomplish this goal, participants were presented with novel jobs that varied with respect to the depiction of the sex of workers and the description of the values that are afforded by the occupations. Dependent measures included participants' ratings of the values afforded by the jobs, the degree to which participants held egalitarian attitudes about the jobs, and the extent to which participants were personally interested in the jobs.

As a first step, we conducted a manipulation check to make sure that participants had acquired intended knowledge of the workers' gender and of the jobs' value affordances. With respect to gender, participants were almost at ceiling in correctly reporting of the sex of workers that had been depicted in the manipulation. With respect to value affordances, data indicated that the experimental manipulation functioned as intended. That is, participants rated each occupation as affording the value that had been depicted in the manipulation more strongly than any of the other three values.

Unexpectedly, the data for the manipulation check revealed interesting developmental changes in the interrelations among different job values. Among adolescents and adults, there were a number of links among the value ratings of occupations. Specifically, among these older participants, ratings of the degree to which jobs afford money were affected by the manipulation of other values: Their money ratings were significantly higher when told that a job was high in power than when told that the identical job was high in family and altruism. Similarly, these older participants' ratings of the degree to which jobs afford power were affected by the manipulation of other values; their power ratings were significantly higher when told that a job was high in money than when told that the identical job was high in family and altruism. Finally, older participants' ratings of the degree to which jobs afford family values were affected by other values; their family ratings were significantly higher when told that a job was high in altruism than when told that the identical job was high in money or power. Collectively, these findings indicate that adolescents and adults (but not children) have developed an occupational schema that includes links between money and power and between altruism and family values. These data may reflect the association between these value pairs in jobs in actual occupations, and these might be mediated through associations with masculine and feminine jobs. The emergence of such links would be interesting to study in its own right.

As discussed in presenting the rationale for Study 2, one possible basis for interpreting jobs as affording different job values is the link between a job and the sex of workers typically employed in the role, or the sex-type of the occupation. Supporting the hypothesized influence of worker sex on judgments of value affordance was the finding that, among adolescents and adults (but not children), sex of worker affected the perceived value affordances of jobs. Specifically, jobs depicted with female workers were perceived as affording more time with one's family than did the identical jobs depicted with male workers.

Theorists have argued that sex of worker is an important variable because a preponderance of one sex within fields leads to the stereotyping of occupations as appropriate for only one gender (Bussey & Bandura, 1999; Eagly, 1987). We tested this possibility by assessing participants' proscriptive belief about the gender appropriateness of the novel occupations (e.g., "Who should do the job of being bensters?"). Results showed that among adolescents and adults, individuals endorsed more egalitarian attitudes toward jobs depicted with male workers than the identical jobs depicted with female workers. That is, jobs that are dominated by females are perceived as "only for females" and jobs that are dominated by males are perceived as "for both males and females." This discrepancy may be the result of individuals' belief that familiar feminine occupations are lower in status (e.g., money and power) than masculine occupations. This finding also may reflect society's acceptance of women in male-dominated professions (and masculine roles more generally), and society's reluctance to accept men in female-dominated professions (and feminine roles more generally).

The analyses most central to our hypotheses concerned the effects of sex of worker and values depicted in novel occupations on participants' occupational interests. With respect to sex of worker, across ages, participants showed significantly more interest in jobs depicted with workers of their own sex than in identical jobs depicted with workers of the other sex. These data are powerful because they indicate that sex of worker per se influences occupational interests, even when all other job characteristics are identical.

With respect to values, experimentally manipulating the values afforded by novel occupations significantly affected individuals' job interests. In addition, as hypothesized, males and females responded differently to the value manipulation. Across all three age groups, males were significantly more interested in jobs that were depicted as high in money than they were in the identical jobs depicted as high in power, family, or altruism. Overall, females, too, were significantly more interested in jobs that were depicted as high in money than in identical jobs depicted as high in power or family; unlike men, however, females were not significantly more interested in high-paying jobs than they were in altruistic jobs. Furthermore, men (but not women) were more interested in jobs depicted as high in power and family than they were in jobs depicted as high in altruism. In sum, the affordance of altruism was associated with sex differences in occupational interest, producing high interest among females but not among males.

This finding is particularly powerful because it is the first to demonstrate that perceived affordance of occupational values per se (i.e., apart from links to the sex-type and duties associated with an occupation) directly affects individuals' interests in occupations. Furthermore, the causal effect of values differed among males and females, as expected. The affordance of altruism was linked to decreased interest among males but not among females. Interestingly, the effects of the manipulation of values were evident in all age groups included in this research Thus, the results suggest that the sex-type of occupations and values afforded by occupations play important roles in shaping children's, adolescents', and adults' occupational interests.

General Discussion

Gender segregation of occupations is pervasive in the United States and elsewhere. Researchers in developmental psychology have long posited that gender cognitions (e.g., gender stereotypes) play a role in shaping occupational interests. In contrast, researchers in vocational psychology have focused on occupational values as shaping occupational goals. In this article, we used both correlational and experimental designs to examine the roles of both factors.

Gender-related cognitions appear to play an important, causal role in individuals' occupational interests. Consistent with research in the gender development literature (e.g., Bigler & Liben, 1990; Liben & Bigler, 2002; Ruble et al., 2006), results from Study 1 indicated that, in general, males show greater interest in traditionally masculine than feminine occupations, whereas females show greater interest in traditionally feminine than masculine occupations. In addition, results from Study 2 indicated that cognitions about gender segregation of occupations (i.e., sex of workers) alone can play a direct role in shaping individuals' job interests. Specifically, participants at all ages were significantly more interested in jobs depicted with workers of their own sex than in identical jobs depicted with workers of the other sex. These data suggest that merely observing that an occupation is performed exclusively by workers of the other sex may well reduce individuals' likelihood of developing or expressing an interest in that field and suggest the existence of a self-perpetuating cycle that makes it difficult to significantly increase the number of gender-nontraditional workers within fields.

Occupational values also appear to play a role in individuals' occupational interests. Evidence from the current studies is consistent with earlier work (Eccles, 1994; Marini et al., 1996; Schulenberg et al., 1993) in suggesting that sex differences in occupational values may lead to sex-typed occupational interests among adults. Furthermore, this pathway seems to develop gradually, beginning in childhood and strengthening across adolescence. Data from Study 1, for example, indicated that sex differences in occupational values (with males tending to endorse money and power values, and females tending to endorse altruistic and family values) were evident in adults and, to a limited extent, in adolescents, but not children. Furthermore, values differentially predicted individuals' interest in familiar masculine and feminine occupations (Study 1) and, perhaps most notably, predicted males' reported interest in entirely new occupations (Study 2). The finding that males—but not females—expressed greater interest in occupations that were depicted as affording money than those depicted as affording altruism is interesting and may help to explain the types of gender segregation typical of the workforce. The finding is consistent, for example, with research indicating that females are often more interested than males in cross-sex-typed jobs as youth and more willing to work in such jobs in adulthood (Lavine, 1982; Leung & Harmon, 1990; Liben & Bigler, 2002).

Although children did not show gender-differentiated values, their values predicted their interests differently as a function of gender. Males—at all ages—showed stronger interest in jobs depicted as affording high pay than identical jobs depicted as afford helping others. Why and how might boys come to value money more strongly than altruism? It seems possible that children are knowledgeable about the higher average earnings of male than female workers and internalize the value of money accordingly. It also seems possible that males and females might, over the course of childhood and adolescence, come to value different types of altruistic activities. Therefore, for example, although both sexes may value helping, females may prefer to provide emotional or instructional assistance (e.g., as in social work, psychology, and teaching), whereas males may prefer to provide instrumental assistance (as in fire fighting, surgery, or law). Emotional or instructional assistance may be more salient when responding to questions about "helping," and may be less strongly associated with money, than instrumental assistance.

It is also important to acknowledge limitations of this work. The cross-sectional design provides only a start toward understanding the pathways between early gender cognitions and values and later occupational choices. Longitudinal designs have increasingly been used with adolescent and college samples (Watt & Eccles, 2008), and should be extended to younger samples. Furthermore, we examined only four values (i.e., money, power, family, altruism) here. Future research should examine the role that other values have in shaping individuals' occupational interests, perhaps especially those values likely to be salient to children (e.g., adventure, danger, fame). Another limitation concerns our participants' work histories. Participants were not members of the full-time workforce, and thus they lacked experiences that may lead individuals to think more deeply about, and prioritize more strongly, their occupational values. Finally, it should be acknowledged that different patterns between age groups could, in part, reflect the different racial demographics of the three groups. Although the samples, in general, were diverse, they were not perfectly matched across ages and studies. Work indicates that race, ethnicity, and socioeconomic status—like gender—are also important for understanding occupational aspirations (Bigler, Averhart, & Liben, 2003; Cook, Church, Ajanaku, Shadish, & Kim, 1996; for a review, see Hughes & Bigler, 2008) and thus the role of these factors should also be explored in future research on developing values. Thus, although the research reported here provides some insights into the factors that affect individuals' occupational interests, it is also clear that additional research will be needed before the gender-differentiated world of work will be understood and, perhaps, thereby more readily open to educational interventions.

Appendix

Occupational Values Scale for Children

All questions were structured as follows: "Some people have jobs that let them ______; other people have jobs that do not let them ______. How much would you like a job that lets you ______?" For each of 16 items, the following job qualities were inserted into the stem question: 1) let them make the rules for other people; 2) let them help other people; 3) let them quit for a while when they have kids and then they can come back to work when the kids are big; 4) let them earn enough money to buy a large house; 5) let them make important decisions; 6) let them take a day or two off of work to spend time with their family; 7) let them earn a great deal of money; 8) let them help people who need it, like people who are sick, poor, and homeless; 9) let them go to work *and* have lots of time with their family; 10) let them be in charge; 11) help others feel better; 12) let them earn more and more money each year; 13) let them be helpful to others; 14) let them be the boss; 15) let them work part-time (only sometimes, like half-days) when they have young kids; 16) let them take home a lot of money each week.

The Head Bone's Connected to the Neck Bone: When Do Toddlers Represent Their Own Body Topography?

Celia A. Brownell, Sara R. Nichols,

Developments in very young children's topographic representations of their own bodies were examined. Sixty-one 20- and 30-month-old children were administered tasks that indexed the ability to locate specific body parts on oneself and knowledge of how one's body parts are spatially organized, as well as body-size knowledge and self-awareness. Age differences in performance emerged for every task. Body-part localization and body spatial configuration knowledge were associated; however, body topography knowledge was not associated with body-size knowledge. Both were related to traditional measures of self-awareness, mediated by their common associations with age. It is concluded that children possess an explicit, if rudimentary, topographic representation of their own body's shape, structure, and size by 30 months of age.

Children begin learning about their own bodies as newborns. Within a few hours of birth, neonates can tell if the hand caressing their cheek belongs to someone else or is their own (Rochat & Hespos, 1995). As infants use their bodies to engage the world—moving through space, watching their own hands and feet, playing with objects and people—they discover how their bodies move, what their bodies are capable of, and how their bodies and body parts relate to other things in the world (see Adolph & Berger, 2006, for a review). Thus, infants differentiate their bodies and actions from the physical and social world very early, developing a prereflective, ''tactile, auditory, and kinesthetic . . . bodily self'' (Butterworth, 1995, p. 93) over the course of the 1st year (Rochat, 1995).

This implicit, perceptually specified bodily self becomes explicit and available to conscious awareness beginning in the 2nd year of life as toddlers become able to take their own bodies and actions as objects of reflective thought (Bertenthal & Rose, 1995; Moore, 2007; Piaget, 1952; Rochat, 2001). Recent studies have shown that children become consciously aware of the size of their own bodies and of their bodies as potential obstacles or impediments late in the 2nd year of life, with development continuing into at least the 3rd year (Brownell, Zerwas, & Ramani, 2007; Moore, Mealiea, Garon, & Povinelli, 2007). The purpose of the current research was to build on and extend these findings to study very young children's explicit awareness of their body's shape and spatial configuration, sometimes termed *body topography* (e.g., Reed, 2002). To do so, we adapted tasks used to index such knowledge in adults and administered them to children between 20 and 30 months of age. This is the age when body self-awareness has been previously studied and when other aspects of objective self-awareness as traditionally measured are also developing, including mirror self-recognition, self-reference, and self-conscious emotions (e.g., Lewis & Ramsay, 2004).

This research was supported in part by grants from the National Institute of Child Health and Human Development, HD043971 and HD055283, to C.A.B. Portions of this research were presented at meetings of the Society for Research in Child Development and the International Conference on Infant Studies. We thank the children and parents who volunteered their time to participate in this research. Special thanks also to Rita Balaporia, Kacie Bartosavage, Prema Chaudhari, Sabrina DellaMea, Kristen Frey, Charla Newhouse, Yuliya Rinberg, Lauren Shuck, Alina Volper, and Diana Whalen for assistance with data collection and coding, to Alexis Brownell for help with artwork and stimulus preparation, and to Stephanie Sivers for help with manuscript preparation.

Dimensions of Body Representation

The conceptual framework underlying the current work rests on the proposal that children's earliest explicit representations of their own bodies are constructed along several distinct dimensions (Brownell et al., 2007). Two dimensions are the focus of the current study: (a) the body as a physical entity with objective attributes such as height and width (body-size awareness) and (b) the body as an organized collection of body parts with particular, stable spatial relations among them (body topography). This framework derives from empirical and theoretical work in cognitive neuroscience, adult neuropsychology, and developmental psychology.

Cognitive neuroscience researchers have confirmed that an abstract spatial representation of one's own body is associated with particular regions in the intact adult brain (Arzy, Thut, Mohr, Michele, & Blanke, 2006; Chaminade, Meltzoff, & Decety, 2005; Churchland, 2002; Devue et al., 2007; Ehrsson, Kito, Sadato, Passingham, & Naito, 2005; LeClec et al., 2000). Importantly, visual representations of the body in the brain are dissociable from movement-related representations of the body (e.g., Sugiura et al., 2006; Urgesi, Candidi, Ionta, & Aglioti, 2007) and also from the cortical network involved in the human mirror neuron system (see Peelen & Downing, 2007, for a review). Thus, the form of the human body is represented independently of the body's actions in the adult brain, raising the possibility that they are developmentally distinct as well.

Converging evidence from neuropsychological research with brain-injury patients has also shown that there are several distinct systems dedicated to the representation of one's own body (e.g., Schwoebel & Coslett, 2005; Sirigu, Grafman, Bressler, & Sunderland, 1991). For example, patients with damage to the left parietal area often cannot point to their own body parts (autotopagnosia) when an examiner names them (e.g., *elbow*, *chin*), even though they can locate body parts on animals, name human body parts after hearing them defined, and identify individual parts of inanimate objects such as bicycles (Guariglia, Piccardi, Puglisi, & Traballesi, 2002; Semenza, 1988). Such findings suggest a disruption in patients' topographic representation of their own body, which is dissociable from semantic representations of body parts. Other patients with left parietal damage find it especially difficult to imitate meaningless gestures (ideomotor apraxia) when the gesture is positioned at specific locations on the body. For example, a patient might watch an examiner model a gesture next to the ear only to imitate it next to the nose (Buxbaum & Coslett, 2001; Goldenberg, 1996). Because meaningless gestures directed to one's own body must be represented in terms of particular spatial configurations of the body and its parts, such errors suggest disrupted knowledge of the structure of the human body (Chaminade et al., 2005; Goldenberg, 1997; Goldenberg & Karnath, 2006). Notably, these sorts of impairments are not routinely associated with deficits in general motor function or the ability to perform everyday motor activities such as getting dressed or moving through space, again consistent with a distinction between visuospatial and movement-related representations of one's body. That these impairments occur in otherwise normally self-aware individuals further suggests that body self-awareness is a distinct aspect of objective self-awareness. However, research from adult neuroscience and neuropsychology cannot tell us how body self-awareness develops or how it might connect with other elements of the developing self.

Development of Body Self-Awareness

The world is represented from both first-person and third-person perspectives, and these two perspectives appear to become integrated relatively late in infancy, in the latter part of the 2nd year (Barresi & Moore, 1996; James, 1890; Kagan, 1981). This developmental achievement may be especially relevant for children's early body representations. To reflect consciously on one's own body shape and configuration requires integrating one's subjective, first-person experience of oneself with an objective, third-person perspective (e.g., Keysers & Gazzola, 2007; Moore, 2007; Povinelli & Cant, 1995).

Body topography. Slaughter and her colleagues (Heron & Slaughter, 2008; Slaughter & Heron, 2004) have systematically examined infants' developing third-person perspective on the human body as revealed in their knowledge about the body's canonical configuration. In a series of studies, they have established that 15- to 18-month-old infants can visually discriminate noncanonical body configurations (e.g., arms protruding from head instead of torso) from typical body shapes, but in a structured object-examination procedure infants do not reliably categorize typical versus scrambled bodies until 24 months. When an explicit categorization judgment was required, only 30-month-old girls were able to categorize typical versus scrambled bodies correctly; boys could categorize typical and scrambled cars by 24 months but could not categorize human body configurations at either 24 or 30 months (Heron & Slaughter, 2008). Thus, a detailed visuospatial representation of the human body becomes available in the 2nd year of life, when infants recognize the body as having a particular configuration, shape, and structure and are sensitive to the canonical spatial relations among body parts. During the 3rd year of life, knowledge of human body configuration becomes more explicit. However, there is no empirical work addressed to children's corresponding spatial representations of their *own* bodies; the primary aim of the current study was to fill this gap.

To this end, we examined the development of 1- and 2-year-olds' topographic knowledge of their own bodies. Two components corresponding to those studied with adults were the focus: the locations of one's own body parts (body-part localization) and the spatial relation among one's own body parts (body configuration knowledge). Because own body topographic representations have not been studied previously in young children, it is also important to know whether these two putative components cohere, that is, whether children develop a higher order, more general topographic self-map that includes both the specific locations of their body parts and the spatial relations among them. It was therefore a further aim to determine whether body-part localization and body configuration knowledge are related.

Body size. Building on research showing that toddlers sometimes try to fit their bodies into miniature objects that are much too small for them (DeLoache, Uttal, & Rosengren, 2004) or try to fit through a much too narrow opening (Garon & Moore, 2002), we recently examined children's body-size errors between 17 and 30 months of age across multiple tasks (Brownell et al., 2007). Although most of the children made such errors, frequency of errors declined with age as children became more likely to take their own size into account when trying to fit into very small doll clothes, trying to squeeze through a small door to reach their mothers on the other side, or playing with doll-size toys or furniture. A third aim of the current research was to replicate those results, given the novelty of the tasks and the potential importance of the findings.

The fourth aim of the study was to evaluate the potential correspondence between body-size awareness and body topography knowledge. If explicit awareness of one's own body size, shape, and structure is, indeed, emerging in this period, it is important to determine whether and how these early developments are interrelated. Finally, given that scholars have suggested that reflective self-awareness may ground body self-awareness (e.g., Moore, 2007), or vice versa (Povinelli & Cant, 1995), the final aim of the study was to examine associations between dimensions of body self-awareness and more traditional measures of reflective self-awareness.

We expected to find age differences for each dimension of body self-awareness over the 2nd year of life, partly based on prior empirical findings, and partly because this is the period when reflective self-awareness first appears and undergoes significant developmental change (Lewis & Brooks-Gunn, 1979; Nielsen, Dissanayake, & Kashima, 2003). We further expected that measures of body-part localization and body configuration would cohere as components of the larger construct of body topography. However, we had no strongly grounded expectations for potential associations between body topography knowledge and body-size awareness. It is possible that these are somewhat distinct dimensions of developing body self-awareness as suggested by the fact that in adults, distortions in the body image that center on body size (e.g., some eating disorders, body dysmorphic disorder) do not covary with disruptions in spatial awareness of one's body (e.g., autotopagnosia, hemi-neglect). Finally, we expected that both body-size awareness and body topography knowledge would be associated with standard measures of reflective self-awareness insofar as body self-awareness would seem to be grounded in objectification of the self more generally.

Method

Participants

Participants were 61 children at two ages: 20 months ($M = 20.4$ months, $SD = 0.99$; 14 girls, 16 boys) and 30 months ($M = 29.6$ months, $SD = 1.2$; 13 girls, 18 boys). Families were recruited from a medium-sized urban area and nearby suburbs, and were predominantly middle class and Caucasian (86% Caucasian, 7% Asian, 5% African American, 2% Hispanic). All children were walking and were healthy and developing normally by parent report. Three additional children participated but their data could not be used because of motor delay, language delay, or probable autism spectrum disorder.

General Procedure

Procedures took place in two adjacent playrooms and were videotaped for later coding. Parents remained with their children at all times. A primary experimenter (E) administered all procedures with an assistant experimenter (AE) for some tasks. Children became comfortable with both experimenters during a warm-up free play period at the beginning of the session.

Five tasks were administered to assess body self-awareness. Two tasks evaluated children's knowledge of their own body topography, and three tasks evaluated children's understanding of their body size. Each task required 5–10 min to administer; all children received all tasks. The standard mirror self-recognition (rouge) task was also administered midway through the session, and parents completed questionnaires to assess children's self-understanding.

Body Topography Tasks

Two new tasks were developed to provide nonverbal assessments of young children's ability to represent the locations and spatial arrangement of their body parts. These were adapted from tasks used to study body representation deficits in adults with focal brain damage, as reviewed earlier. One task requires adults to point to their own body parts as the examiner names them. Another task requires adults to imitate meaningless gestures directed to particular locations on the body. Toddler versions of both tasks were created and extensively pilot-tested with 40 children between 18 and 32 months of age to provide the assessments used in the current study.

Sticker task: Body-part localization. This task assessed children's ability to locate particular body parts on themselves. Children were asked to place a sticker on an *unnamed* body location on themselves after watching E place a sticker at that location on AE. No body-part names or labels were used, to avoid confounds with developing lexical knowledge.

The child and both experimenters were seated on the floor, with AE directly across from the child, approximately 50 cm away. E drew the child's attention to AE and said, ''Watch, I'm going to put a sticker right there on [name],'' as she placed the sticker on AE. She then said again, ''See, I put a sticker right there,'' while she pointed to or touched the location on AE. She then handed a sticker to the child and said, ''Now you put your sticker on you right there, so it's just like [name]. You put your sticker right there on you.''

The first location was always the nose since previous research has shown that it is one of the first body parts learned: Eighty-five percent of 18-month-olds and 100% of 24-month-olds can point to their nose on request (Witt, Cermak, & Coster, 1990). Based on existing research on body-part naming (MacWhinney, Cermak, & Fisher, 1987; Witt et al., 1990) and parent report from pilot data, the six most often known body locations among 18- to 24-month-olds were determined (nose, hand, foot, head, back, and neck) as well as the six least known locations (forehead, wrist, elbow, calf, temple, and nape). We included both to guard against either floor or ceiling effects; we neither expected every child to know the most familiar, nor did we expect every child to fail the least familiar. These constituted the 12 standard locations presented to each child. Each location was demonstrated one at a time by E. The sticker remained fully visible on AE until the children placed their own sticker on themselves.

Children's sticker placements were scored from video records for accuracy (within 1 in. of location; adjacent location on same body part, different body part, nonbody location, refuse) by two trained coders. Because young children's motor limitations sometimes made it difficult for them to place the stickers with high precision and because it is unlikely that children of this age understand the notion of spot-on accuracy, accurate and adjacent locations were combined to yield the total number of ''correct'' sticker locations. Proportion correct was the measure used in analyses (number of correct sticker placements divided by 12). Interrater agreement was calculated for each coder with a master coder (one of the authors) on 31% of the sample (11% and 20% respectively; $\kappa s = 1.0$ and .96).

Meaningless gesture imitation: Body-part Configuration. This task assessed children's ability to represent the spatial relation among their own body parts. In adults, being able to maintain a meaningless hand gesture and to position it on the body requires explicit awareness and representation of one's individual body parts and the spatial relations among them (Goldenberg, 1996; Goldenberg & Karnath, 2006). Children were asked to imitate a meaningless gesture, a closed fist, positioned at particular body locations. Pilot testing had determined that children within this age range could imitate a closed fist without difficulty.

The child was seated at a child-sized table (65 cm × 45 cm × 40 cm). E sat diagonally to the child, approximately 40 cm to the child's right. She explained to the child that they would play a turn-taking game and then demonstrated one of nine different actions. Each action was demonstrated twice while the child watched. The child was encouraged to imitate after the second demonstration and was given approximately 30 s to do so. If the child did not imitate, the action was demonstrated once again with another opportunity to imitate. If the child failed to imitate again, the next action was demonstrated. For six of the actions, the experimenter demonstratively placed her closed fist on a specific body location (forearm, stomach, cheek, chin, forehead, or top of head). To control for individual differences in motor control, imitative ability, and/or motivation, the child was also asked to imitate three different actions with objects, all directed to the table top (slide a wooden block on the table, pat the table with a plastic dishwashing scrubby, and pound the table with a wooden cylinder). Each of these actions required the child to place the hand approximately in a fist shape to grasp the object, and all of the objects were nonspecific to the action demonstrated, thus all were novel action–object combinations.

Children's performance was scored from video records by two trained coders for the number of correct imitations. A response was considered correct if the child imitated the experimenter's action at the same location (within 1 in., and without penalty for confusions between left and right), using the same hand configuration (for gestures) and orientation (for gesture and objects) as the experimenter's. Interrater agreement for the number of correct trials was calculated on 21% of the sample ($\kappa = .91$).

Body-Size Tasks

Three tasks indexed children's ability to reason about their own body size relative to objects in the world. These were identical to those used in our prior study (Brownell et al., 2007) since one aim of the current study was to replicate those findings. Additional details about the tasks can be found in that publication.

Doll clothes. In this task, children were offered much too small doll clothes to wear. The child watched as the experimenter dressed a 30-cm doll in a doll-sized hat, jacket, and shoes. After placing each piece of clothing on the doll, the experimenter handed the child an identical piece of doll clothing and said simply, "Here's your [hat, jacket, shoe]." Attempts by children to put the doll clothes on themselves as if the clothing were full-sized were scored as errors (coding details given later).

Door choice. This task required the child to choose one of two doors to reach a parent on the other side of a 1 m × 2 m foamboard wall, only one of which the child could fit through (adapted from Garon & Moore, 2002). One door was a 30 cm × 30 cm hole in the wall, with a 10-cm square window above it through which the child could see the parent. Children could easily crawl through this door. The second door was tall and narrow (10 cm wide × 80 cm tall), and the child could also see the parent through this hole; however, it was much too narrow for the child's body. The child was placed equidistant between the doors, and the parent then called the child. Once the child had joined the parent on the other side, the experimenter called the child to return. Children's attempts to squeeze their bodies through the too small door were scored as errors.

Replica toys. In this task (adapted from DeLoache et al., 2004), children played with a standard set of child-sized toys (Little Tikes™ slide, toddler chair, cozy coupe car; Little Tikes Company, Hudson, OH) and then several minutes later played with a separate set of small, doll-sized replicas of the same toys; these were approximately 8–14 cm high, and one fifth to one sixth the height of the child-sized toys. Children were free to play with the replica toys however they wished for approximately 5 min. Attempts to use the replica toys as if they were full-sized, without considering that their bodies are too big for such small toys (e.g., trying to sit in the doll chair), were scored as errors.

Body-size awareness measures. Children's behavior was coded from the video records by two trained coders. An error was defined as a serious, nonpretend attempt, based on the child's action, facial expression, and effort. For example, a serious attempt to wear the doll jacket meant attempting with clear effort to put the hand and forearm fully into the sleeve; a serious attempt to sit in the doll-sized replica chair involved positioning the body appropriately and then sitting with one's full weight on the chair with a neutral facial expression (and perhaps surprise at the outcome). Each independent attempt was counted as an error. Interobserver reliability for the number of errors on each task was calculated on 21% of the sample; because the codes were not mutually exclusive and exhaustive, percent agreements rather than Kappas were calculated for the individual tasks, and ranged from 82% to 89%.

Reflective Self-Awareness

Three independent, age-appropriate measures of reflective self-awareness were obtained using established procedures: (a) mirror self-recognition, (b) parental report of the child's self-description and self-evaluation, and (c) parental report of the child's comprehension and production of personal pronouns. Mirror self-recognition was assessed using the standard, well-replicated ''rouge task'' (Amsterdam, 1972) in which the parent surreptitiously placed a dab of red lipstick on the child's nose during free play. A brief period of continuing play ascertained that the child neither noticed the lipstick nor tried to remove it spontaneously. The experimenter then held a 30 cm × 30 cm mirror in front of the child so that a full view of his or her own face was visible, drawing the child's attention to the mirror. If the child did not respond after approximately 10 s, the experimenter asked ''Who's there?'' while pointing to the mirror; if the child did not attend after an additional 10 s the experimenter asked ''What's on his or her nose?'' again pointing to the mirror.

Children's mirror-related behavior was independently coded from video records by two trained coders. Behaviors included touching or turning away from the mirror, saying own name, touching own nose, touching other parts of the face, attempting or requesting to remove the lipstick, and self-conscious behavior such as embarrassment. Children's performance was scored on a 3-point scale (after Asendorpf, Warkentin, & Baudonniere, 1996; Courage, Edison, & Howe, 2004; Rogdon & Kurdek, 1977): *pass* (2) if they said their own name, touched their own nose, or attempted or requested to remove the lipstick (48% of 20-month-olds, 81% of 30-month-olds); *ambiguous* (1) if they touched other parts of their face but not their nose, touched their nose upon hearing the word *nose* in the experimenter's attention-eliciting cue, or were self-conscious in front of the mirror (24% of 20-month-olds, 19% of 30-month-olds); *fail* (0) if they engaged in any other behavior, including saying ''baby,'' touching the mirror, ignoring it, or turning away from it without self-conscious behavior (28% of 20-month-olds, 0% of 30-month-olds). Interobserver reliability was calculated on 21% of the sample ($\kappa = .88$).

Parents completed the UCLA Self-Understanding Questionnaire developed for this age group (Stipek, Gralinski, & Kopp, 1990), with 17 items rated on a 3-point scale (0 = *definitely not*, 1 = *sometimes/just starting to*, 2 = *definitely*). Items tap self-recognition, self-description, and self-evaluation (e.g., recognizes self in photos; uses own name; says ''me,'' ''mine''; uses terms like *good* or *bad* about self); Cronbach's alpha = .91. Parents also completed the toddler form of the MacArthur Communicative Development Inventory (MCDI; Fenson et al., 1994). Because we were interested in words referring to self and other, and because use of personal pronouns has previously been shown to relate to mirror self-recognition in this age group (Lewis & Ramsay, 2004), we used the *Pronouns* subscale of the MCDI for which the parent indicates whether the child understands (a) or understands and says (b) eight personal pronouns (e.g., *her, you, me*); Cronbach's alpha = .93. The three measures of reflective self-awareness were significantly intercorrelated (*r*s = .35–.59, *p*s = .001–.005), so were standardized and summed to produce a single, global measure of reflective self-awareness (Cronbach's alpha = .77).

Results

Preliminary analyses indicated that there were no sex differences on any measure; thus, analyses were collapsed over sex. Table 1 shows mean values and standard errors for all variables. Substantive analyses were conducted to address several questions. The first set of analyses examined age differences for each aspect of body knowledge (body-part localization, body configuration, body size) and for reflective self-awareness. The second set tested associations between body-part localization and body configuration to determine whether there was evidence for a general topographic representation of one's own body in children of this age. The third set examined associations between body-size awareness and body topographic knowledge to determine whether they are part of a more general body-awareness construct or whether they are distinct. The final set of analyses examined associations between elements of body knowledge and reflective self-awareness. Not all children completed all tasks; thus, *n*s vary slightly across analyses.

Reflective self-awareness (z score)[a]	−0.04 (0.32)	−1.83 (0.22)	1.69 (0.23)	60.89	.001

[a] MSR + UCLA self-understanding + CDI personal pronouns.

30 months) were conducted as appropriate on the measures of each dimension of body representation and on the composite measure of reflective self-awareness. As expected, we found systematic age differences for each measure.

Body-part localization. Children were asked to place stickers on 12 different body locations on themselves after watching a sticker placed at each location on another person. A univariate ANOVA with proportion of correct sticker placements as the dependent variable yielded a significant age effect, $F(1, 59) = 4.87$, $p = .031$, $\eta^2 = .08$. Older children placed nearly twice as many stickers on or adjacent to the correct body part as did younger children (see Table 1), although it should also be noted that even older children were still far from perfect. Some children frequently placed stickers on surrounding objects instead of on themselves or refused to place several stickers anywhere ($n = 15$). When these children were removed from the analysis, average performance rose (20 months, $M = 0.23$; 30 months, $M = 0.47$), and the significant age effect remained, $F(1, 44) = 9.57$, $p = .003$, $\eta^2 = .18$.

Body configuration. Children were asked to imitate a meaningless gesture directed to their own bodies at six different locations; in the comparison condition they were asked to imitate three different actions with an object directed to a table top. A repeated measures ANOVA with location (self, table) as the within-subjects factor and age as the between-subjects factor was conducted on the proportion of correct imitations (see Table 1). A significant effect for location emerged, $F(1, 55) = 17.20$, $p < .001$, $\eta^2 = .76$, as well as a marginally significant interaction between age and location, $F(1, 55) = 3.69$, $p = .06$, $\eta^2 = .06$. As evident in Table 1, younger children performed as well as older children when imitating actions directed toward the table but performed less accurately than older children when they had to imitate a gesture directed to their own body.

Body size. The number of times children attempted to fit themselves into small doll clothes, through small openings, or onto or into miniature toys that were much too small was recorded. A multivariate ANOVA with the three measures of body-size awareness (doll clothes errors, door choice errors, and replica toys errors) as dependent variables yielded a significant age effect, multivariate $F(3, 52) = 6.48$, $p = .001$, $\eta^2 = .27$. The follow-up univariate tests for age differences on each dependent variable were also significant (see Table 1, for Fs and p values). Thus, on all three measures, 30-month-olds produced significantly fewer errors than did 20-month-olds, replicating the findings of Brownell et al. (2007). Also as in Brownell et al., children's performance in the current study was correlated across the three tasks (rs = .22–.35, ps = .10–.006).

Reflective self-awareness. A composite measure of reflective self-awareness was created from mirror self-recognition scores, children's self-description and self-evaluation, and their personal pronoun comprehension and use. The ANOVA yielded a significant age effect, $F(1, 59) = 60.89$, $p < .001$, $\eta^2 = .51$, as expected (see Table 1).

Evidence for a Topographic Body Representation

To determine whether children's body-part localization and body configuration knowledge

constituted related components of a higher order topographic representation of their own bodies, Pearson correlations were calculated between children's performance on the sticker task and their performance on the imitation task (see Table 2 for correlation coefficients). The significant association suggests that young children do possess a general topographic representation of their own bodies.

Unexpectedly, however, children's ability to locate stickers on their own body was also associated with their imitation of object actions directed to the table (see Table 2), suggesting that some factor related to general imitative skill or motivation might also be at work and could explain the above association. To control for this possibility, we recalculated the correlation between children's score for imitating gestures to their own bodies and their score for placing stickers on particular body parts, partialing out their ability to imitate actions with objects; the correlation remained significant, partial $r(57) = .43$, $p = .001$. Finally, we further partialed age; children's ability to imitate meaningless gestures to their own body remained significantly associated with their ability to locate particular body parts on themselves above and beyond both general imitative ability and age, partial $r(56) = .32$, $p = .014$.

Associations Between Topographic Body Representations and Body Size Awareness

To determine to what extent topographic body knowledge and body-size awareness are distinct or related, Pearson correlations were calculated between a composite measure of body-size awareness (the total number of body-size errors across all tasks; Cronbach's alpha = .61) and the measures of each of the other two components of body awareness, that is, body-part localization and body configuration. Neither of these correlations was significant (see Table 2 for correlation coefficients), including when age was partialed from the calculations. A composite score for body topography knowledge was also created as the sum of z scores for the sticker and gestural imitation tasks, and was likewise unrelated to the number of body-size errors. It thus appears that there are two distinct aspects of early body self-awareness, one related to children's knowledge of their own body size and one related to the topographic representation of their body and its parts.

Associations Between Body Representation and Reflective Self-Awareness

Finally, to determine whether the different aspects of body self-awareness indexed in the current study were associated with reflective self-awareness as traditionally assessed, Pearson correlations were calculated between the composite self-awareness measure and the composite measures for body-size awareness (number of errors), $r(59) = -.33$, $p = .01$, and body topography knowledge (number correct), $r(64) = .38$, $p = .002$. The same results were obtained when the self-awareness composite was correlated with the separate measures for body-part localization and body configuration knowledge individually (see Table 2), as well as when the composite measure of reflective self-awareness was decomposed into its individual constituents. When age was partialled, associations became nonsignificant ($rs < .20$). Thus, as expected, reflective self-awareness was associated with each dimension of body self-awareness studied here;

however, these relations were carried by their common association with age.

Discussion

Early developments in children's explicit, conscious representations of their own body's objective physical characteristics such as shape, size, and configuration were explored in the current study. Development of body self-awareness is relatively uncharted despite continuing interest in the growth of self- and other-understanding (Brownell & Kopp, 2007), and the potential for identifying the roots of childhood body image in infancy (Smolak, 2004). We report evidence that children's topographic representation of their own bodies emerges between 20 and 30 months of age.

We further found that this aspect of early body knowledge appears to be constituted of two related dimensions. One dimension reflects knowledge about where specific body parts are located on one's own body even when these are not named or previously known. The second reflects knowledge about how one's body is spatially configured, that is, how one's body parts are arranged or spatially organized in relation to one another. Both appear to be still relatively immature at 2½ years of age, pointing to continuing development over the preschool years. We also found that children become aware of their own body size during the 2nd year of life, replicating previous findings (Brownell et al., 2007). Interestingly, children's awareness of their body's topographic characteristics was unrelated to their body-size awareness. Both were related, however, to a multifaceted measure of self-recognition and self-awareness, albeit mediated by their common associations with age.

Together with other recent research (e.g., Brownell et al., 2007; Moore et al., 2007; Nielsen, Suddendorf, & Slaughter, 2006), the findings from the current study confirm that body self-awareness is a unique aspect of the development of an objective, conscious self. The results further suggest that the child's developing body image, even in its initial and relatively primitive form, is constituted of multiple, distinct dimensions. In particular, previous research showed that body self-awareness emerges in the 2nd year as explicit awareness of one's physical characteristics like size, mass, or solidity, and of being able to enter into object–object relations with other physical objects by serving as an obstacle, tool, encumbrance, or container (Brownell et al., 2007; Moore et al., 2007). The current results suggest that it is somewhat later, in the 3rd year of life, that awareness of the topographic or spatial organization of one's body also appears. By age 2½, then, children have a beginning knowledge of their own body's size, shape, and structure.

Of course, toddlers' conscious awareness of their own body size and configuration does not arise de novo, but emerges out of and builds on an extensive implicit and perceptually based bodily self established over infancy. This includes sensitivity to body dimension parameters (e.g., Adolph & Avolio, 2000) and to one's own body parts such as hands (McCarty, Clifton, & Collard, 1999). For example, before 12 months of age infants can scale motor actions like reaching or throwing to take account of object size, position, orientation, speed, or function in motor planning tasks (e.g., Claxton, Keen, & McCarty, 2003; Lockman, Ashmead, & Bushnell, 1984; von Hofsten, Vishton, Spelke, Feng, & Rosander, 1998; Witherington, 2005). With the advent of reflective self-awareness in the latter half of the 2nd year, this implicit, sensorimotor knowledge of one's body becomes available to conscious awareness. As Moore (2007) has argued, it is during this period that infants' developing first-person knowledge of their own bodies becomes integrated with their developing third-person knowledge of others' bodies. This, in turn, permits conscious reflection on body characteristics of both self and others, thereby also grounding the subsequent development of the body image.

Own Body Topography

To study toddlers' own body representations, we created age-appropriate modifications of tasks used by investigators of adults' representations of their own body configuration (e.g., Goldenberg & Karnath, 2006; Guariglia et al., 2002; Schwoebel, Buxbaum, & Coslett, 2004). In one task, children were asked to locate body parts by placing a sticker on a particular location on their own body after watching an adult place a sticker at that location on an assistant's body without naming the location or body part. On average, 20-month-old children were able to locate only two or three common body parts (e.g., nose, hand, foot), whereas 30-month-olds were able to locate four or five (e.g., nose, hand, foot, head, neck). These findings indicate that children's knowledge of the specific locations of their own body parts is quite primitive at 20 months of age, but is well in evidence by 30 months, even though still immature.

A similar procedure was used by DeLoache and Marzolf (1995) to study preschoolers' ability to use a doll to represent their own body. In that study, when an experimenter placed stickers on four specific places on the child's body (forearm, knee, foot, and neck) and then asked the child to place stickers in the same places on the doll, 32-month-old children placed only 1.6 stickers correctly out of the 4 possible. Moreover, children found it equally difficult to perform the procedure from doll to self. This suggests that for 2-year-olds, mapping between one's own body and a doll's body may be even more difficult than mapping between one's own body and an adult's body, possibly because of additional cognitive demands in forming a representational relation between self and a pretend object. More relevant for the current study, these findings confirm that during the 3rd year of life children's spatial knowledge of their own bodies undergoes substantial progress.

In contrast to the findings from these two studies, lexical acquisition studies indicate that 12-month-olds can identify two body parts on average when asked to point to them by name (Witt et al., 1990) and that by 18–24 months of age children can name and point to several specific body parts on themselves (Bretherton, McNew, & Beeghly-Smith, 1981; Kopp, 1994). However, learning to point to specific body parts on command may be a result of highly practiced routines and thus need not depend on or reflect a more general representation of the spatial configuration of the body, including where various unrehearsed body parts are located and how body parts are arranged and organized in relation to one another. This is why, in the current study, we included body parts for which children did not yet have names (e.g., elbow) and refrained from naming those body parts for which they were likely to possess a label (e.g., nose, foot). We are confident, therefore, that children's performance in the current study was not a result of stereotyped routines for pointing to specific, well-rehearsed body locations on request. Instead, we conclude that children's explicit self-representations undergo significant developmental change at the end of the 2nd year of life and into the 3rd year.

In the second task used to index their body topography knowledge, children were asked to imitate a meaningless gesture (closed fist) placed at different locations on the body (e.g., top of head, stomach). This requires consideration of multiple relation among specific body parts, both those involved in making and maintaining the gesture itself, and the location on the body at which the gesture is placed (Goldenberg, 1996). We found that 30-month-old children were able to position their fists accurately on their own bodies more than 3 times as often as were younger children. Importantly, younger and older children were equivalent in their ability to imitate object-related actions directed to a table top. Thus, it was not general imitative ability that limited the younger children's performance, but the specific ability to imitate a gesture directed to locations on their own bodies. Like the results for children's knowledge of where their body parts are specifically located, these findings indicate that knowledge of how their own body is spatially organized is also quite rudimentary in 1-year-olds, becoming evident in young 2-year-olds, though clearly still primitive even then.

These data are consistent with previous findings that imitation of unfamiliar and/or nonvisible bodily movements and gestures is more difficult than imitation of familiar movements or imitation with objects, both in normal children under 24 months and in children with autism (Abravanel, Levan-Goldschmidt, & Stevenson, 1976; Brownell, 1988; Jones, 2007; Masur, 1993; Masur & Ritz, 1984; Rogdon & Kurdek, 1977; Rogers, Hepburn, Stackhouse, & Wehner, 2003; Stone, Ousley, & Littleford, 1997). They are also consistent with several recent anecdotal reports of children's inaccurate matching responses when they imitate behavior with or on specific body parts. For example, when 14- or 18-month-old infants watched an adult illuminate a light by using her forehead or elbow to touch the light, they imitated body-part-specific actions only approximately; that is, they used their mouth, chin, cheek, or even ear to touch the light, rather than the forehead as modeled (Herold & Akhtar, 2008; Southgate, Gergely, & Csibra, 2009), or they used the back of the hand instead of the elbow as modeled (Herold & Akhtar, 2008). In a different study, when 12- and 18-month-old infants were asked to imitate actions with objects on their own body after watching an experimenter model the behavior on herself (e.g., roll a car on an arm, tap a plastic ring against the cheek), children often failed to use the correct body part when they imitated; for example, they would tap the ring on their chin instead of their cheek (Carpenter, Tomasello, & Striano, 2005). Together, these data converge on the conclusion that the ability to represent explicitly the spatial relation among one's own body parts begins to take form late in the 2nd year of life, between 20 and 30 months of age.

Despite the rather pronounced demand differences in the sticker (body-part localization) and imitation (body configuration) tasks, children who performed better on one task also performed better on the other, even with both age and general imitative ability controlled. Performance on body-part localization and meaningless gesture imitation tasks is also strongly associated in adults with brain damage ($r = .78$; Schwoebel et al., 2004), and seems to call on similar regions of the brain (Goldenberg & Karnath, 2006). Our data thus suggest that by 30 months of age young children, like adults, begin to access consciously a general representation of their own bodies' spatial organization. Even these 2-year-olds, however, were far from ceiling on either task, which indicates that development of this complex aspect of body self-awareness must be ongoing well past the toddler years.

Own Body-Size Awareness

The current study provided an independent replication of our previous work in which we found developmental changes over the 2nd year in children's knowledge of their body size (Brownell et al., 2007). Interestingly, a recent study has shown that young children between 16 and 60 months of age are poor at scaling their reaching actions to the size of their own hands; 1- and 2-year-olds, in particular, tried repeatedly to fit their hands through impossibly small openings to reach something on the other side, even after their hands became stuck (Ishak & Adolph, 2008). Thus, the ability to imagine and attend to one's own body size begins to emerge in the 2nd year of life and appears to continue developing over the preschool years.

The fact that body-size awareness and body topography knowledge were not associated with each other suggests that these body representations are somewhat distinct and may develop partly independently of one another. Christie and Slaughter (2009) similarly found no associations between infants' sensorimotor body representations and their visuospatial body representations, prompting those authors to suggest that different body representation systems may initially be differentiated, then become integrated over the course of infancy and early childhood. Another possibility is that there are additional task demands, or perhaps affordances, unique to some of the body-size awareness tasks used here and by Brownell et al. (2007). If fitting through doorway openings, for example, relies on children's affordance detection rather than (or in addition to) explicit knowledge of their own body size, then failure may reflect other performance factors such as immature impulse control, or other demand factors such as low cost for failure. Teasing apart potential contributions to failure on such tasks holds promise for better understanding the mechanisms that contribute to eventual success, and the circumstances in which explicit body knowledge can or must be invoked.

Reflective Self-Awareness and Body Self-Awareness

Body-size awareness and body topography knowledge were associated with traditional measures of reflective self-awareness, including mirror self-recognition, self-description and self-evaluation, and language about self and other. However, this association was carried by the strong common associations with children's age. These findings contrast with those of Moore et al. (2007) who found that toddlers' ability to move themselves off a rug attached to the rear of a shopping cart before pushing it was related to mirror self-recognition, even with age controlled. However, the association with self-recognition was modest in that study, leading the authors to propose that body self-awareness and mirror self-recognition tap different, but related, aspects of developing self-awareness. We draw the same conclusion from the findings of the current study, noting further that mirror self-recognition is mastered by most children by 24–30 months of age, whereas children's body self-awareness remains rather rudimentary at 30 months of age, with development extending into early childhood. Reflective self-awareness may thus be a necessary foundation, but not sufficient to account specifically for growth and change in body-size awareness or topographic body knowledge.

This proposal is consistent with recent arguments for a somewhat extended developmental course for other complex aspects of self-recognition (Suddendorf, Simcock, & Nielsen, 2007). For example, there is a developmental lag of about 1 year between children's mirror self-recognition and their ability to recognize themselves in real-time video, even after controlling for differences in the perceptual features of the two types of display. Suddendorf et al. (2007) speculate that this developmental asynchrony is explained by an immature mental self-image among younger children, which is lacking in the abstraction necessary to support a general, intermodal representation of their own appearance. It would be interesting in future research to determine whether the child's primitive body image, as reflected in the kinds of tasks used in the current study, consolidates during the same period in development as video and shadow self-recognition, which are presumably also based on an objective, integrated, spatially configured own body representation. Such a general representation of one's appearance may serve as a developmental link between the perceptually specified bodily self of infancy and the later emergence of the body image in early childhood.

This experiment tested whether peer approval and disapproval experiences can cause immediate change in children's state self-esteem. Children's narcissistic traits and evaluator perceived popularity were examined as potential moderators. A total of 333 preadolescents (M = 10.8 years) completed personal profiles on the Internet that were ostensibly judged by a jury consisting of popular and unpopular peers. Participants randomly received negative, neutral, or positive feedback from the jury. Next, they could examine the feedback that each individual judge gave them. As expected, peer disapproval decreased self-esteem, especially in children high in narcissism. In contrast, peer approval increased self-esteem. Moreover, disapproved children's self-esteem recovery was dependent on the extent to which they subsequently viewed positive feedback from popular judges. These findings support sociometer theory.

> *As social beings we live with our eyes upon our reflection, but have no assurance of the tranquillity of the waters in which we see it.*
>
> —Charles Horton Cooley, 1902, p. 247

Is children's self-esteem dependent on how much they are liked by others? Classical theory holds that throughout development, children gradually come to internalize the opinions that others hold of them into more or less stable patterns of self-esteem (Cooley, 1902; Mead, 1934). Supporting this view, research shows that children's *trait* self-esteem (i.e., their enduring appraisal of value as a person) tends to reflect the cumulative appraisals of others in the past (e.g., Boivin, Hymel, & Hodges, 2001; Cole, Jacquez, & Maschman, 2001; Felson & Zielinski, 1989; Ladd & Troop-Gordon, 2003; but see Salmivalli & Isaacs, 2005, for an exception). Another classical view holds that self-esteem is open to temporary fluctuations, and may wax and wane from moment to moment around an "average tone of self-feeling" (James, 1890). This latter, fluctuating type of self-esteem is called *state* self-esteem. Surprisingly little is known about the extent to which children's state self-esteem is sensitive to appraisals from others in the here and now. One possibility is that children's state self-esteem is only marginally reactive to current approval experiences, because these experiences are embedded in a long history of previous social interactions. Another possibility is that children's state self-esteem is profoundly reactive to current approval experiences, because these experiences are highly salient and meaningful in the present. This study uses an in vivo, experimental peer evaluation design to examine children's interpersonal state self-esteem reactivity in real time. In addition, it examines some theoretically relevant factors that may influence children's state self-esteem reactivity, namely narcissism and the perceived popularity of the person providing the appraisal.

Interpersonal Appraisals and the Modulation of State Self-Esteem

A pivotal contemporary account of interpersonal influences on self-esteem is found in sociometer theory (Leary & Baumeister, 2000; Leary & Downs, 1995). The basic assumption underlying the theory is that human beings possess a pervasive drive to

be valued and accepted by others, a drive that evolved because our ancestors were more likely to survive and reproduce when they belonged to social groups (e.g., Ainsworth, 1989; Baumeister & Leary, 1995; Leary & Baumeister, 2000). Sociometer theory posits that self-esteem has evolved to (a) monitor how much one is valued and accepted by others, (b) evoke positive or negative feelings that signal change in others' approval, and (c) provide an outlook for how one may be approved in future interactions so that one can try to prevent possible disapproval. Thus, according to sociometer theory, interpersonally based changes in self-esteem are not just accidental by-products of positive or negative social interaction; they are central in enabling people to gain, maintain, and restore approval from others.

These functions of self-esteem are thought to operate in the short run and in the long run. Trait self-esteem is proposed to function as a long-term gauge that monitors the amount of approval obtained from others, instills enduring negative mood (e.g., depression) when one is disapproved by others, and motivates people to prevent long-term exclusion. State self-esteem is proposed to function as a short-term gauge that continuously monitors one's social environment and signals changes in immediate approval obtained from others. Social cues that connote approval or disapproval are assumed to *modulate* state self-esteem and trigger positive or negative affect (e.g., feelings of pride or shame), signaling that one's "relational value" is bound to change. The pleasure or pain associated with state self-esteem fluctuations should motivate people to prevent exclusion in near future interactions. Research involving adult participants supports both the trait and state self-esteem postulates of sociometer theory. Trait self-esteem is a direct function of the extent to which adults generally feel approved by others (e.g., Leary, Cottrell, & Phillips, 2001; Leary, Tambor, Terdal, & Downs, 1995). Interpersonally based changes in trait self-esteem elicit longer term changes in negative mood and one's outlook for others' approval (e.g., Johnson, Meyer, Winett, & Small, 2000). State self-esteem, in contrast, fluctuates according to how adults feel approved by others *in the moment*, and these fluctuations bring about short-term changes in negative mood and alert individuals to possible exclusion in the near future (e.g., Leary & Downs, 1995; Leary, Haupt, Strausser, & Chokel, 1998; Oosterwegel, Field, Hart, & Anderson, 2001).

Empirical evidence for sociometer theory in children, however, is incomplete. That is, research in children has focused almost exclusively on long-term trait self-esteem and its interpersonal determinants (e.g., Boivin et al., 2001; Felson & Zielinski, 1989; Ladd & Troop-Gordon, 2003), and has largely neglected short-term state self-esteem and its interpersonal determinants. This seems unfortunate, because the psychological foundation for sensitivity to others' appraisals is laid early in life (Rubin, Bukowski, & Parker, 2006). From middle childhood to preadolescence, two cognitive advances allow for interpersonal influences on self-esteem (Harter, 1999, 2006). First, improved perspective taking skills help preadolescents to better appreciate the appraisals of others. Second, the newfound ability to form higher order concepts allows preadolescents to make global self-evaluations (e.g., "I am satisfied with myself as a person") rather than more concrete and domain-specific self-evaluations (e.g., "I am good at soccer") that are typical for younger children. Because self-esteem is relatively unstable in preadolescence (Harter, 1999, 2006), one might expect ongoing appraisals of others to have a particular strong impact at this age. Appraisals of peers should be especially important because the peer group exerts an increasingly salient socializing function in preadolescence (Harter, Stocker, & Robinson, 1996; Rubin et al., 2006; Rudolph, Caldwell, & Conley, 2005).

A few studies have examined how children *think* their self-esteem depends on current peer appraisals (Burwell & Shirk, 2006; Harter & Whitesell, 2003; Harter et al., 1996; Rudolph et al., 2005). To our knowledge, however, only one study examined the self-esteem fluctuations that children actually *experience* following current peer appraisals, and the evidence from this single study was inconsistent with sociometer theory (Nesdale & Lambert, 2007). Specifically, Nesdale and Lambert (2007) found that experimentally manipulated social rejection triggered negative affect (e.g., sadness, anxiety) but triggered no changes in children's self-esteem. Two limitations of Nesdale and Lambert's pioneering work should be noted, however. First, children were asked to role play a situation in which they were socially rejected; the social rejection was not played out in vivo. Although children can be responsive to role play (Rubin et al., 2006), their experience of pretended social encounters does not necessarily correspond well to their experience of actual social encounters (Robinson & Clore, 2002). Second, a measure of *trait* self-esteem was used (sample item: "I think I can do things as well as anyone else"), whereas sociometer theory predicts that current interpersonal appraisals influence children's *state* self-esteem (Leary, 1999; Leary et al., 1995). The first goal of the present experiment is to examine whether peer approval and disapproval modulate preadolescents' state self-esteem using an in vivo experimental peer evaluation manipulation.

Individual Differences in the Interpersonal Modulation of State Self-Esteem

According to sociometer theory, interpersonal self-esteem reactivity likely is a universal human trait. Of course, this is not to say there are no individual differences in the degree to which children's self-esteem is dependent on others' appraisals. Whereas some children's state self-esteem may be stable and relatively unaffected by current peer approval or disapproval experiences, other children's state self-esteem may be unstable and highly reactive to those experiences (Rudolph et al., 2005). The logic underlying sociometer theory implies that these individual differences should be a direct function of the importance children attach to being valued by others (see also Harter, 1999). Children who are greatly concerned with being valued by others should theoretically show pronounced interpersonal self-esteem reactivity.

An excessive need for external validation is a hallmark feature of the trait of narcissism. Whereas narcissism is a personality disorder in its extreme form (*DSM–IV*; American Psychiatric Association, 1994), most current psychological research (including our own) focuses on ''normal narcissism,'' operationalized as a personality trait on which people in the general population vary (Morf & Rhodewalt, 2001; Raskin & Terry, 1988). ''Normal narcissists'' believe they are superior to others, yet at the same time they worry obsessively about what others think of them. They crave to be respected and admired by others, and tend to respond with intense emotions when they receive negative interpersonal feedback (Baumeister & Vohs, 2001; Morf & Rhodewalt, 2001; Rhodewalt & Morf, 1998). Thus, narcissistic self-esteem is not only grandiose but is also markedly vulnerable to negative social experience (Morf & Rhodewalt, 2001). Recent research found that individual differences in narcissistic traits can be meaningfully measured in children at least 8 years old (Thomaes, Stegge, Bushman, Olthof, & Denissen, 2008) and that narcissistic children are emotionally reactive to negative social events (Thomaes, Bushman, Stegge, & Olthof, 2008). The second goal of this experiment is to examine narcissism as a potential moderator of the interpersonal modulation of state self-esteem. To establish discriminant validity, the moderating effect of narcissism is contrasted with the moderating effects of self-perceived social acceptance and peer-perceived social preference. These variables were chosen as controls because they are often considered indexes of social vulnerability (e.g., McElhaney, Antonishak, & Allen, 2008; Patterson, Kupersmidt, & Griesler, 1990) but do *not* involve an excessive need for external validation, which is presupposed to be a key determinant of individual differences in interpersonal self-esteem reactivity.

Interpersonal Appraisals and the Regulation of State Self-Esteem

Similar to other evolutionary-based monitoring mechanisms (e.g., hunger), self-esteem can reach certain critical low levels at which it is experienced as unpleasant, which then motivate behaviors intended to decrease the unpleasantness. Just as hunger feels bad and therefore motivates people to seek for food, lowered state self-esteem feels bad (i.e., triggers emotional distress) and therefore may motivate people to seek praise and positive feedback from others (Leary & Baumeister, 2000). Theoretically, the more positive feedback that disapproved children with lowered state self-esteem obtain, the more their self-esteem should recover. We therefore propose that interpersonal appraisals are involved not only in the modulation of state self-esteem but also in the subsequent *regulation* of state self-esteem.

One might be inclined to assume that when disapproved children with lowered state self-esteem manage to subsequently acquire positive social feedback, they should invariably show pronounced increases in state self-esteem. Such a position may be oversimplified, however. From a young age, children attach differential importance to the appraisals that others hold of them, typically based on salient characteristics of others that cue group membership (Crick & Dodge, 1994; McAninch, Manolis, Milich, & Harris, 1993; Mrug & Hoza, 2007). In elementary school, one important characteristic that children use to judge each other is perceived popularity (LaFontana & Cillessen, 2002). Children who are perceived as popular exert a strong influence on their peers. They are on the top of the social hierarchy and to a large extent they determine the social rules according to which some children are valued and accepted whereas others are not (Adler & Adler, 1998; Hawley, Little, & Pasupathi, 2002; LaFontana & Cillessen, 2002). Thus, if state self-esteem functions as a monitor of children's relational value, it should be particularly reactive to appraisals provided by perceived popular peers. The third goal of this experiment is to examine how peer appraisals influence the regulation of disapproved children's lowered state self-esteem. In particular, it will be examined whether positive appraisals from perceived popular peers have a stronger regulatory impact on state self-esteem than appraisals from unpopular peers.

Present Study

An experimental peer evaluation manipulation was used to examine the modulation and subsequent regulation of children's state self-esteem. Children's narcissistic traits and evaluator perceived popularity were examined as potential moderators of children's state self-esteem reactivity. Participants ranged in age from 8 to 12 years. This age group was chosen for four reasons. First, children this age have acquired the abilities to appreciate others' appraisals of them and to evaluate their global worth as a person (Harter, 1999, 2006). Second, children this age attach great importance to the opinions and appraisals of peers, much more so than younger children (Damon & Hart, 1988; Harter, 1999, 2006; Rosenberg, 1979). Third, given their heightened concern with who is popular and who is not, children this age may be especially susceptible to the appraisals of perceived popular peers (Adler & Adler, 1998; LaFontana & Cillessen, 2002). Fourth, individual differences in narcissism can be reliably measured in children this age (Thomaes, Stegge, et al., 2008), who typically have outgrown the unrealistically positive self-views that are normative in younger children (Marsh, Craven, & Debus, 1998).

Peer approval and disapproval were manipulated using the Survivor Game, which is an ostensible Internet contest shown to be highly effective at inducing credible peer approval and disapproval experiences in children (e.g., Reijntjes, Dekovic, Vermande, & Telch, 2007; Reijntjes, Stegge, Meerum Terwogt, Kamphuis, & Telch, 2006). Participants created a personal profile containing self-disclosing information as well as a photograph of themselves. By random assignment, they received negative social feedback (i.e., the lowest likability score), neutral social feedback (i.e., neither the lowest or the highest likability score), or positive social feedback (i.e., the highest likability score) on their profile from an Internet peer jury. In a subsequent self-esteem regulation period, participants could examine the feedback that each individual judge gave them. The individual judges provided either positive or negative feedback and were either perceived popular or unpopular. Thus, whereas the manipulated jury feedback was between subjects, the individual judges' feedback that participants subsequently viewed was within subjects. State self-esteem was assessed at baseline (T1), immediately after the manipulated jury feedback (T2), and immediately after viewing the individual judges' feedback (T3).

Based on sociometer theory, we predicted that from T1 to T2 children's state self-esteem would significantly decrease after disapproval, would not change after neutral feedback, and would significantly increase after approval. We predicted that children showing largest decreases in state self-esteem following disapproval would be high in narcissism (but would not differ from others in self-perceived social acceptance and peer-perceived social preference). Although narcissists may be more reactive to negative than to positive social events (Bushman & Baumeister, 1998; Rhodewalt & Morf, 1998), we also explored whether children showing largest increases in state self-esteem following approval were high in narcissism. Regarding the interpersonal regulation of state self-esteem, we predicted that positive feedback from perceived popular judges would have strong regulatory effects. Specifically, we predicted that disapproved children would show more state self-esteem recovery from T2 to T3 the more time they spent examining positive feedback from perceived popular judges (relative to positive feedback from perceived unpopular judges, or negative feedback). We also predicted that disapproved children would generally spend more time examining positive feedback from popular judges than other types of feedback.

Method

Participants

Participants were 333 preadolescents (49% boys) who ranged in age from 8 to 12 years ($M = 10.8$, $SD = 0.9$). They were recruited from 10 randomly selected public elementary schools serving lower (i.e., 4.2% below average Dutch income) to upper (i.e., 7.3% above average Dutch income) middle-class communities in the Netherlands. The regions where the schools are located are representative of the Netherlands in terms of socioeconomic status, level of urbanization, and cultural or ethnical diversity. Most participants were ethnic Dutch (88%); others mainly had mixed cultural or ethnical origins. All participants received informed parental consent (consent letters were sent home from schools, were signed and returned; consent rates ranged between schools from 68% to 95%; *M* consent rate = 83%). Participants received a small gift (e.g., mechanical pens, markers) in exchange for their voluntary participation.

Measures

A few weeks prior to the experiment (*M* = 2 weeks, range = 1–3 weeks), participants completed measures of narcissism, self-perceived social acceptance, and a sociometric nomination procedure in their classes. Trained female psychology students provided instructions and answered questions. During the experiment, participants completed a measure of state self-esteem.

Narcissism

Narcissism was measured using the Dutch version of the 10-item Childhood Narcissism Scale (Thomaes, Stegge, et al., 2008). This psychometrically sound scale assesses grandiose views of self and inflated feelings of superiority and entitlement in children. Sample items include: ''Without me, our class would be much less fun,'' ''Kids like me deserve something extra,'' and ''I often succeed in getting admiration.'' Items are rated along a 4-point scale ranging from 0 (*not at all true*) to 3 (*completely true*). Responses were summed, with higher scores indicating higher levels of narcissism (Cronbach's $\alpha = .79$).

Self-perceived social acceptance. Self-perceived social acceptance was measured using the Dutch version of the six-item social acceptance subscale of Harter's Self-Perception Profile for Children (1985; translated and validated by Veerman, Straathof, Treffers, Van den Bergh, & ten Brink, 1997). This scale assesses children's evaluation of how well they can get along with their peers. Children first choose which of two contrasting descriptors describes themselves best (e.g., ''Some kids would like to have a lot more friends, but other kids have as many friends as they want''). They then indicate whether the chosen descriptor is ''sort of true'' or ''very true'' for them. Items are rated along a 4-point scale ranging from 0 to 3. Responses were summed, with higher scores indicating higher levels of self-perceived social acceptance (Cronbach's $\alpha = .70$).

Peer-perceived social preference. Peer-perceived social preference was measured using sociometric nominations (Coie, Dodge, & Coppotelli, 1982). Children nominated the children who they ''like most'' and ''like least'' in their classes. Following conventional procedures (e.g., Cillessen & Mayeux, 2004), the number of nominations children received was standardized within each classroom. Then, the ''like least'' standardized score was substracted from the ''like most'' standardized score, and the resulting score was restandardized to create a measure of social preference.

State self-esteem. During the experiment, participants completed a six-item state self-esteem measure at baseline (T1; Cronbach's $\alpha = .68$), immediately after the manipulated jury feedback (T2; Cronbach's $\alpha = .80$), and immediately after viewing the individual judges' feedback (T3; Cronbach's $\alpha = .78$). The measure was modeled after standard measures of trait self-esteem (i.e., global self-worth subscale of Harter's Self-Perception Profile for Children, 1985; Rosenberg's Self-Esteem Scale, 1965), but assessed children's overall sense of worth *right now, at the present time*. Items reflected both a positive sense of self (e.g., ''I feel good about who I am right now'') and a negative sense of self (e.g., ''I am dissatisfied with myself right now''; see the Appendix for all items). Items were rated along a 5-point scale ranging from 0 (*not at all*) to 4 (*very much*). Responses were summed with higher scores indicating higher levels of state self-esteem. In a recent study involving 405 children and young adolescents, our measure of state self-esteem was found to be strongly associatiated with a one-item pictorial measure of state self-esteem ($r = .71$, $p < .0001$; Thomaes, Bushman, Orobio de Castro, Cohen, & Denissen, 2009). In addition, significant associations in the predicted direction were found between our measure of state self-esteem and trait measures of self-esteem (Harter, 1988), depression (Kovacs, 1981), and social anxiety (La Greca & Stone, 1993).

Experimental Procedure

Participants were individually tested in a quiet room at their school by a female research assistant. First, they completed the T1 state self-esteem measure. Next, they were told they would be competing in a popularity contest on the Internet called Survivor Game (a bogus game created for research purposes). Participants were told they would play the game with four opponents of the same sex and age from different schools, and that all players would be evaluated by a panel of 16 peer judges. Each judge would give them a ''likability score'' between 0 (*not at all likable*) and 100 (*extremely likable*), and would also provide concrete written feedback. Participants were then told that we were interested in how the game ''would make them feel'' and what they ''would think about'' the judges' feedback. They were also informed that they were free to cease participation at any time they wanted and still receive their gift (2 children stopped before the game began). Next, participants completed a personal profile, so that the peer judges could ostensibly learn more about them. Questions concerned participants' hobbies, future occupation, things they like and dislike about themselves, how well they get along with other children, academic performance, and self-ratings on several personal traits (e.g., sense of humor, agreeableness, intelligence, trustworthiness). Participants were told that their personal profile and their picture would be posted on the Survivor Game Web page to be evaluated by the peer judges.

To enhance credibility, participants then viewed the personal profiles of their opponents, taken from actual profiles provided by participants in a different study (consent for using the profiles was obtained; names were changed). After viewing the last profile, a message appeared on screen indicating that the computer would now tally the judges' scores for each player. After a short waiting period, the names of the players with the highest and the lowest scores appeared in capital letters on screen. Participants were randomly assigned to one of three conditions. In the approval condition, the participant received the highest score, whereas one randomly chosen opponent received the lowest score. In the disapproval condition, the participant received the lowest score, whereas one randomly chosen opponent received the highest score. In the control condition, two randomly chosen opponents received the highest and lowest scores. Because participants allegedly scored in between they did not see their own name.

Immediately after receiving the jury results, participants completed the T2 state self-esteem measure. Next, an announcement appeared on screen informing participants that they would have 5 min to look over the feedback comments that the judges wrote about them. An overview screen appeared containing pictures of all 16 judges (8 boys and 8 girls). By clicking on the picture of a targeted judge, a new screen opened containing concrete feedback provided by that judge. The judges were counterbalanced to be either perceived popular or unpopular, and to provide either positive or negative feedback. The peer status of the judges was manipulated through the two key determinants of children's perceived popularity: their physical appearance and number of friends (LaFontana & Cillessen, 2002). Popular judges were good looking and wrote they had ''many friends,'' whereas unpopular judges were not good looking and wrote they had ''few friends.'' In a pilot study, 10 children (M = 10.8 years) rated the judges' pictures (accompanied by a written statement about their number of friends) on a scale from 0 to 10, and considered the popular judges as better looking ($M = 7.6$, $SD = 0.6$ vs. $M = 3.9$, $SD = 1.4$) and as ''probably more popular'' ($M = 7.7$, $SD = 0.7$ vs. $M = 3.9$, $SD = 1.1$) than the unpopular judges, $t(14) = 6.93$, $p < .0001$, $d = 3.46$, and $t(14) = 8.24$, $p < .0001$, $d = 4.12$, respectively. The valence of the judges' feedback (positive or negative) was manipulated through the likability ratings and concrete feedback comments they provided. Positive judges provided favorable ratings (M likability score = 80 of 100) and wrote only positive comments (e.g., ''I would like to be friends with this person''). Negative judges provided unfavorable ratings (M likability score = 40 of 100) and wrote only negative comments (e.g., ''I would not like to be friends with this person''). Regardless of the experimental condition, all participants saw the same feedback from the 16 peer judges (i.e., 4 popular judges gave positive feedback, 4 popular judges gave negative feedback, 4 unpopular judges gave positive feedback, 4 unpopular judges gave negative feedback). The time (in seconds) that participants spent examining the four different types of feedback was recorded by the computer. Immediately after the feedback viewing period, participants completed the T3 state self-esteem measure.

Finally, participants were thoroughly debriefed. They were informed that the other players, the judges, and the evaluations they received were entirely fictitious. They were also informed about the study purposes, and the need for deception. They were assured that responses during the game would remain strictly confidential, and they were encouraged to ask questions or voice their concerns. To reduce possible lingering effects of the manipulation, participants were interviewed at length about a recent positive social experience in which they felt good.

Ethical Concerns

Ensuring children's psychological well-being during the experiment was a priority of this research. Accordingly, recommendations for experiments involving child participants that require deception and a risk of emotional discomfort were strictly followed (see Hurley & Underwood, 2002). Institutional Review Board approval was obtained, parents received a detailed consent letter describing the study, and children were preinformed about their rights to withdraw, were monitored for possible expressions of undue emotional distress, and were thoroughly debriefed. Research has shown that debriefings as described earlier are effective for preadolescent children; they typically understand how and why they were deceived, and what confidentiality entails (Hurley & Underwood, 2002). In addition, preadolescents generally are well able to regulate their emotional responses, reducing the risk of prolonged emotional discomfort (Saarni, 1999). Our own work showed that children generally are positive about participation in the Survivor Game, and report no objections against the deception or other procedural details, both immediately after the experiment and 1 week later (Reijntjes et al., 2006, 2007).

Results

Preliminary Analyses

Table 1 presents the descriptive statistics for the study variables and the results of the preliminary analyses.

Sex differences and age. Analyses of variance (ANOVAs) showed that boys reported higher state self-esteem than girls at T2 ($p < .02$) and T3 ($p < .02$), but not at T1 ($p > .07$). Sex differences in state self-esteem were not large ($ds < 0.27$). Children's age was not significantly related to any of the study variables ($ps > .08$). Because there were no interactions involving sex or age, the data for boys and girls of different ages were combined for subsequent analyses.

Equivalence of Experimental Conditions

Analyses of variance showed that children's baseline state self-esteem, narcissism levels, self-perceived social acceptance, peer-perceived social

preference, and age did not differ in the disapproval, control, and approval groups (*p*s > .37), indicating that random assignment to conditions was successful.

Primary Analyses

Interpersonal appraisals and the modulation of state self-esteem. Data were analyzed using a mixed-model repeated measures analysis, with state self-esteem serving as the dependent variable, condition (disapproval, control, approval) serving as the between-subjects factor, and time (T1 vs. T2 state self-esteem assessment) serving as the within-subjects factor. A significant Condition × Time interaction was found, $F(2, 330) = 40.25$, $p < .001$ (see Figure 1). As predicted, disapproved children displayed a sharp decrease in state self-esteem, $F(1, 107) = 44.62$, $p < .0001$, $d = 1.29$. Control children displayed no significant change in state self-esteem, $F(1, 114) = 2.10$, $p > .14$, $d = 0.27$. Approved children displayed a sharp increase in state self-esteem, $F(1, 109) = 19.18$, $p < .0001$, $d = 0.84$. These findings show that peer approval and disapproval experiences cause immediate change in children's state self-esteem, consistent with sociometer theory.

Importantly, the effects reported earlier reflect normative, or "average" patterns of self-esteem reactivity. They provide no information on *individual differences* in self-esteem reactivity. Therefore, we computed a reliable change (RC) index (Christensen & Mendoza, 1986) to distinguish children who showed statistically significant intraindividual change in state self-esteem following the manipulated jury feedback from those who did not. The RC index provides a psychometrically sound criterion for how much change should occur between two assessments to reflect more than just random variation of an imprecise measurement instrument. Thus, it provides an ideal method to distinguish genuine self-esteem change from artifactual change (Jacobson & Truax, 1991). Using this stringent criterion, in the disapproval condition 31 children (29%) showed a significant decrease in state self-esteem. In the control condition, 4 children (4%) showed a significant increase in state self-esteem, whereas 7 children (6%) showed a significant decrease in state self-esteem. In the approval condition, 15 participants (14%) showed a significant increase in state self-esteem. Thus, in our findings substantial minorities of children who experienced peer approval or disapproval showed genuine intra-individual change in state self-esteem.

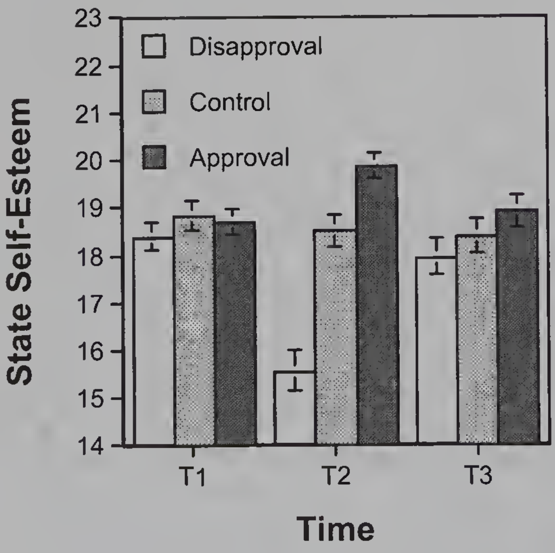

Figure 1. State self-esteem means at T1 (baseline), T2 (after jury feedback), and T3 (after viewing the individual judges' feedback) for children in the disapproval, control, and approval conditions. *Note.* Error bars represent ± 1 *SE*.

We predicted that children who showed genuine decreases in state self-esteem following disapproval would be high in narcissism but would not differ from their less reactive counterparts in self-perceived social acceptance and peer-perceived social preference. The results confirmed our expectation. An ANOVA showed that disapproved children who showed significant decreases in state self-esteem (i.e., decreases that exceeded the RC cutoff) were significantly more narcissistic ($M = 10.71$, $SD = 6.04$) than disapproved children who showed no significant decreases in state self-esteem ($M = 7.74$, $SD = 4.65$), $F(1, 106) = 7.54$, $p < .01$, $d = 0.53$. Both groups did not differ in self-perceived social acceptance ($p > .60$) or in peer-perceived social preference ($p > .47$). Similar effects were explored in the approval condition, by testing whether children who showed genuine increases in state self-esteem following approval would be high in narcissism. This was not the case. Narcissism scores were not significantly higher in approved children who showed significant increases in state self-esteem ($M = 9.40$, $SD = 5.26$) than in approved children who showed no significant increases in state self-esteem ($M = 8.59$, $SD = 4.30$), $F(1, 108) = 0.43$, $p > .51$, $d = 0.13$. Both groups did also not differ in self-perceived social acceptance ($p > .36$) and peer-perceived social preference ($p > .97$). Thus, narcissism can be considered a specific but asymmetric moderator of children's interpersonal state self-esteem reactivity, such that it is associated with increased reactivity following negative, but not positive social feedback.

Interpersonal regulation of state self-esteem. Based on sociometer theory, we predicted that peer appraisals should also influence the regulation of disapproved children's lowered state self-esteem. Specifically, positive feedback from perceived popular peers was predicted to have strong regulatory effects (Adler & Adler, 1998; Hawley et al., 2002; LaFontana & Cillessen, 2002). Data were analyzed using hierarchical regression analysis. The dependent variable was residualized state self-esteem change from T2 to T3. Residualized state self-esteem change from T1 to T2 was entered as control variable in Step 1. This statistical approach allowed us to examine regulatory change in state self-esteem (from T2 to T3) above and beyond the change that could simply be predicted from prior modulatory change in state self-esteem (from T1 to T2). The main effects for time spent viewing positive feedback from perceived popular judges and RC (i.e., a significant decrease) in state self-esteem from T1 to T2 (*no* = 0, *yes* = 1) were entered in Step 2. The two-way interaction was entered in Step 3.

The results of this hierarchical regression analysis are presented in Table 2. In Step 2 of the analysis, disapproved children showed more recovery of state self-esteem the more time they spent viewing positive feedback from perceived popular judges, $t(104) = 3.89$, $p < .001$, $b = 0.39$, $\beta = .36$. This effect, however, was qualified by its significant interaction with RC in state self-esteem from T1 to T2 in Step 3, $t(103) = 2.78$, $p < .01$, $b = 0.58$, $\beta = .29$. Despite the relatively small sample size of this group, a large and significant effect was found for disapproved children who significantly decreased in state self-esteem from T1 to T2. These children showed sharp increases in state self-esteem the more time they spent viewing positive feedback from perceived popular judges, $t(28) = 4.07$, $p < .001$, $b = 0.81$, $\beta = .57$. This relation was not significant for disapproved children who did not significantly decrease in state self-esteem, $t(74) = 1.52$, $p > .13$, $b = 0.17$, $\beta = .18$ (see Figure 2). Thus, these findings show that attending to positive feedback from perceived popular peers may help in regulating one's lowered state self-esteem, especially among children who experience marked state self-esteem losses.

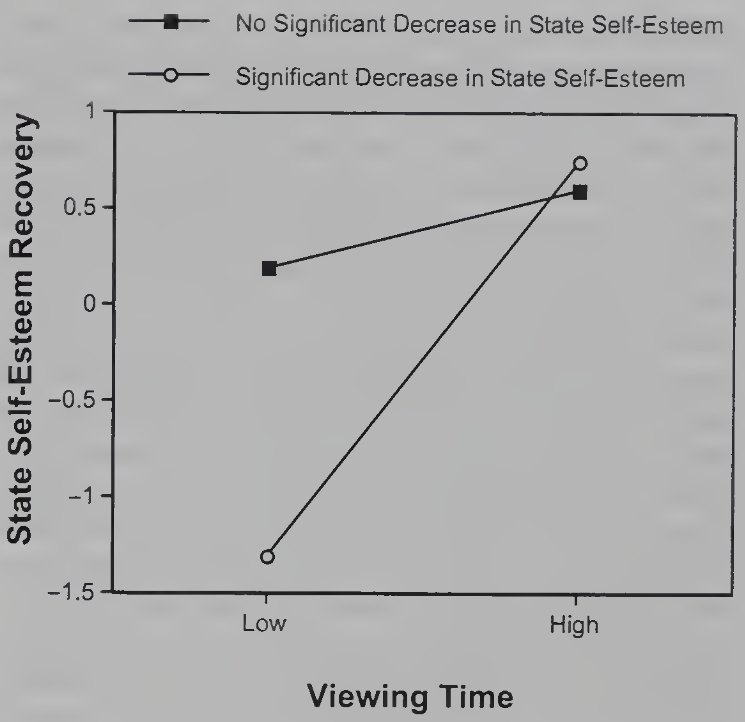

Figure 2. Relation between time spent viewing positive feedback from perceived popular judges and state self-esteem recovery for disapproved children who *did* or *did not* show a significant decrease in state self-esteem following the jury feedback.

To test the specificity of this regulatory effect of positive feedback from perceived popular judges, we conducted a series of three similar regression analyses for the other three types of feedback (i.e., positive feedback from unpopular judges, negative

Table 2

Results of Hierarchical Regression Analysis of Residualized State Self-Esteem Change From T1 to T2, the Time Children Spent Viewing Positive Feedback From Perceived Popular Judges, and Reliable Change in State Self-Esteem From T1 to T2 (No = 0, Yes = 1) *on Residualized State Self-Esteem Change From T2 to T3*

Step no.	Variable	*t*	*p* value	*b* (*SE*)	β
Step 1	Residualized state self-esteem change T1–T2	−1.84	> .06	−0.17 (0.09)	−.18
Step 2	Residualized state self-esteem change T1–T2	−2.57	< .02	−0.33 (0.13)	−.35
	Viewing time positive feedback perceived popular judges	3.89	< .001	0.39 (0.10)	.36
	Reliable change in state self-esteem	−1.24	> .21	−0.40 (0.32)	−.17
Step 3	Residualized state self-esteem change T1–T2	−2.45	< .02	−0.30 (0.12)	−.32
	Viewing time positive feedback perceived popular judges	1.82	> .07	0.21 (0.12)	.19
	Reliable change in state self-esteem	−1.29	> .20	−0.40 (0.31)	−.17
	Viewing Time × Reliable Change	2.78	< .01	0.58 (0.21)	.29

Note. $R^2 = .03$ for Step 1; $\Delta R^2 = .13$ ($p < .01$) for Step 2; $\Delta R^2 = .06$ ($p < .01$) for Step 3.

feedback from popular judges, and negative feedback from unpopular judges). No significant effects were found (*ps* > .12). Thus, the extent to which disapproved children recovered from a blow to their state self-esteem was specifically dependent on the extent to which they subsequently spent time viewing positive feedback from perceived popular judges.

If it benefits disapproved children to attend to positive feedback from perceived popular peers, one might wonder whether they also have a preference for attending to this kind of feedback over other types of feedback. Results are presented in Table 3. As expected, disapproved children spent more time viewing positive feedback from perceived popular judges than any other type of feedback (*ps* < .0001). Importantly, however, the subset of disapproved children who showed significant decreases in state self-esteem did not spend more time viewing positive feedback from perceived popular judges than did disapproved children who showed no significant decreases in state self-esteem, $F(1, 106) = 0.04$, $p > .84$, $d = 0.04$. In addition, both groups showed no different viewing times for any of the other types of feedback (*ps* > .44). Thus, although disapproved children were inclined to view positive feedback from perceived popular judges over other types of feedback, we found no evidence that their feedback viewing patterns were associated with the amount of state self-esteem they had lost.

Discussion

The present experiment found strong support for sociometer theory's core postulate that interpersonal appraisals can have an immediate, causal effect on state self-esteem. First, we found that both peer approval and disapproval experiences *modulate* children's state self-esteem. In fact, the effect size for peer approval (i.e., $d = 0.84$) exceeded Cohen's (1988) conventional value for a "large" effect (i.e., $d = 0.80$), and the effect size for peer disapproval (i.e., $d = 1.29$) was even larger. Second, we found that peer appraisals can also function to *regulate* children's state self-esteem. Specifically, the recovery of disapproved children's state self-esteem was dependent on the amount of time they spent viewing positive feedback from perceived popular peers. In contrast, the amount of time they spent viewing positive feedback from unpopular peers had no impact on their state self-esteem.

These results provide the first empirical evidence that short-term sociometer processes already operate in preadolescence, a time of great concern about others' approval (Damon & Hart, 1988; Harter, 1999, 2006; Rosenberg, 1979). At this age, children have just acquired the ability to evaluate their global worth as a person. Cognitive advances in the ability to appreciate others' appraisals in this same age period allow interpersonal experiences to have a direct impact on self-esteem (Harter, 1999, 2006). Prior longitudinal research already found that preadolescents' trait self-esteem tends to be influenced by cumulative peer experiences they have had in the past (e.g., Boivin et al., 2001; Ladd & Troop-Gordon, 2003). Our results show that preadolescents' state self-esteem is a highly dynamic psychological entity that can be immediately reactive to the social context as it currently unfolds.

The present experiment also extends the literature by examining the role of individual differences

Table 3

Time Spent by Disapproved Children on Different Types of Feedback

Viewing time in seconds (total viewing time = 300 s)	Range	All disapproved children (regardless of state self-esteem decrease; *N* = 108)	Disapproved children showing significant decrease of state self-esteem (*N* = 31)	Disapproved children showing no significant decrease of state self-esteem (*N* = 77)
		M (*SD*)	*M* (*SD*)	*M* (*SD*)
Positive feedback from perceived popular judges	11–252	94 (39)	93 (40)	95 (39)
Positive feedback from perceived unpopular judges	0–173	76 (31)	79 (35)	75 (30)
Negative feedback from perceived popular judges	0–175	66 (33)	68 (34)	65 (33)
Negative feedback from perceived unpopular judges	0–163	63 (33)	59 (38)	65 (31)

in sociometer processes. Prior research in adults primarily approached sociometer processes as universal (Denissen, Penke, Schmitt, & Van Aken, 2008; Leary & Downs, 1995; Leary et al., 1998; but see Srivastava & Beer, 2005, for a notable exception). In our study, the strength of sociometer effects varied substantially between participants. Only subsets of participants showed significant intra individual change following approval and disapproval when judged by the RC criterion (Christensen & Mendoza, 1986). It should be emphasized that this criterion is stringent. Still, this finding may raise the question whether sociometer processes are as prevalent in preadolescent children as they are in adults (Leary et al., 2003). For example, one may speculate that although preadolescents typically have acquired the cognitive abilities that allow interpersonal experiences to influence their self-esteem, these abilities are perhaps not yet as fully ingrained and habitually employed as they are later in development. It would be premature to draw such a conclusion based on our findings, but clearly, establishing the generality of sociometer processes in these relatively early stages of development will be an important direction for future research.

We predicted that the strongest sociometer effects would be found among those children who are most concerned about obtaining approval from others. Consistent with that notion, we found that children who showed marked state self-esteem losses following disapproval were high on narcissism—a trait that reflects children's preoccupation with being valued and admired by others (Morf & Rhodewalt, 2001; Thomaes, Stegge, et al., 2008). Narcissists constantly seek external self-affirmation, possibly in order to create desired self-views or to meet self-evaluative needs (Morf & Rhodewalt, 2001). Our results suggest that when they do not succeed, they immediately lose state self-esteem. Importantly, the subset of disapproved children who showed marked state self-esteem losses did not differ from others in self-perceived social acceptance and peer-perceived social preference. Thus, consistent with sociometer theory, these results suggest that interpersonal state self-esteem reactivity is most pronounced in children with a heightened need for external validation, and not just a default characteristic of children holding social vulnerabilities.

Perhaps most important was our finding that children's state self-esteem reactivity is influenced not only by the traits of the person being evaluated but also by the traits of the evaluator. In preadolescence, the perceived popularity of peers is a highly salient dimension along which children judge each other. The social power of perceived popular children reaches so far that they can dictate to a large extent what members of a social group are valued and accepted and what members are not (Adler & Adler, 1998; Hawley et al., 2002; LaFontana & Cillessen, 2002). In this light, it should come as no surprise that the manipulated popularity of judges who gave positive feedback strongly influenced the extent to which children recovered from prior disapproval. Being approved by a popular peer is significant, because it implicitly conveys the prospect that one is likely to be valued by peers in the future. Being approved by an unpopular peer is much less significant, because it tells little about how one will be valued by peers in the future.

One might be inclined to infer from these findings that disapproved children intentionally sought positive feedback from popular peers in an effort to regulate their lowered self-esteem. Although we did not test children's intentional feedback-seeking strategies (rather, we simply recorded how much time they spent viewing different types of feedback), our findings are inconsistent with such an inference. If disapproved children engaged in intentional self-esteem regulation, one would expect their feedback viewing patterns to depend on the amount of self-esteem they had lost (i.e., one would expect that disapproved children who lost the most self-esteem would spend the most time viewing positive feedback from popular peers). We found no such effect, however. Thus, although attending to positive feedback from popular peers has pronounced self-esteem regulatory effects, we have no indications that disapproved children intentionally seek such feedback to regulate their lowered self-esteem.

Limitations and Future Research

We have argued that preadolescence is a critical age period for the present experiment. However, our developmental focus limits the ability to make generalizations to children of other ages. Future research should test how interpersonal self-esteem reactivity is influenced by age. For example, is preadolescence indeed the earliest developmental period in which interpersonal self-esteem reactivity can be observed? Is interpersonal self-esteem reactivity stronger in developmental periods marked by enhanced interpersonal concern (i.e., preadolescence to middle adolescence) than in other developmental periods? Answers to such questions will help us further understand the interpersonal processes that underlie children's self-esteem development.

Laboratory experiments are the method of choice if one wants to test causal hypotheses about psychological processes. Within the confines of the laboratory, we tried to create an ecological valid peer appraisal procedure by having children interact with (ostensible) peers through the Survivor Game on the Internet. Preadolescents generally are very familiar with using social networking facilities on the Internet to communicate with peers (Valkenburg & Peter, 2007). Future research is needed to ensure that our findings generalize to other contexts of peer interaction.

It is unlikely that demand characteristics or social desirability effects have influenced the present study findings. No participants expressed suspicion about the study purposes, even when explicitly asked during the debriefing. Moreover, even if some participants had inferred the study purposes, this could not explain the interaction effects we observed (e.g., this could not explain why narcissists would be more prone than their peers to report losing self-esteem following disapproval). Still, future research focusing on more implicit measures of self-esteem (e.g., Greenwald & Farnham, 2000) may be valuable to corroborate the present study findings.

This study was conducted in the Netherlands. The determinants of self-esteem tend to be very similar across individualistic countries (Markus & Kitayama, 1991; Oyserman, Coon, & Kemmelmeier, 2002), suggesting that our findings should be generalizable to children living in North America and most Western European countries. Theoretically, sociometer effects should even be stronger in individuals from collectivistic cultures (e.g., East Asian cultures), who tend to view and evaluate themselves more in terms of their relationships with others (Oyserman et al., 2002). Future research is needed to test this hypothesis.

Our findings are at odds with the single study that examined preadolescents' actually experienced, approval-based self-esteem fluctuations (Nesdale & Lambert, 2007). One possible explanation is that Nesdale and Lambert (2007) used pretend-play peer appraisal procedures, whereas we led children to believe that they were actually appraised by others. Another possible explanation is that Nesdale and Lambert measured potential change in children's trait self-esteem, not in their state self-esteem. Continued research on the boundary conditions of the sociometer effect will enhance our understanding of the interpersonal nature of children's self-esteem.

Conclusion

This study found that children's state self-esteem can wax and wane as a function of how much they are liked by peers in the immediate present. Our findings are consistent with the view that state self-esteem functions as a sociometer, a psychological gauge of how much one is currently valued and accepted by others. As is a common characteristic of other human monitoring mechanisms (e.g., hunger), the sensitivity of the sociometer varies substantially between individuals. Just as some individuals experience changes in hunger and satiation more readily than others, some individuals experience changes in state self-esteem more readily than others. Just as some types of food alleviate hungry feelings more effectively than others, some types of social feedback seem to alleviate lowered state self-esteem more effectively than others. When children's interpersonal gauge of state self-esteem is low, praise from popular peers is likely to make it go up again.

Individual and Peer Group Normative Beliefs About Relational Aggression

Nicole E. Werner and Laura G. Hill
Washington State University

Studies show that children who use relational aggression process social information in unique ways; however, findings have been inconsistent and limited by methodological weaknesses. This short-term longitudinal study examined developmental changes in 245 (49% female; ages 8–13) 3rd through 8th graders' normative beliefs about relational aggression and tested the hypothesis that individual and classroom-level norms predict relational aggression 1 year later. Results showed that the transition to middle school was marked by increased approval of relational aggression, and individual norms predicted future relational aggression. Importantly, a contextual model showed that students in peer groups highly supportive of relational aggression became increasingly aggressive. Findings extend social information processing theories of relational aggression to focus on the role of peer group cognitions.

Empirical support for social information processing (SIP) models of children's social behavior suggests that patterns of both distal (i.e., latent knowledge structures) and proximal (i.e., online) processing of social information predict individual differences in overt aggression (see Crick & Dodge, 1994, for a review). Although some evidence suggests that SIP mechanisms may be important for understanding the development and maintenance of *relational aggression*—a form of aggression characterized by actual or threatened damage to relationships (e.g., Crick & Grotpeter, 1995), results of prior work in this area have been mixed (e.g., Crain, Finch, & Foster, 2005; MacBrayer, Milich, & Hundley, 2003; Werner & Nixon, 2005). The current study was designed to further examine SIP factors and relational aggression by focusing on children's normative beliefs. This study extends previous work by exploring developmental differences in children's beliefs about relational aggression and by examining the influence of peer-group-level normative beliefs in the prediction of relational aggression.

SIP and Relational Aggression

SIP models of children's social adjustment suggest that aggressive behavior results from deficient or biased online processing of social information (Crick & Dodge, 1994), and a large body of literature links overtly aggressive behavior with maladaptive SIP patterns. In contrast, only a few studies of SIP and relational aggression have been published to date. Crick and colleagues (Crick, 1995; Crick, Grotpeter, & Bigbee, 2002) found that children who use relational aggression at high levels attribute hostile intent to peers in ambiguous relational conflicts (i.e., involving threats to their acceptance by friends or the peer group) whereas physically aggressive children's hostile attribution biases are limited to instrumental provocation situations. Although promising, Crick and colleagues' findings have not been replicated (cf. Crain et al., 2005; Nelson, Mitchell, & Yang, 2008). Moreover, several studies of other SIP steps (e.g., goal clarification, response evaluation) have failed to find that relationally aggressive children display unique SIP patterns (Crick & Werner, 1998; Delveaux & Daniels, 2000).

Normative Beliefs About Aggression

One component of the SIP model that has received increasing attention is the "database." SIP theory posits that knowledge structures function as a cross-situational, distal storehouse of information that controls children's behavior by imposing limits on the processing of specific information in the social environment (i.e., online

processing). Huesmann (1988) and Crick and Dodge (1994) argued that children's memories of past experiences are stored in long-term memory and, over time, integrated into generalized knowledge structures such as scripts, schemas, or working models (Dodge, 1993). Knowledge structures simplify the task of processing cues in the immediate social environment, resulting in more efficient, but not necessarily more accurate or adaptive, processing.

One line of work on latent knowledge structures has explored children's generalized beliefs about the legitimacy or normative nature of aggression. Converging evidence suggests that children who view aggression as an acceptable response are more likely to engage in aggressive behavior concurrently and in the future (Henry et al., 2000; Huesmann & Guerra, 1997). Several studies have explored children's normative beliefs about relational aggression. Musher-Eizenman et al. (2004) surveyed 778 children in Grades 4–6 and found that those children who were more approving of indirect aggression (a construct similar to relational aggression) reported higher levels of indirect aggression. Similar findings were reported by Werner and Nixon (2005) in a study of sixth through eighth graders, and by Bailey and Ostrov (2008) in a study of college students. Only one study has examined children's normative beliefs and relational aggression using an independent informant of aggression. Murray-Close, Crick, and Galotti (2006) found that fourth and fifth graders' judgments of the appropriateness of relational aggression were marginally associated with peer reports of relational aggression.

In sum, prior research has yielded some evidence to support the application of the SIP model to children's relational aggression. However, the failure to replicate some findings has led some researchers to call into question the utility of the SIP model for understanding relational aggression (Crain et al., 2005; Nelson et al., 2008). Methodological limitations, including the reliance of many studies on self-reports of aggression and cross-sectional designs, might explain, in part, the lack of compelling findings. It is also possible that the sole focus on *individual* social cognitive processes in prior research has limited our understanding of the significance of SIP for relational aggression. In this study, we hypothesized that social cognitions at the level of the *peer group* will provide important information about the development and/or maintenance of children's relational aggression.

The Role of the Peer Group for Relational Aggression

A growing body of literature points to the significant role that peer relationships play for relational aggression during childhood and adolescence. Several studies have found that close friends tend to resemble each other in levels of relational aggression (Duffy & Nesdale, 2008; Ellis & Zarbatany, 2007; Werner & Crick, 2004), and having relationally aggressive friends predicts increases in children's relational aggression over time (Werner & Crick, 2004). Socialization processes at the dyadic and larger peer group level might explain these findings. Werner and Crick (2004) hypothesized that relational aggression is selectively reinforced within the close friendships of children who exhibit relationally aggressive behaviors through a process similar to deviancy training that characterizes the friendships of antisocial males (Dishion, Patterson, & Griesler, 1994). Consistent with this notion, Cillessen and Mayeux (2004) interpreted findings of strong associations between relational aggression and perceived popularity as indicating that relational aggression is increasingly reinforced in the peer group with age, via the benefits incurred from high status.

The previously described findings raise the possibility that peer group norms, such as the level of acceptance of aggression, may play an important role in the development and maintenance of relationally aggressive behaviors. The literature on bullying has long recognized the impact of group processes, although operational definitions of group norms have varied widely across studies. Salmivalli and Voeten (2004) measured students' expectations of the social consequences of bullying in their classroom and found that group norms explained classroom variance in bullying behavior above and beyond individuals' beliefs about the appropriateness of bullying. Duffy and Nesdale (2008) defined group norms as students' ratings of "how happy" their peer group would be if one of its members bullied. Students in peer groups more supportive of bullying reported engaging in higher levels of bullying themselves.

In this study, we hypothesized that both individual beliefs about the acceptability of relational aggression, and those of the larger peer group (i.e., the classroom), influence students' engagement in relationally aggressive behavior. In the most direct test of this hypothesis, Henry et al. (2000) examined the roles of individual and classroom-level normative beliefs in predicting individual overt aggression and norms 2 years later in a sample of urban second through sixth graders. Classroom norms were positively associated with sixth graders' individual levels of aggression after controlling for earlier levels of aggression. In addition to this direct effect, an indirect effect of group norms was found for the whole sample, such that classroom norms predicted individual norms, which in turn were associated with individual aggression.

Another way to conceptualize group norms for aggression is to consider levels of aggression in the peer group, sometimes referred to as descriptive norms. Espelage, Holt, and Henkel (2003) identified peer groups within middle schools and gathered self-reports of bullying and fighting behavior. Peer group levels of bullying predicted individual levels of bullying assessed 6 months later after controlling for the stability of individual bullying. In a recent study, Kuppens, Grietens, Onghena, Michiels, and Subramanian (2008) found that third- through fifth-grade children in classrooms characterized by higher relational aggression became increasingly relationally aggressive across a 1-year period. Together, these findings support the hypothesis that normative (i.e., frequent) behavior in the peer group influences individual children's behavior via modeling or peer socialization processes (Bandura, 1986).

The current investigation was designed to increase our understanding of SIP factors in relational aggression by exploring the independent and interactive effects of individual- and classroom-level normative beliefs for children's relationally aggressive behaviors. Methodologically, this study extends prior research about relational aggression in two ways: (a) we used a short-term longitudinal design and studied a wide range of grades, and (b) relational aggression was assessed using an independent informant (teachers).

Our first goal was to examine developmental differences in normative beliefs about relational aggression, a previously unexplored area. Zelli, Dodge, Lochman, and Laird (1999) found that mean levels of normative beliefs changed little from third through fifth grade and that individual differences in beliefs were moderately stable. van Schoiack-Edstrom, Frey, and Beland (2002) collected pre- and posttest data on middle school students' beliefs about social exclusion in schools receiving a prevention program (Second Step©) and comparison schools. Students in the comparison schools became increasingly approving of social exclusion over the course of one semester, relative to students in the intervention schools who decreased their approval of social exclusion. Given the lack of previous work on the development of normative beliefs about relational aggression, our predictions should be considered exploratory. We hypothesized that children become increasingly approving of relational aggression across childhood and adolescence, whereas approval of overt aggression either remains stable or decreases (cf. Zelli et al., 1999). Because our longitudinal design included children who transitioned from elementary to middle school during the study, we also examined whether this developmental transition is marked by changes in approval of both forms of aggression, as might be predicted by Pellegrini and Bartini (2001).

Our second goal pertained to the role of individual and peer group normative beliefs in predicting changes in relational aggression. Consistent with previous studies of overt aggression (e.g., Henry et al., 2000; Huesmann & Guerra, 1997), we expected that both individual and group norms about relational aggression would explain significant variance in relationally aggressive behavior. We further hypothesized that individual and group norms would interact, such that the highest levels of relational aggression were expected among children who approved of relational aggression *and* who were a part of peer groups in which relational aggression was viewed positively. We also tested a reciprocal model whereby students' level of relational aggression predicted change over time in normative beliefs. Drawing on the work of Huesmann and Guerra (1997), we expected to find that for children in this age group, aggression would not explain significant variance in individual norms.

Method

Participants

Participants in the current study were drawn from a 3-year longitudinal study of school climate. The 2nd-year sample (referred to here as Time 1 or T1) included third through eighth graders and their teachers from all three elementary schools and one middle school in a midsized town in the Western United States. A total of 726 students completed the survey (53% female and 73% of the population of third through eighth graders). We did not collect information about student ethnicity or race. However, the population from which this sample was drawn consisted of 77% White, 5% Black, 12% Asian, and 4% Hispanic students. Students were fairly evenly distributed across Grades 3 through 8, with slightly more than half of participants in elementary school (third–fifth grades). Teachers completed ratings for 523 of participating students.

Elementary school teachers were more likely to complete ratings than were middle school teachers ($\chi^2 = 82.1$, $p < .001$). Comparison of students with and without teacher ratings on normative beliefs and aggression variables revealed no significant differences.

The following year, students in Grades 3 through 8 were again recruited for participation. We did not have permission to collect data in the single local high school; thus, we were unable to recruit T1 eighth graders who transitioned to the ninth grade the next year. At Time 2 (T2), 467 students repeated the survey (64% of the T1 sample), and teachers completed ratings for 305 of these students. Again, comparison of students with and without teacher ratings revealed no significant differences on variables of interest in this study.

Procedure

Consent forms were sent home with all third- through eighth-grade children during the 1st year of the study. Parents were required to give active consent for their child to participate in this research. The following year, a passive consent process was used. Parents of participating children from the prior year received a letter from the school reminding them of the study and indicating that they should contact the school if they did not want their child to participate. Consent forms were sent home with all children who were new to the school and who had not received a permission form in the previous year. Before administering surveys to children, children were read an assent statement and asked to sign a form indicating assent.

In both years, surveys were administered by trained research assistants and the study authors during a 1-week period in the middle of fall semester. In each classroom, one person read survey items aloud while the other canvassed the room to assist students who needed help. Data collection took approximately half an hour in each classroom. Absent students were surveyed in groups during the week after initial administration.

Teachers completed survey instruments assessing child adjustment during the same semester. Elementary school children's primary teacher completed assessments. For students in middle school, we selected fourth-period teachers to complete the ratings because students spent the equivalent of two class periods in fourth period. We therefore reasoned that these teachers would have the most knowledge of students' social behavior. All study procedures were approved by the Institutional Review Board of the university where the authors were employed.

Measures

Teacher ratings of aggression. Teacher ratings of child aggression were obtained using two measures validated in prior research. Relational aggression was assessed with five items from the Children's Social Behavior Scale–Teacher Form (Crick, 1996). Sample items included, "when this child is mad at a peer, s/he gets even by excluding the peer from the group" and "this child spreads rumors or gossips about some peers." Each item was rated on a 5-point scale (*never true* to *almost always true*). Crick (1996) reported that the scale emerged as a separate factor from overt aggression and prosocial behavior in a principal components factor analysis (PCFA), and the alpha was .94 in a sample of third through sixth graders. The scale also correlated with peer reports of relational aggression, .57 for boys and .63 for girls. Overt aggression was assessed with three items from the Teacher Observation of Classroom Behavior–Revised (TOCA–R; Corrigan, 2003; Werthamer-Larsson, Kellam, & Wheeler, 1991). Sample items included "fights" and "harms others." Items were rated on 6-point Likert-type scales ranging from 1 (*never*) to 6 (*almost always*).

We conducted a confirmatory factor analysis using MPlus 4.21 (Muthén & Muthén, 1998–2007) on the eight aggression items. A one-factor model fit the data poorly, $\chi^2(20, N = 533) = 319.35$, $p < .001$; root mean square error of approximation (RMSEA) = .168, standardized root mean square residual (SRMR) = .094, comparative fit index (CFI) = .905. In contrast, a two-factor model fit the data significantly better, $\chi^{2\mathrm{diff}}(1) = -218.42$, $p < .001$. The final model provided an adequate fit to the data, $\chi^2(19) = 100.93$, $p < .001$; RMSEA = .09, SRMR = .049, CFI = .97. We computed scores for relational aggression ($\alpha = .94$) and overt aggression ($\alpha = .80$).

Normative Beliefs About Aggression

Normative beliefs about relational and overt aggression were assessed at T1 and T2 with items used in prior research (Huesmann & Guerra, 1997; Werner & Nixon, 2005). Participants rated the acceptability of aggressive behaviors on 5-point Likert scales ranging from 1 (*no!*) to 5 (*yes!*). Higher scores reflected greater approval of aggression. Normative beliefs about relational aggression were assessed with three items (e.g., "In general, it is OK to tell your friends not to be friends with someone you don't like''). Beliefs about overt aggression were assessed with four items (e.g., ''In general, it is OK to hit other people'').

We conducted a confirmatory factor analysis using MPlus 4.21 (Muthén & Muthén, 1998–2007) on the seven normative belief items. A one-factor model yielded good fit, $\chi^2(14) = 72.0$, $p < .001$; RMSEA = .08, SRMR = .04, CFI = .97. However, a two-factor model fit the data significantly better, $\chi^{2\text{diff}}(1) = -46.83$, $p < .001$. The final model provided an excellent fit to the data, $\chi^2(13) = 25.17$, $p = .02$; RMSEA = .04, SRMR = .02, CFI = .99. In the current study, the beliefs about relational aggression and beliefs about overt aggression scales demonstrated acceptable reliability (αs = .64 and .87, respectively).

Creation of peer group variables. To evaluate the contextual effects of peer group normative beliefs on changes over time in aggression, we calculated a mean score on the normative belief scale for each classroom and subtracted it from each individual's score (Hofmann & Gavin, 1998; Raudenbush, 1989). Thus, each student had two scores for normative beliefs about relational and overt aggression: the contextual score, a within-classroom peer-group average; and the ''pure'' individual score with peer group average subtracted.

Attrition and Missing Data

T1 to T2 attrition was 36% in this study (although this rate is somewhat misleading given that T1 eighth graders were not invited to participate in T2). Rates of 40%–50% are not uncommon in school-based longitudinal studies (Foshee et al., 2005; Horton & Lipsitz, 2001). Attrition analyses indicated that the longitudinal sample did not differ from the group of students with only Time 1 data on variables relevant for this study. Some analyses reported in this study were limited to students with complete self-report and teacher-report data from both T1 and T2 assessments ($N = 245$; 49% female). A one-way analysis of variance (ANOVA) comparing this subsample with the T1 only and T2 only samples revealed no significant differences on any of the study variables. In order to account for possible bias introduced by attrition between Times 1 and 2, we conducted analyses with multiply imputed data (Schafer, 1999) using the MI and MI-Analyze procedures available in SAS version 9 (Yuan, 2000). Significance of findings was the same with and without multiple imputation; therefore, we present all results using the original data.

Results

Developmental Differences in Individual Normative Beliefs

Our first goal was to examine developmental differences in students' normative beliefs about relational and overt aggression. We computed a repeated measures ANOVA with time and aggression type (relational norms, overt norms) as within-subjects factors, and sex and school change (elementary, middle, transition to middle) as the between-subjects factors (Table 1).

The analysis yielded several significant main effects: sex, $F(1, 459) = 6.85$, $p < .01$; school change, $F(2, 459) = 45.08$, $p < .001$; aggression type, $F(1, 459) = 5.21$, $p < .001$; and time, $F(1, 459) = 16.77$, $p < .001$. Examination of means showed that males were more approving of aggression than were females (Ms = 1.76 vs. 1.64), and students in middle school ($M = 1.92$) and those who transitioned to middle school during the study ($M = 1.72$) were more approving of aggression compared to elementary school students ($M = 1.45$). Students were more approving of relational aggression than overt aggression (Ms = 1.99 vs. 1.41), and students became increasingly approving of aggression over the 1-year study period (Ms = 1.64 vs. 1.76). The main effects of time, aggression type, and school change were qualified, however, by significant two-way and three-way interactions. For the sake of parsimony, we report only three-way interaction results and follow-up analyses.

There was a significant multivariate interaction of time, aggression type, and school change, $F(2, 459) = 7.27$, $p < .001$. To explore this effect further, we recomputed the analysis separately for students in elementary school, middle school, and those who transitioned to middle school during the study. The interaction of time and aggression type was nonsignificant for elementary students, $F(1, 208) = 1.87$, $p < .07$, but significant for middle school students, $F(1, 148) = 34.66$, $p < .001$, and transition students, $F(1, 103) = 28.53$, $p < .001$.

To probe these effects further, we recomputed the analysis of middle school and transition students' beliefs separately for relational aggression norms and overt aggression norms, thus focusing on the time effect singly. In the analysis of overt aggression norms, the effect of time was nonsignificant for both middle school students, $F(1, 148) = .04$, $p > .05$, and transition students, $F(1, 103) = 3.51$, $p < .10$. Thus, students' normative beliefs about overt aggression remained relatively stable across the 1-year period. The effect of time on relational

aggression norms was significant for both middle school students, $F(1, 148) = 32.53$, $p < .001$, and transition students, $F(1, 143) = 30.46$, $p < .001$. Both groups of students reported increases in approval of relational aggression over time (middle school: *Ms* = 2.05 vs. 2.39; transition: *Ms* = 1.83 vs. 2.29).

Prediction of Relational Aggression From Individual Normative Beliefs (Model 1)

Hierarchical linear regression was used to test the hypothesis that students' normative beliefs about relational aggression would predict future (T2) relational aggression. The results of this analysis are presented in Table 2 (Model 1). In the first step of the model, sex and school type were entered. At the second step, we entered T1 scores for relational and overt aggression. This allowed us to: (a) predict *changes* in relational aggression by controlling for initial levels and (b) predict unique variance in relational aggression by controlling for overlap with overt aggression. At the third step we entered T1 normative beliefs as well as concurrent normative belief variables (T2; relational and overt norms). Thus, we explored whether normative beliefs about relational aggression predicted unique variance in the corresponding aggressive behavior 1 year later, after controlling both for the stability of normative beliefs and aggression and the overlap between relational and overt aggression.

The final regression model was significant, $F(8, 240) = 6.36$, $p < .001$. Importantly, variables entered at the third step showed that the addition of initial normative beliefs scores explained a significant unique proportion of variance in T2 relational aggression, $F\Delta(5, 232) = 4.85$, $p < .01$. Examination of beta weights in the final model showed that T1 relational aggression ($\beta = .26$, $p < .001$) and T1 normative beliefs about relational aggression ($\beta = .20$, $p < .01$) were the only significant predictors of T2 relational aggression scores.

To test whether these results were robust across school types, we recomputed the above analysis and included the interactions of the two school type dummy variables with normative beliefs about relational aggression at T1 at the final step. Again, the overall regression model was significant, $F(11, 240) = 5.21$, $p < .001$. The final step that included the interactions, however, was nonsignificant, $F\Delta(2, 229) = 2.96$, $p < .06$. We therefore concluded that these findings were robust across school types.

Finally, we tested a reciprocal model to rule out bidirectional effects, with relational aggression at T1 predicting normative beliefs at T2 and using the same control variables. In this model, normative beliefs at T1 predicted normative beliefs at T2 ($\beta = .30$, $p < .001$), but T1 relational aggression did not predict T2 normative beliefs ($\beta = .02$, $p < .73$).

Effects of Peer Group Normative Beliefs on Relational Aggression (Model 2)

To test the hypothesis that both individual and classroom-level norms would explain significant

[a] These variables represent the decomposition of the unitary score on relational aggression normative beliefs into the two scores (individual and classroom normative beliefs) and their interaction, used in Model 2. Interactions of normative beliefs with grade level were not significant and were dropped from the model.
$^{*}p < .05$. $^{**}p < .01$.

variance in future levels of relational aggression, we recomputed the above model with three changes. First, we replaced the individual normative belief variables with the corresponding "pure" variable representing the individual norm effect minus the classroom effect. Second, we included classroom-level scores for relational aggression norms in the analysis. Finally, we computed the interaction of pure individual norms and classroom-level norms and included this variable in the analysis (refer to Table 2, Model 2 for results).

As predicted, results showed that peer group norms for relational aggression significantly predicted increases in relationally aggressive behavior over time ($\beta = .31$, $p < .001$). In other words, students in classrooms high in approval of relational aggression became increasingly aggressive across the 1-year period. Interestingly, and in contrast to the previous analysis, the relation of individual norms to later aggression was nonsignificant ($\beta = -.36$, $p < .37$) when peer-level norms were included in the model.

Consistent with our expectations, increases in levels of relational aggression were lower for elementary school students ($\beta = -.16$, $p < .05$) than for the middle school and transition comparison groups. Model fit was significantly higher than that of the model that assessed relational aggression as a unitary construct $F\Delta(2, 230) = 8.35$, $p < .01$.

Discussion

The results of this study provide important information about children's normative beliefs about relational aggression and the significance of these beliefs at the peer group level for the development of relational aggression during middle childhood and early adolescence.

Using a conservative analytic approach, we found that students who reported greater approval of relational aggression were more relationally aggressive 1 year later, even after controlling for the across-time stability of relational aggression and normative beliefs, and for the overlap between relational and overt forms of aggression. We also tested a reciprocal model and found that, consistent with Huesmann and Guerra (1997), by the late elementary school years individual differences in aggressive behavior did not significantly influence children's normative beliefs about aggression. Together, these results provide support for the SIP framework whereby normative beliefs operate as a script or schema that increases the efficiency with which the child processes social information in the immediate environment. For example, scripts should increase the likelihood that the child will encode threatening cues in peer conflict situations (e.g., a peer is standing too close to my romantic partner), make maladaptive attributions about others' intentions (e.g., a peer is threatening my social status), access aggressive responses from memory, and enact those responses. Although this study did not explore online information processing as a mediator of the link between normative beliefs and relational aggression, an important direction for future research, our findings strengthen results from previous investigations by using independent informants of relational aggression and a longitudinal design. These findings illustrate the need for continued investigation into the social-cognitive bases of relational aggression, particularly in the ''database'' of the SIP model.

Our results also demonstrated remarkable specificity in norms–behavior associations by form of aggression. Despite the moderate to high intercorrelations of aggression forms and beliefs about aggression forms within assessments, relational aggression and relational aggression norms were the only unique predictors of future relationally aggressive behavior. These results provide further evidence of the distinctiveness of relational and overt forms of aggression.

The most compelling results of the current study, however, focus on the role of the peer group for the development of relational aggression. Using a contextual analytic approach, we found that when support for relational aggression in the classroom was high, students in those classrooms were more relationally aggressive the following year compared to students in peer groups less supportive of relational aggression. Contrary to expectations, when normative beliefs were partitioned into peer-group-level and individual-level components, individual normative beliefs did not explain significant variance in, nor did they interact with group norms in the prediction of, future relational aggression.

One explanation for the significance of peer-group-level norms for individuals' aggressive trajectories in this study might lie in the link between relational aggression and peer status. In early adolescence, relationally aggressive youths are perceived by their peers as ''popular'' (Rose, Swenson, & Waller, 2004), an association that strengthens across the adolescent period (Cillessen & Mayeux, 2004). We expect that perceptions of popularity are interconnected with students' approval of the behavior exhibited by popular youth, and these linkages are likely bidirectional in nature. Observations that youth who use relational aggression confer privileged status in the peer group might contribute to more positive evaluations of the behaviors exhibited by those youth, a hypothesis that is supported by our finding that early adolescence was marked by a significant increase in approval of relational aggression and higher levels of relational aggression. At the same time, as relationally aggressive behaviors come to be viewed more positively by adolescents, perceptions of youth who engage in these behaviors should improve. Regardless of the direction of effects, the benefits of high social status incurred by youth who use relational aggression are likely to act as reinforcement of relational aggression, thus explaining the impact of group norms on individual behavior.

Another explanation for the significance of peer group normative beliefs relates to deviancy training and peer contagion. Dishion and colleges have convincingly shown that aggregating high-risk peers increases the risk for escalation of deviant behavior (e.g., Dishion, Eddy, Haas, Li, & Spraklen, 1997; Dishion, McCord, & Poulin, 1999). If group-level norms mirror levels of actual aggression in the peer group, then our findings could reflect peer contagion of relational aggression. Support for this hypothesis lies in a recent study that found variation among classrooms in levels of relational aggression explained significant variance in elementary school-aged children's relational aggression assessed 1 year later (Kuppens et al., 2008). An important direction for future research will be to tease out the influence of peer group aggression and peer group norms in the prediction of children's relational aggression, and to examine the mediating role of children's SIP patterns in this process.

Two additional findings warrant mention. First, although we did find gender differences in approval of aggression (males were more approving) and in overt aggression (males were rated higher), gender was unrelated to relational aggression. These findings are consistent with the growing literature showing that gender differences in relational aggression are generally small (Card, Stucky, Sawalani, & Little, 2008). Concerns about lack of power precluded us from testing gender-specific models; however, on the basis of past research we did not expect gender differences in the relations of normative beliefs and relational aggression (Werner & Nixon, 2005) or of classroom norms and aggression (e.g., Salmivalli & Voeten, 2004). Given previous findings of the importance of friendships for girls' relational aggression (Werner & Crick, 2004), however, it will be important for future studies to explore group norms and socialization processes within more intimate peer groups. Laboratory studies of micro-level interaction dynamics hold particular promise in this area (e.g., Underwood & Buhrmester, 2007).

Second, the developmental and grade-related effects found in this study point to the need to consider how the middle school context contributes to students' beliefs about relational aggression. As noted by other researchers, middle schools are typically characterized by a larger student body, shifting peer groups, more impersonal teacher–student relationships, and less adult monitoring (e.g., Eccles et al., 1993). These contextual factors might contribute to increases in relational aggression directly, by reducing adult sanctions against the behavior. Indirect influences, however, are also possible. The majority of school-based bullying prevention efforts emphasize overt forms of aggression. Under these circumstances, students are likely to observe that adults pay little attention to relationally aggressive behavior (relative to overt aggression) and internalize these reactions as supportive of relational aggression. These processes might explain, in part, the increases in acceptability of relational aggression and growth in relational aggression among older students in this study.

Not only do these results contribute to the theoretical and empirical literature on relational aggression, they provide important directions for prevention and intervention work. Previous work has demonstrated the malleability of children's SIP patterns (Conduct Problems Prevention Research Group, 1999; Hudley & Graham, 1993, 1995; Hudley et al., 1998). Most notably, van Schoiack-Edstrom et al. (2002) reported that the Second Step© program resulted in decreases in approval of social exclusion among students in the intervention group relative to controls. Similar results were reported by Nixon and Werner (2009) in an evaluation of a schoolwide relational aggression prevention program. Decreases in sixth graders' beliefs supportive of relational aggression covaried with decreases in relational aggression between pre and posttest, although the lack of control group in this study precludes drawing firm conclusions. The fact that children as young as preschool believe that relational aggression is more acceptable than overt aggression (Goldstein, Tisak, & Boxer, 2002) points to the potential importance of targeting normative beliefs about relational aggression early in development.

As discussed previously, this study has significant conceptual and methodological strengths including the focus on individual and group-level social cognitive processes and the use of independent informants of aggression, and a longitudinal design. It is not without limitations, however. The sample studied here was ethnically homogenous, thus limiting our ability to generalize findings to diverse populations. That being said, little evidence of variation across ethnic groups in relational aggression has been found (e.g., Herrenkohl, Catalano, Hemphill, & Toumbourow, 2009), and Zelli et al. (1999) found no evidence that ethnicity moderated the associations of children's normative beliefs with overt aggression. Nonetheless, these results need replication with a more diverse sample and a longitudinal design that spans multiple years.

Another limitation centers on the assessment of normative beliefs about aggression. The majority of current assessments of SIP patterns with children, including that of normative beliefs, tap into reflective or conscious cognitive processes, despite knowledge that much SIP takes place in an automatic or unconscious manner (e.g., Bargh, 1984; Schneider & Schriffen, 1977). Children's *explicit* evaluations of specific behaviors (assessed in the current study) might differ from their *implicit* representations of relational aggression. It is worth noting that students in this study reported low levels of approval of aggression overall, a pattern that might be explained by our measurement strategy. Clearly, alternative methods for assessing normative beliefs are needed. Burks and colleagues' work on children's internal representations of peers and hostile knowledge structures provides direction for future research (Burks, Dodge, Price, & Laird, 1999; Burks, Laird, Dodge, Pettit, & Bates, 1999). In addition, a recent study with undergraduates used a reading time paradigm and found that students who self-reported higher levels of relational aggression read target sentences depicting aggressive responses to interpersonal conflicts faster than did students reporting lower levels of relational aggression (Linder, Werner, & Lyle, 2009).

Finally, the use of teacher ratings might have underestimated students' actual levels of more covert forms of aggression, particularly among students in middle school. If this is the case, we might expect to find stronger results in future studies using self-reports or peer reports of aggression. On the other hand, if teachers were only able to identify students who openly used relational aggression or who had a pronounced reputation for being relationally aggressive, our results might indicate that peer group norms play an important role for this subgroup of children only, and that the effects reported here would not occur among youth with very low levels of relational aggression. Future research using multiple informants and person-centered analyses to explore possible subgroupings of relational aggression is needed.

Antecedents and Correlates of the Popular-Aggressive Phenomenon in Elementary School

Philip C. Rodkin and Glenn I. Roisman
University of Illinois at Urbana-Champaign

This study identified correlates and developmental antecedents that distinguish popular-aggressive elementary school children from other youth. Drawing on the National Institute of Child Health and Human Development Study of Early Child Care and Youth Development ($N = 1022$), popular-aggressive children were identified through teacher ratings over Grades 3–6. Potential correlates included social competence as rated by observers, mothers, and teachers. Potential developmental antecedents included cognitive functioning, maternal sensitivity, and participation in child care through age 4.5. Multinomial regressions allowed for the determination of group differences net of covariates such as gender, ethnicity, maternal education, and income-to-needs. Results showed that popular-aggressive elementary school children were distinguished from other youth as having had an extensive child-care history. Discussion focuses on developmental associations between child-care quantity and aggression.

The paradox of aggressive behavior is that it is simultaneously adaptive and maladaptive (Milgram, 1976). What makes aggression maladaptive is all too obvious: Aggressive children endanger others, and are themselves at risk from early in life for a host of serious adjustment problems. What makes aggression adaptive is also well documented (Rodkin & Wilson, 2007). Aggression is highly evolved over phylogeny (Pellegrini, 2007), is often successful in changing other's behavior (Farmer, Xie, Cairns, & Hutchins, 2007), and can be used to acquire resources and maintain group boundaries (Hawley, 2007). Indeed, the functionality of aggressive behavior is such that Cairns (1979, p. 170) understood the relevant question for behavioral scientists to be not "*why* aggression?" but "why *not* aggression?"

One manifestation of the dual adaptive-maladaptive nature of aggression is the presence of a small group of children who are simultaneously aggressive and popular with their peers (Bagwell, Coie, Terry, & Lochman, 2000; Estell, Cairns, Farmer, & Cairns, 2002; Farmer, Estell, Bishop, O'Neal, & Cairns, 2003; LaFontana & Cillessen, 2002; Lease, Musgrove, & Axelrod, 2002; Luthar & McMahon, 1996; Rodkin, Farmer, Pearl, & Van Acker, 2000). Much of this research has been person oriented, that is, focused on the co-occurrence of high popularity and high aggression among certain children. For example, Rodkin et al. (2000) cluster analyzed teachers' ratings of the popularity, aggression, and other personality characteristics of 450 fourth- through sixth-grade boys, finding popular-aggressive ("tough") and popular-nonaggressive ("model") configurations. Boys in the tough configuration were seen by peers and viewed themselves as popular, cool, aggressive, and athletic—but not prosocial, shy, friendly, or academically oriented. In contrast, model boys were viewed by peers and themselves as popular, athletic, academically oriented, friendly, outgoing, and nonaggressive. Model and tough boys were classroom leaders, affiliating with one another (Farmer et al., 2002) and setting the tone for who and what was cool (Rodkin, Farmer, Pearl, & Van Acker, 2006).

Complementing this literature are variable-oriented studies that show no relation or significant positive associations between continuously distributed measures of popularity and aggression assessed over whole samples (Cillessen & Mayeux,

2004; Gest, Sesma, Masten, & Tellegen, 2006; Parkhurst & Hopmeyer, 1998; Prinstein & Cillessen, 2003; Rose, Swenson, & Waller, 2004; Schwartz, Gorman, Nakamoto, & McKay, 2006; Vaillancourt & Hymel, 2006; Xie, Li, Boucher, Hutchins, & Cairns, 2006; Zeller, Vannatta, Schafer, & Noll, 2003). Whether personified in the "tough," popular-aggressive child, or as reflected in bivariate associations, the co-occurrence of popularity and aggression has been demonstrated across early childhood (e.g., Estell et al., 2002), middle childhood (e.g., Rodkin et al., 2000), and adolescence (e.g., Vaillancourt & Hymel, 2006).

Although popular-aggressive children have been identified across development, early factors that enable a coupling between popularity and aggression are not clear (Cillessen & Mayeux, 2007). There are no studies of popular-aggressive children that extend from early childhood to early adolescence, infrequent use of observational measures in this literature (but see Pellegrini, 2007; Pepler, Craig, & Roberts, 1998), and relevant study designs have not assessed broad domains of developmental functioning such as cognition and parenting that at least theoretically might distinguish aggressive children who are versus are not popular. Thus, the goal of this study was to identify correlates and antecedents that distinguish popular-aggressive elementary school children from other youth, particularly other aggressive children who are not popular.

Study questions were addressed using data from the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care and Youth Development (SECCYD). The NICHD SECCYD is well suited for evaluating the early developmental history of popular-aggressive children. Children in the NICHD SECCYD have been followed longitudinally from infancy to age 15 (and age 17.5 year assessment is ongoing). Multiple teacher ratings of popularity and aggression are available. Covariates that may function as selection factors and/or confounds (e.g., sex, ethnicity, family income-to-needs, and maternal education) are included. The sample is also large enough to identify the infrequent configuration of popular-aggressive children. In the present study, the concurrent social competence and disruptiveness of popular-aggressive children as rated by mothers, teachers, and classroom observers was first determined. Two early developmental resources widely regarded as protective of adaptation, high cognitive functioning and sensitive parenting (Masten, 2001), were next evaluated. Finally, effects were determined for the social factor of participation within the early peer ecology of child care, a developmental context that been implicated in the generation of aggressive behavior (Dmitrieva, Steinberg, & Belsky, 2007).

Social competence should correlate with popular aggressiveness. An image of the sophisticated, ruthless, acquisitive child pervades scholarship on the popular-aggressive phenomenon (e.g., Hawley, 2007; Sutton, Smith, & Swettenham, 1999; Vaughn, Vollenweider, Bost, Azria-Evans, & Snider, 2003). Hawley (2002, 2007) identified children who are bistrategic controllers, meaning that they use both prosocial and coercive means to obtain resources. Bistrategic controllers are distinguished from other aggressive children through their savoir faire, ability to impress others, and "moral astuteness" (Hawley, 2007, p. 15). Thus, popular-aggressive children, compared to other aggressive children, should score higher on observer reports of social competence—although perhaps not on measures of social skills as rated by parents and teachers who heavily emphasize compliance.

Developmental antecedents that may distinguish popular-aggressive children from aggressive children who are not popular include early maternal sensitivity and high cognitive functioning. Clearly, the protective resources of high cognitive functioning and maternal sensitivity can promote peer social capital in middle childhood. Studies on popularity and aggression examine factors such as academic engagement and grades (e.g., Rodkin et al., 2000; Schwartz et al., 2006), but for popular-aggressive children, it may be necessary to assess cognition early, before the advent of school disengagement and conflict. The possibility that popular-aggressive children have acquired social resources through effective parenting has simply not been evaluated, as studies of popularity and aggression have tended not to include parenting or family constructs. However, maternal sensitivity has had large and broad effects on developmental adaptation in previous reports of the NICHD Early Child Care Research Network (ECCRN; 2003b; see also Thompson, 2009).

Although it is possible that the popular-aggressive child benefits from broad adaptational resources unavailable to other aggressive children, the main hypothesis that guides this study is that popular-aggressive children will have had more time in child care than other children, including other aggressive children who are not popular. Bronfenbrenner (1979, p. 203) hypothesized that children who spent many hours in child care would be "more likely to engage in egocentric, aggressive, and antisocial behavior both during the preschool years and through later childhood into adolescence.'' Early reports from the NICHD ECCRN confirmed a linkage between child-care quantity and aggression in the SECCYD. When children were in child care at 2 and 3 years of age, child-care quantity (as measured in mean hours per week since birth) was related to negative peer play as rated by caregivers but positive and skilled play as rated by observers (NICHD ECCRN, 2001). When children reached the kindergarten transition at age 4.5, child-care hours were directly associated with externalizing problems, conflicts with adults, and aggression (NICHD ECCRN, 2003a). The association between child-care hours and aggression appears to dissipate by Grade 3 (Belsky et al., 2007; NICHD ECCRN, 2004a, 2005). Nonetheless, some features of child care within the SECCYD continue to show links to aggression into middle childhood (Belsky, 2009). As Bronfenbrenner (1979) predicted, children spending more hours in child care with small- and medium-sized peer groups continue to be rated as more aggressive by Grade 3 teachers (NICHD ECCRN, 2008). Moreover, proportion of time in center-based care has been associated with increased aggression at Grade 6 (Belsky et al., 2007) and lower awakening cortisol levels at age 15 (Roisman et al., 2009) in the SECCYD sample.

The construct of popularity might be able to clarify purported associations between child-care quantity and later aggression. Some children with an extensive child-care background might find that their early expressions of aggression have social value within the child care context and beyond. Dmitrieva et al. (2007), using data from the Early Childhood Longitudinal Study, reported that kindergarteners manifested more externalizing problems by the end of the school year when they had many classmates with extensive child-care histories. This effect of classroom composition was evident even for children who did not themselves attend child care. One interpretation of this finding is that some aggressive children with a history of extensive child care had sufficient popularity and status to influence their peers. Once a linkage between popularity and aggression is established, it may endure over similar peer ecologies with potential for broad social influence.

In this study, NICHD SECCYD participants were classified into popular-aggressive (''tough''), popular-nonaggressive (''model''), aggressive-nonpopular (''aggressive''), and nonpopular-nonaggressive groups using teacher ratings aggregated over Grades 3–6 (see Rodkin et al., 2000, 2006), and then validated through observational assessment. A variety of study measures enabled the determination of the unique developmental effects of early and concurrent cognitive functioning, early and concurrent maternal sensitivity, and early child care (i.e., quantity, quality, center-based care). The robustness of study findings was evaluated by using multiple criteria for popularity and by testing continuous Popularity × Aggression interactions over the entire sample.

Method

Participants

Families were recruited during hospital visits to mothers shortly after the birth of a child in 1991 at 10 locations in the United States. Recruitment and selection procedures are described in detail elsewhere (see http://secc.rti.org; NICHD Early Child Care Research Network, 2003a). The NICHD SECCYD sample is diverse: Twenty-four percent of mothers were minority, 11% of mothers had not completed high school, and 14% were single at the time of the infant's birth. Data for the current report are based on 1,022 children with any data on physically aggressive behavior (as assessed by the Teacher Report Form [TRF]; Achenbach, 1991; ''hits others,'' ''defiant,'' ''mean,'' etc.) and teacher-rated popularity in Grades 3, 4, 5, and 6. These grade school assessments were used due to continuity of measurement (identical measurement of aggression and popularity were available in these grades) and because prior studies of popular aggressiveness have focused on this age range.

Identification of Groups

From the subsample of 1,022 participants, groups were identified based on a cross-classification of teacher-reported aggression and popularity in Grades 3, 4, 5, and 6. The TRF aggression scale showed high internal consistency ($\alpha = .95$ at each assessment). In addition, because TRF reports across Grades 3, 4, 5, and 6 scaled were strongly intercorrelated (mean $r = .54$, range = .50 to .59, all $ps < .001$), a mean TRF aggression score was computed to create groups ($\alpha = .82$). Teachers were asked to rank children's ''popularity with the other same-sex children in your class'' using a measure developed by the NICHD ECCRN and computed at each grade as the sum of the total number of same-sex children plus one, minus study child popularity ranking (teachers ranked all same-sex children in the classroom from most to least popular), all divided by the total number of same-sex children. The range of scores computed in this manner is all positive numbers up to one. Again, because teacher-reported popularity in Grades 3, 4, 5, and 6 were strongly intercorrelated (mean $r = .46$, range = .39 to .52, all $ps < .001$), scores were averaged ($\alpha = .78$) across time to create groups. Note finally that the mean TRF aggression and mean popularity variables were moderately negatively correlated, $r(1{,}022) = -.25$, $p < .001$.

Achenbach (1991) reports that a T score of 60 can be used to define the clinical cut-point of TRF scales. In primary analyses, a cutoff for popularity was used that identified the top third. Using these criteria, four groups were identified as follows: *nonpopular-nonaggressive* ($n = 467$: 240 males, 227 females)—scored below 60 on the TRF and below .66 on teacher-reported popularity; *model* ($n = 418$: 199 males, 219 females)—scored below 60 on the TRF but at or above .66 on teacher-reported popularity; *aggressive* ($n = 104$: 54 males, 50 females)—scored at or above 60 on the TRF but below .66 on teacher-reported popularity; *tough* ($n = 33$: 18 males, 15 females)—scored at or above 60 on the TRF and at or above .66 on teacher-reported popularity. Groups were also recomputed using a more stringent definition of popularity (top 20%; see the Results section); using these more conservative criteria nonpopular-nonaggressive, model, aggressive, and tough groups contained 714, 171, 121, and 16 participants, respectively.

Participants in the analysis subsample ($n = 1{,}022$) differed from those excluded (i.e., the remaining members of the full SECCYD cohort; $N = 1{,}364$) in several ways, although effects were trivial to small. Children in the subsample had higher income-to-needs scores (in sample $M = 3.7$, $SD = 2.8$ vs. excluded $M = 3.2$, $SD = 3.0$), $t(1,\ 1{,}300) = 2.59$, $p < .01$; higher maternal education (in sample $M = 14.5$, $SD = 2.4$ vs. excluded $M = 13.6$, $SD = 2.6$), $t(1,\ 1{,}361) = 5.66$, $p < .001$; were less likely to be male (in sample = 50% vs. excluded = 57%), $\chi^2(1) = 4.64$, $p < .05$; and were less likely to be African American (in sample = 11% vs. excluded = 18%), $\chi^2(1) = 9.88$, $p < .01$.

Procedure

Mothers and children were visited at home and came to university laboratories multiple times from when the children were 1 month to Grade 6. The teachers of participating children completed questionnaires about the children from school entry through Grade 6. The study's Manuals of Operation (http://secc.rti.org) has additional details.

Measures

Demographic characteristics. Child sex and maternal education level were obtained by maternal report at 1 month. Family income was reported by mothers at each major data collection point and converted to an income-to-needs ratio by dividing total family income by the U.S. Census-based poverty-level income for that family size. Ratios were averaged from data obtained at 6–54 months. Child race/ethnicity was coded as 1 = African American, 0 = all others, as previous research suggests that popular-aggressive children may be disproportionately African American (Luthar & McMahon, 1996; Rodkin et al., 2000).

Classroom observations of disruptiveness and social skills. Children's classroom experiences and behavior were observed several times over the course of the NICHD SECCYD. This analysis highlights third- and fifth-grade assessments, which were concurrent with the identification of groups. Using the Classroom Observational Assessment for Third Grade (NICHD ECCRN, 2005) and Fifth Grade (NICHD ECCRN, 2004b), participants were observed for eight 44-min cycles distributed across the school day. Among the 7-point ratings made by observers at each grade were disruptiveness and social/cooperates with peers. In addition to ensuring reliability by having coders rate a set of "gold standard" videos, "live" reliability was ascertained via a second coder. Intercoder intraclass correlations were .87 and .85 for disruptiveness in third and fifth grades, respectively, and .88 and .95 for social/cooperates with peers in third and fifth grades, respectively. Because scores were significantly correlated in third and fifth grades—and analyses conducted separately by assessment yielded an identical pattern of results—two across-time composites were created, standardized on the subsample under investigation: mean disruptiveness, third and fifth grade scores, $r(753) = .18$, $p < .001$, and mean social/cooperates with peers, third and fifth grade scores, $r(928) = .22$, $p < .001$.

Mother and teacher reports of social skills. Mothers completed the 38-item Social Skills Questionnaire from the Social Skills Rating System (SSRS; Gresham & Elliott, 1990) when children were in Grades 3, 4, 5, and 6, indexing general social competence with adults and other children. All items that indexed social competence were summed to obtain a standardized measure of total social skills (αs at the four assessments ranged from .88 to .91), and a composite was created by averaging scores in Grades 3–6 (α = .92). Similarly, teachers completed the 30-item school version of the SSRS (Gresham & Elliott, 1990) when children were in Grades 3, 4, 5, and 6. A standardized total social skills scale was created by summing items indexing social competence (αs at the four assessments ranged from .93 to .94), and a teacher-reported social skills composite was created by averaging scores in Grades 3–6 (α = .77).

Early cognitive functioning. Early cognitive functioning was assessed by standardizing and taking the mean of the total scores on the Bayley Mental Development Index at 15 and 24 months (Bayley, 1991), the Bracken Scale of Basic Concepts (School Readiness Scale; Bracken, 1984) at 36 months, and the Woodcock–Johnson Psycho-Educational Battery–Revised (WJ–R; Woodcock, 1990) at 54 months (α = .79).

Later cognitive functioning. Cognitive functioning in grade school was assessed by standardizing and taking the mean of WJ–R (Woodcock, 1990) scores administered to participants in Grades 1, 3, and 5. W (standard) scores for subscales at each time point were standardized and averaged (subscale reliability within time ranged from .84 to .94 in the subsample) before compositing across the three measurement occasions (α = .95).

Early maternal sensitivity. Early maternal sensitivity was calculated from ratings of mothers' behavior during a videotaped interaction between mother and child under semi-structured, free-play conditions at 6, 15, 24, 36, and 54 months (detailed in NICHD Early Child Care Research Network, 1998, 2002, 2003a, 2003b). The early maternal sensitivity score represents child-centered interactions that: reflect emotional support for the child that is responsive to the child's needs and warmly encouraging of the child's positive engagement with the toys and tasks in the interaction procedures (sensitivity to nondistress, supportive presence), is respectful of the child's interests and efforts (lack of intrusiveness, respect for autonomy), and is affectively positive (positive regard, lack of hostility). Internal consistency of the sensitivity composite ranged from αs = .70 to .84, and interrater reliabilities of the composites, calculated with intraclass correlations across raters, ranged from .83 to .87. Mean (standardized) sensitivity scores at 6, 15, 24, 36, and 54 months were used in analyses as a measure of early sensitivity (α = .76).

Later maternal sensitivity. In Grade 1, NICHD ECCRN staff videotaped an interaction between mother and child under semi-structured, free-play conditions. In Grades 3 and 5, the context shifted to two tasks requiring participants to discuss areas of disagreement and to engage in a planning exercise. Sensitivity was computed as a composite of supportive presence, respect for autonomy, and hostility (reversed) at each assessment. Internal consistency of the sensitivity composite ranged from αs = .80 to .85, and interrater reliabilities of the composites, calculated with intraclass correlations across raters, ranged from .84 to .91. Mean (standardized) sensitivity scores in Grades 1, 3, and 5 were used in analyses as a measure of later sensitivity (α = .71).

Early child care. Child-care information was obtained through phone calls with the mother and observations of the child's primary child-care setting. Mothers were called every 3 months between the time the baby was 1 month and 36 months, and at 4-month intervals through 54 months, and asked to list the various places the child received care and the hours per week that the child spent in each arrangement. The quantity of care is the average hours per week from 1 to 54 months that the child spent in regular nonmaternal care; the amount of center care is expressed as the proportion of phone calls from 1 to 54 months in which the child was reported to be attending a child-care center for at least 10 hr/week.

Quality of care was assessed via live observation of primary nonmaternal arrangements that were used for 10 or more hr per week at 6, 15, 24, 36, and 54 months, focusing on caregiver behaviors toward the study child. Observations were conducted during two half-day visits scheduled within a 2-week interval at 6, 15, 24, and 36 months and one half-day visit at 54 months. At each half-day visit, observers completed two 44-min cycles of the Observational Record of the Caregiving Environment (ORCE; NICHD ECCRN, 1996, 2002). Reliability exceeded .90 at 6 months, .86 at 15 months, .81 at 24 months, .80 at 36 months, and .90 at 54 months. The aggregated scores from 6, 15, 24, 36, and 54 months were standardized and averaged to form the child-care quality composite.

Results

Analytic Plan

Planned comparisons, which are ideal in protecting against Type II error when a priori contrasts can be specified (e.g., they eliminate the need for omnibus *F*s; see Hays, 1988), were conducted in preliminary analyses. Each set of analyses contrasts the popular-aggressive (i.e., "tough") group with the other three groups (e.g., nonpopular-nonaggressive, model, and aggressive). In addition to *t* statistics and their associated two-tailed *p* values, standardized differences between means (Cohen's *d*; effect sizes) were calculated. Note that (a) *n*s vary across analysis to maximize data available from each assessment (see Table 1, which presents *n*s, *M*s, *SD*s for all dependent measures by group) and (b) because Levene's test of homogeneity was significant for all planned comparisons except observed social skills, child-care quantity, and child-care quality, *t*s reported for all other planned comparisons do not assume equal variances across groups and *df*s are estimates rounded to the nearest whole number.

Analyses are reported in five sets. First, the tough group was externally validated by examining convergent evidence drawn from contemporaneous measures from Grades 3 and 5. The question here was whether children in the tough group are in fact simultaneously aggressive and socially effective—although not necessarily socially skilled based on adult standards. The second set of analyses examined whether two crucial developmental resources—adequate or better antecedent and contemporaneous parenting and cognitive functioning—served as explanatory factors in accounting for the presence of tough children. The third set of analyses examined early child-care experiences as an alternative explanation for tough children's co-occurring aggression and popularity.

The fourth set of analyses turns to the unique effects of predictors in aggregate using multinomial regression analysis with the tough participants as the reference group. These analyses were conducted to examine which of the developmental resources (i.e., contemporaneous and antecedent cognitive functioning and sensitivity) and alternative explanatory factors (i.e., child-care experiences) accounted for popular-aggressive status in grade school, even after controlling for background characteristics that might function as selection factors or confounds (i.e., demographic covariates; child sex, child African American vs. not, maternal education, and income-to-needs from 6 to 54 months). Fifth, to confirm that findings can not be attributed to the specific ways in which groups were created, robustness analyses considered whether: (a) groups constructed using a more conservative threshold for defining popularity (i.e., top 80% of class as compared to top third) yielded convergent evidence in follow-up multinomial regressions and (b) multinomial regression results could be replicated in a variable-based regression examining the predictive significance of the interaction of popularity and

Note. Mean values reported for all observational measures are *z* scores standardized on the subsample classified into one of the groups. Groups were defined using a 66% cutoff for popularity and $T \geq 60$ cutoff for defining significantly elevated levels of aggression. Obs = observed; T = teacher; M = mother; CC = child care.

aggressiveness (controlling for main effects) over the entire analysis sample.

Contemporaneous Correlates

Observations of classroom behavior. Observers rated tough children as significantly more disruptive during Grades 3 and 5 than model children, $t(33) = 3.02$, $p < .01$, $d = 0.70$, and nonpopular-nonaggressive children, $t(33) = 2.91$, $p < .01$, $d = 0.66$, but not more disruptive than aggressive children, $t(43) = 0.79$, $p = .43$, $d = 0.17$. Consistent with their status as popular, observers rated tough children as significantly *more* socially skilled than nonpopular-nonaggressive, $t(995) = 2.40$, $p < .05$, $d = 0.43$, and aggressive children, $t(995) = 2.43$, $p < .05$, $d = 0.47$, and comparable to model children, $t(995) = 0.38$, $p = .70$; $d = 0.07$.

Teacher and mother ratings of social skills. Teachers rated tough children as significantly less socially skilled on the SSRS in Grades 3–6 than model children, $t(36) = 11.89$, $p < .001$, $d = 2.24$, and nonpopular-nonaggressive children, $t(38) = 5.70$, $p < .001$, $d = 0.99$, although *more* socially skilled than aggressive children, $t(53) = 2.58$, $p < .05$, $d = 0.52$. Mothers rated tough children as significantly less socially skilled in Grades 3–6 than model children, $t(33) = 3.79$, $p < .001$, $d = 0.78$, and nonpopular-nonaggressive children, $t(33) = 2.34$, $p < .05$, $d = 0.45$, and comparable to aggressive children, $t(47) = 1.24$, $p = .22$; $d = 0.26$.

Developmental Resources

Cognitive functioning. Prior to grade school, tough children had significantly lower levels of cognitive functioning than model children, $t(35) = 2.84$, $p < .01$, $d = 0.54$, but were comparable to nonpopular-nonaggressive children, $t(36) = 1.00$, $p = .32$, $d = 0.18$, and aggressive children, $t(59) = 1.01$, $p = .32$, $d = 0.20$. Results in grade school were identical. Tough children had significantly lower levels of cognitive functioning than model children, $t(33) = 2.31$, $p < .05$, $d = 0.49$, but were comparable to nonpopular-nonaggressive children, $t(33) = 1.25$, $p = .22$, $d = 0.26$, and aggressive children, $t(51) = 0.41$, $p = .69$, $d = 0.08$.

Maternal sensitivity. Prior to grade school, tough children had significantly less sensitive mothers than model children, $t(35) = 3.53$, $p < .01$, $d = 0.70$, and nonpopular-nonaggressive children, $t(35) = .68$, $p < .05$, $d = 0.52$, but were comparable to aggressive children, $t(54) = 0.38$, $p = .70$, $d = 0.08$. Results in grade school were identical. Tough children had significantly less sensitive mothers than model children, $t(33) = 3.69$, $p < .001$, $d = 0.77$, and nonpopular-nonaggressive children, $t(33) = 2.81$, $p < .01$, $d = 0.56$, but were comparable to aggressive children, $t(47) = 0.24$, $p = .81$, $d = 0.05$.

Early Child-Care Experiences

Groups were examined on three measures of child care measured through 54 months: hours per week in nonmaternal child care (quantity), quality, and proportion of time in center-based care. Tough children spent significantly more time in nonmaternal child care than model, $t(1018) = 3.12$, $p < .01$, $d = 0.58$; nonpopular-nonaggressive, $t(1018) = 3.30$, $p < .001$, $d = 0.62$, and aggressive, $t(1018) = 3.16$, $p < .01$, $d = 0.68$, children. Tough children experienced significantly lower quality child care than model children, $t(919) = 2.13$, $p < .05$, $d = 0.41$, although the quality of their child care was comparable to nonpopular-nonaggressive children, $t(919) = 1.39$, $p = .16$, $d = 0.26$, and aggressive children, $t(919) = 0.02$, $p = .99$, $d = 0.004$. Tough children spent a marginally larger proportion of time in center-based care than model children, $t(35) = 1.70$, $p = .098$, $d = 0.32$, and nonpopular-nonaggressive children, $t(34) = 1.98$, $p = .06$, $d = 0.39$, but comparable time as aggressive children, $t(45) = 1.24$, $p = .22$, $d = 0.26$.

Aggregate Effects of Predictor Variables

A multinomial regression predicting group was conducted with the tough group as the reference category (see Table 2). We simultaneously entered four demographic covariates (child sex, maternal education, family income-to-needs, African American vs. not), the entire set of developmental resource variables (early and later cognitive functioning and maternal sensitivity) and the early child-care variables (quantity, quality, and proportion of center-based care). The overall model fit the data well, $\chi^2(33, N = 898) = 127.36$, $p < .001$, and the Nagelkerke pseudo-R^2 was .15 (details regarding likelihood ratio tests are available from the authors). Three sets of parameter estimates are provided in Table 2 (nonpopular-nonaggressive vs. tough; model vs. tough; and aggressive vs. tough). As can be seen, only two variables consistently distinguished the tough children from each of the other groups. Specifically, net of other effects, tough children were disproportionately African American and spent more hours per week in nonmaternal child care before they transitioned to grade school (i.e., through 54 months). In addition, a follow-up analysis examined whether the significant effect of child-care quantity was moderated either by child-care quality or center-based care exposure in a simplified multinomial regression in which the three main effects of early child care (quantity, quality, and center care) and the two relevant interaction effects (Quantity × Quality and Quantity × Center-Based Care) were entered. Neither interaction effect was significant, but the main effect of quantity continued to distinguish tough children from other groups.

Robustness Analyses

To examine whether study findings were a product of the top 33% popularity criterion used in primary analyses, the multinomial regression of Table 2 was recomputed using a more stringent criterion that required "popular" participants to be in the top 20% in teacher-related popularity. As detailed in Table 3, the pattern of results was largely unchanged, suggesting that results are largely insensitive to the popularity criterion. Specifically, the model fit the data well, $\chi^2(33, N = 898) = 116.10$, $p < .001$, and the Nagelkerke pseudo-R^2 for the model was .15 (details regarding likelihood ratio tests are available from the authors). Once again, only percent African American and early child-care quantity consistently discriminated the tough children from all other groups. Of note, however, African Americans were only marginally overrepresented in the tough versus aggressive group in this analysis.

Two multiple regressions examined whether early child care and percent African American were associated with simultaneously high aggression and popularity levels in variable-based analyses. First, child-care quantity was regressed onto mean aggression (Grades 3–6), mean popularity (Grades 3–6), and their interaction ($R^2 = .01$, $p < .01$). Results showed significant main effects of aggression ($\beta = .11$, $p < .01$) and popularity ($\beta = .07$, $p < .05$), as well as the expected significant interaction between popularity and aggression ($\beta = .07$, $p < .05$). The interaction is graphed in Figure 1 along Aiken and West's (1991) guidelines (i.e., ± 1 *SD*) and indicates that higher aggression and more child care are correlated only for more popular children. In contrast, a binary logistic regression examining whether the interaction of popularity and aggression was correlated with percent African American (Nagelkerke $R^2 = .18$, $p < .001$) yielded evidence only for a sig-

Note. For this analysis, $n = 14$ for tough, $n = 627$ for nonpopular-nonaggressive, $n = 152$ for model, and $n = 105$ for aggressive. Groups were defined using an 80% cutoff for popularity. Positive *B*s indicate that the group scored higher on the variable in question compared to the reference group (popular-aggressive) net of other variables. For sex, 1 = male, 0 = female. For African American, 1 = African American, 0 = not African American, CC = child care.

Discussion

This study was conducted in order to learn more about a small but influential group of children who paradoxically are both very aggressive and very popular with their peers. The first study question was whether the social competencies that popular-aggressive ("tough") children enjoy are visible to objective observers, and to the mothers and teachers of these children. The second question we explored was whether the developmental resources of high cognitive functioning and maternal sensitivity distinguish tough children from the majority of aggressive children who are not popular. The third question, and the primary focus of this study, was whether tough children might have had a unique history of extensive participation in early child care through the age of 54 months. Research questions were addressed by making use of the public access data of the NICHD SECCYD through Grade 6. The NICHD SECCYD allowed study analyses to take account of many features that are not typical in studies of the popularity-aggression phenomenon, such as longitudinal data at regular intervals from infancy to Grade 6, measures of popularity and aggression aggregated over four annual assessments from Grades 3 to 6, classroom observations aggregated over Grades 3 and 5, and information on potential covariates and multiple domains of

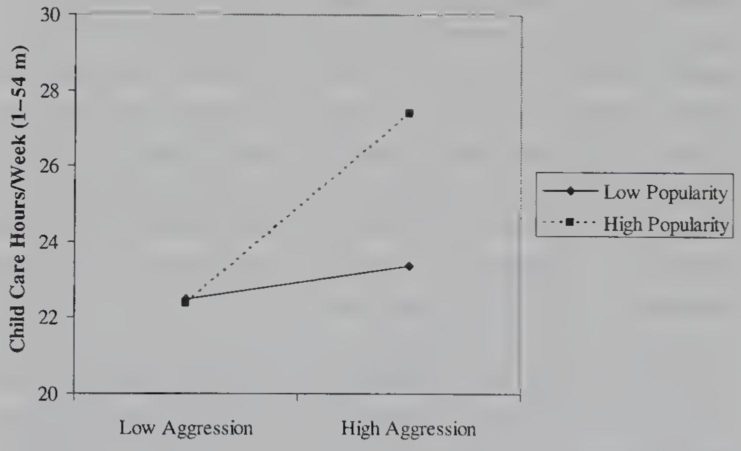

Figure 1. Associations between early child-care quantity (1–54 months) and the interaction of popularity and aggression (Grades 3–6), computed over the entire analysis sample using Aiken and West's (1991) guidelines (i.e., "High" = +1 *SD*, "Low" = −1 *SD*).

developmental functioning. Study findings indicated one correlate that consistently distinguished tough children from all other children: an extensive early history of nonmaternal child care.

The first study question addressed validity by asking whether children rated as popular and aggressive by teachers showed additional evidence of social competence. Can observers discern the social engagement that peer popularity entails, even when popularity is conjoined with aggression? Indeed, they can. Tough children were observed to be extremely disruptive yet highly sociable and cooperative with their peers. According to observers, tough and ''model'' (popular-nonaggressive) children had similar and high levels of social competence—and higher levels of social competence than nonpopular children. Do teachers and mothers recognize the social competencies of the popular-aggressive children in their midst? No, they do not. Mothers and teachers rated tough children as having poorer social skills than model and nonpopular-nonaggressive children. Thus, tough children were viewed as socially skilled and aggressive by disinterested observers who focused on peer interaction quality, but as not socially skilled by adults who may have a frustrating history of trying to guide tough children toward prosocial behavior.

The second study question asked whether tough children enjoy developmental resources similar to model children, and more resources than aggressive children who are not popular. Given the interpersonal skills of tough children, might they have a history of high cognitive functioning? Might tough children benefit from effective, sensitive parenting, in contrast to other aggressive children who suffer from hostile, inconsistent parenting? To both these questions, the answer appears to be no. Model children had higher levels of cognitive functioning and more sensitive parenting than tough children, who were similar to aggressive-nonpopular children in these respects. Multinomial regressions did not show earlier or later cognitive functioning or maternal sensitivity to uniquely distinguish tough children. Aggressive children had relatively low cognitive functioning and insensitive parenting irrespective of their popularity.

The third study question examined three features of children's early child care: quantity, quality, and proportion of center-based care. Children who were popular and aggressive in middle childhood had an extensive history of early child care. From the period of 1–54 months of age, popular-aggressive children had an average of 31.8 hr per week of child care compared to 23.6 hr for other children. Using a more stringent criterion for popularity (top 20% vs. top third), the effect of child-care quantity increases to an average of 34.6 hr per week for popular-aggressive children and 23.7 hr per week for all other children, a difference of almost 11 hr per week. Multinomial regressions confirmed child-care quantity differences to be significant when Tough children were contrasted with aggressive-nonpopular, popular-nonaggressive, and nonpopular-nonaggressive children net of other factors. Moreover, when popularity and aggression were treated continuously over the entire sample, there was a significant Popularity × Aggression interaction, such that more hours of early child care were associated with the combination of high popularity and high aggression in middle childhood.

Why might an extensive history of early child care distinguish popular-aggressive children from other children, including other aggressive children, over the grade school years? Three factors may be considered: the sometimes aggressogenic nature of early child-care contexts, the relation between the prevalence of aggression and its peer acceptance, and the enduring effects of aggression that has an actual or perceived base of social support.

Early childhood peer ecologies can sometimes appear to be conducive to the development of aggressive behavior. Children who spend a large part of their day in child care may be in the best position to learn how to employ aggression so as to garner social and material resources. Here, it is worth keeping in mind Luthar and McMahon's (1996, p. 601) conclusion that ''what is valued or admired within the peer group is often diametrically opposed to what is viewed as positive adjustment from the standpoint of adults in conventional mainstream society.'' Luthar and McMahon were speaking of adolescents, but their comments hold true for early childhood as well. Aggressive, agonistic behavior can promote popularity, dominance, and status throughout the early childhood years (Estell et al., 2002; Hawley, 2002; Murphy, Murphy, & Newcomb, 1937; Pellegrini et al., 2007; Stormshak, Bierman, Bruschi, Dodge, Coie, & Conduct Problems Prevention Research Group, 1999; Strayer, 1980; Vaughn et al., 2003).

There is reason to suspect that the early peer ecologies of SECCYD participants may sometimes have been aggressogenic, so that children with extensive child care may have had greater potential to conjoin aggressive behavior with peer (but not adult) perceived social competence. For example, NICHD Early Child Care Research Network (2001) focused on relations between time in child care with other children and peer interaction skills at 2 and 3 years of age. Average weekly hours of care since birth was associated with negative peer play as rated by caregivers (e.g., teases, bullies others) and positive, skilled play as rated by observers (e.g., complex, reciprocal, frequent engagement). NICHD Early Child Care Research Network questioned these results: "How could caregivers perceive and rate children as more negative, whereas observers rated the same children's actual interactions in the same setting as more positive?" The answer may be that children who spend well over 30 hr per week in child care have had time and opportunity to master a peer reward structure in which aggressors can become socially well integrated, but nonetheless problematic for caregivers concerned with order and positive socialization.

The developmental question of whether child care–aggression linkages dissipate, endure, or spread might best be answered by reconsidering Bronfenbrenner's (1979) hypothesis that the relation between child-care quantity and later aggression is elicited and continually supported by peer-based social experiences (see also Belsky, 2009; Belsky et al., 2007; Dmitrieva et al., 2007; Fabes, Hanish, & Martin, 2003; Maccoby & Lewis, 2003). Although the main effect between child-care quantity and later aggression in the SECCYD dissipates after kindergarten (NICHD Early Child Care Research Network, 2004a, 2005), it could be that the effect becomes concentrated toward child-care arrangements with peers, such as: nonrelative care (NICHD Early Child Care Research Network, 2005), center-based care (Belsky et al., 2007; NICHD Early Child Care Research Network, 2005), and quantity of time in child care with small- and medium-sized peer groups (NICHD Early Child Care Research Network, 2008). The present study suggests that a carrier of these peer group effects may be the popular-aggressive child, who has spent on average 8–11 more hours a week in child care than other children over a 4½-year period. By Grade 6, these tough children may have enduring patterns of peer aggression, possibly influencing other children toward antisocial behavior as well.

Of course, the mechanisms proposed here are speculative. Moreover, in some cases the child care–aggression association is null, or negative. For example, Côté et al. (2007) reported that nonmaternal child care *reduced* the risk of later aggression when care commenced before 9 months of age, but only for children with mothers with less than a high school education. Additionally, positive effects of high quality child care have been demonstrated within the SECCYD and other samples, including more advanced linguistic functioning and higher mathematics and reading achievement (e.g., Dmitrieva et al., 2007; NICHD Early Child Care Research Network, 2005).

It is important also to emphasize that the effects found in this report are not exhaustive of all possible developmental antecedents of popular aggressiveness. For example, Vaillancourt and Hymel (2006) suggest that popularity is associated not only with aggression (i.e., "explicit power") but also with peer-valued characteristics (i.e., "implicit power") such as being stylish, good looking, athletic, funny, tough, and wealthy (see also Adler & Adler, 1998; Sippola, Paget, & Buchanan, 2007). Athleticism, attractiveness, material resources, and related qualities are clearly important from early childhood to adolescence and beyond (Hawley, Johnson, Mize, & McNamara, 2007; Pellegrini, 2007; Vaughn et al., 2003), but the NICHD SECCYD does not include many measures of the developmental resource of peer-valued characteristics.

Additionally, aggression and popularity measures drawn from the NICHD SECCYD were reliable, but were assessed in ways that are not typical in the peer relations literature. The focus of this report was on physical aggression as represented by the Achenbach (1991) TRF aggression scale. Along with not including many items on relational, social, or indirect aggression, the TRF aggression scale has limited capacity to detect gender differences because the scale is standardized by gender. Popularity was rated by teachers, as the NICHD SECCYD does not include peer nominations in middle childhood. Peer nominations represent a gold standard in the peer relations literature (but see Olweus, 2010), but previous studies on popular aggressiveness have used teacher ratings (e.g., Rodkin et al., 2000), and there is generally strong concordance between teacher and peer representations of classroom social networks (Gest, 2006; Pearl, Leung, Van Acker, Farmer, & Rodkin, 2007). On a related note, a clear limitation of the present analysis is that the NICHD SECCYD does not include extensive measures of the peer social networks of early child-care environments. Without these data, it remains speculative that children who are popular and aggressive in middle childhood are also central in early childhood peer ecologies (see also Lintong & van IJzendoorn, 2009). Dynamic peer network data throughout the child care and grade school years would yield rich information in which social influence patterns could be developmentally mapped and modeled (Hanish & Rodkin, 2007).

Bronfenbrenner (1944, 1979), an early scholar of social status, warned that aggression could emerge as an adaptive short-term response for young children with extensive child-care experiences (see also Belsky & Steinberg, 1978). The aggression discussed in pre-NICHD SECCYD reports of child-care quantity corresponds with the kind of instrumental, proactive aggression typically associated with peer status—social skills (Haskins, 1985), ''fearless aggressive nonconformity'' (Moore, 1975, p. 257), and ''independence rather than disturbed behavior'' (Clarke-Stewart, 1989, p. 269). The aggression-as-adaptation perspective lost ground to deficit approaches once child-care quantity failed to differentially predict externalizing subscales of the Achenbach (1991) at age 4.5 that theoretically ranged from ''more adaptive'' and less risky (i.e., assertiveness) to ''less adaptive'' and more risky (i.e., aggression, the same TRF subscale used in the present study over middle childhood; NICHD Early Child Care Research Network, 2003a, Table 9).

However, the adaptational significance of childhood aggression depends less on its form than on *who* is aggressing and the *context* in which aggression is elicited. This restatement of Wright, Giammarino, and Parad's (1986) person-group similarity model (see also Chang, 2004; Stormshak et al., 1999) may hold true for many educational settings in America. Bronfenbrenner (1979) and Maccoby and Lewis (2003) stressed that quality child care could support socioemotional development under certain conditions, including knowledgeable scaffolding for the peer ecologies of youth. Indeed, the prevalence of the popular-aggressive child reminds us of the challenge that still awaits: To design educational systems in which children and adults share the same goals of learning and character, a challenge first pointed out by Coleman (1961) almost 50 years ago. As for the popular-aggressive children of the NICHD SECCYD, time will tell whether their social status can be transformed into social capital once high school is left behind, and the peer ecology of the school is replaced by new social challenges in emerging adulthood.

The Rise in Cortisol in Family Day Care: Associations With Aspects of Care Quality, Child Behavior, and Child Sex

Megan R. Gunnar, Erin Kryzer,
and Mark J. Van Ryzin
University of Minnesota

Deborah A. Phillips
Georgetown University

This study examined the increase in salivary cortisol from midmorning to midafternoon in 151 children (3.0–4.5 years) in full-time home-based day care. Compared to cortisol levels at home, increases were noted in the majority of children (63%) at day care, with 40% classified as a stress response. Observations at day care revealed that intrusive, overcontrolling care was associated with the cortisol rise. For girls, the cortisol rise was associated with anxious, vigilant behavior, while for boys the rise was associated with angry, aggressive behavior. Child behavior did not mediate or moderate relations between care quality and the cortisol rise, except for evidence that boys scoring low on angry, aggressive behavior were more sensitive to variations in warm, supportive care than boys scoring high on this behavior.

Years of study of the impact of child care on children's development has led to the general conclusion that whereas child care can confer benefits (e.g., Ahnert & Lamb, 2003; Love et al., 2003; Phillips, McCartney, & Sussman, 2006), long hours in care may have some negative impacts that may be more pronounced for experiences in child-care settings of poorer quality (e.g., Belsky et al., 2007; Gunnar & Donzella, 2002; National Institute of Child Health and Human Development Early Child Care Research Network [NICHD ECCRN], 1998, 2001, 2003). Specifically, higher quality care has been associated with more positive peer interactions and lower levels of externalizing behavior (Howes et al., 1996; NICHD ECCRN, 1998, 2001, 2001, 2003; Votruba-Drzal, Coley, & Chase-Lansdale, 2004) and long hours in care are associated with the emergence of behavior problems in childhood (Belsky et al., 2007; NICHD ECCRN, 2001, 2003). Although the association between quantity of care and externalizing behavior is generally maintained in models with controls for family background and child-care quality, a recent re-analysis of data from the NICHD Study of Child Care and Youth Development has documented that this association is moderated by the quality of care children experienced prior to school entry (NICHD ECCRN, 2010). Hours of child care over periods when the child was in care was a stronger predictor of externalizing behavior at 24 and 54 months in lower quality compared to higher quality care.

In attempts to understand the mechanisms through which child care may operate to increase risks of negative developmental outcomes, researchers have begun to explore relations between child care and activity of the hypothalamic–pituitary–adrenocortical (HPA) system. The HPA system produces cortisol, a steroid hormone that plays critical roles in adaptation to stressors (for discussion of the HPA axis and the neurophysiology of stress, see Gunnar & Quevedo, 2007). Chronic or frequent activations of this neuroendocrine system early in life have been shown in animal models to increase fearfulness and impair behavior and physiological regulatory competence (Gunnar & Quevedo, 2007).

Interest in child care as a stressor capable of activating the HPA axis can be traced to a serendipitous finding published a decade ago (Tout, de Haan,

---

This research was supported by the National Institute of Mental Health through a grant (MH62601) and a Senior Scientist Award (MH066208) to Megan R. Gunnar and through a grant provided by the National Institute of Child Health and Human Development (MH165802) to Deborah A. Phillips. We would like to thank Deborah Vandell and Carollee Howes for their assistance in modifying and developing the M-ORCE. Finally, this study would not have been possible without the generous cooperation of the participating family day-care providers and families they serve.

Campbell, & Gunnar, 1998). Tout et al. (1998) were studying associations between day-to-day variability in cortisol levels and children's socioemotional behavior. When they examined their morning and afternoon cortisol data, they found that most of the children showed a rise in cortisol from morning to afternoon and they did so on most of the days they were in child care. This was remarkable as the typical basal pattern of cortisol production between midmorning and midafternoon tends to be level or declining for children of this age (Watamura, Donzella, Kertes, & Gunnar, 2004).

Since publication of the Tout et al. (1998) study, there have been a number of studies examining cortisol activity at child care. Two recent meta-analyses have summarized those findings (Geoffroy, Côté, Parent, & Séguin, 2006; Vermeer & van IJzendoorn, 2006). Both papers concluded that the rise in cortisol from morning to afternoon at child care has been convincingly documented and that this rise is not seen in the same children when they are at home on non-child-care days. Both meta-analyses also concluded that age is a relevant factor, with larger increases being observed among the younger children (2- and 3-year-olds) compared to the older children (4- and 5-year-olds). However, the two meta-analyses differed with regard to two critical issues: (a) whether child-care quality influences the magnitude of the cortisol stress response over the day at child care and (b) whether elevations in cortisol at child care are associated with children's temperament or behavior in the care setting.

Regarding quality of care, the first meta-analysis (Geoffroy et al., 2006) concluded that it has been shown conclusively that cortisol levels are higher and rise more over the day in poorer quality child care, whereas the second meta-analysis (Vermeer & van IJzendoorn, 2006) noted that nearly all of the child-care studies of cortisol activity have been conducted in relatively high-quality care settings and thus child-care quality cannot be the primary factor determining increases in cortisol at child care. The Vermeer and van IJzendoorn (2006) analysis was restricted to studies of children in child care, whereas the Geoffroy et al. (2006) analysis included a broader range of social settings. Thus, a conservative conclusion is that the relation between care quality and the cortisol increase over the child-care day has not been fully explored.

Indeed, only a few studies that have directly examined increases in cortisol in relation to measures of child-care quality. Legendre (2003) examined structural characteristics of eight child-care centers and found that both the presence of large (> 15) numbers of children and more than four adults, in addition to a wide age spread, were associated with greater cortisol increases. Sims, Guilfoyle, and Parry (2006) examined child-care settings and grouped them as high quality, satisfactory, and unsatisfactory. Among 3- to 5-year-old children, significant *decreases* in cortisol over the day were noted for high-quality centers, whereas in unsatisfactory centers, significant *increases* were noted. To our knowledge, there has been only one study examining whether care quality is associated with cortisol activity in family day-care settings. Dettling, Parker, Lane, Sebanc, and Gunnar (2000) examined a small number of family day-care settings targeting one child in each setting. They noted that poorer quality of care using items from the Observational Rating of Care Environments (NICHD Early Daycare Research Network, 2000) was associated with larger increases in cortisol, but found no evidence that group size in these day-care homes was a significant factor. Thus, the evidence that quality of child care affects the rise in cortisol at child care is not conclusive, especially with regard to family day care. Furthermore, the association between the facets of quality, including structural characteristics (e.g., group size, age range, ratio of caregivers to child) and child–provider interactions (i.e., process measures of quality) needs further exploration. The first two goals of the study were to (a) determine whether cortisol increases over the day in family day-care settings and (b) determining whether increases over the child-care day in these settings were associated with structural or process measures of child-care quality.

The third goal was to examine relations between child behavior and the rise in cortisol over the child-care day. As noted, the two meta-analyses also differed in their conclusions about child behavior. The Geoffroy et al. (2006) analysis concluded that children with difficult temperaments exhibit higher cortisol levels at child care, whereas the Vermeer and van IJzendoorn (2006) analysis concluded that the association between children's emotional dispositions and the rise in cortisol has yet to be shown conclusively. Again the difference in conclusions lies partly in the fact that the two meta-analyses included different studies, with the Geoffroy et al. analysis including studies of children in settings other than child care. Because the question pertains to child behaviors associated with the rise in cortisol over the child-care day, focusing specifically on full-day child-care settings is essential to answering the question.

Based on the human and animal literature, there are two aspects of child behavior that might impact HPA axis stress responses in child-care settings: anxious, vigilant behavior and angry, aggressive behavior. Regarding anxious vigilance, neuroscience evidence on the neural pathways activating stress hormone reactions documents the importance of input from the amygdala and distributed systems involved in fear and anxious vigilance (for a review, see Rosen & Schulkin, 1998). Thus, it has long been suspected that children who are more anxious and vigilant would be more vulnerable to producing activation of the HPA axis (e.g., Kagan, Reznick, & Snidman, 1987). The neuroscience evidence regarding angry and aggressive behavior is mixed. Whereas there is some evidence that children extreme in these behaviors (e.g., oppositional defiant disorder) have lower than normal basal and response levels of cortisol (for a review, see van Goozen, Fairchild, Snoek, & Harold, 2007), there is also evidence that among preschool-aged children aggressive and under controlled behavior in peer group settings is associated with higher cortisol levels (for a meta-analysis, see Alink et al., 2008). This latter finding may partly reflect cortisol increases in response to peer rejection, which occurs more among children who are aggressive and undercontrolled (Gunnar, Sebanc, Tout, Donzella, & van Dulmen, 2003). Thus, the third goal of the study was to examine how patterns of anxious, vigilance and angry, aggressive behavior at child care might relate to cortisol stress reactions over the day in family day-care settings.

In examining these aspects of child behavior, we were aware that boys and girls might exhibit these anxious, vigilant and angry, aggressive behaviors with different frequencies. In particular, boys have often been noted to be more physically aggressive with peers (Crick et al., 2006; Fabes, Martin, & Hanish, 2003), although girls may exhibit relational aggression somewhat more than boys (Card, Stucky, Sawalani, & Little, 2008; Crick et al., 2006). To the extent that these behaviors reflect challenges the children were having in these settings, then their different prevalence might also be related to gender differences in patterns of association with cortisol increases over the child-care day. Indeed, studies of cortisol–behavior associations for children in group settings do report sex differences in patterns of findings, although the direction of effects is not consistent. Several of the studies report associations for one sex but not the other, and sometimes for different measures for each sex within the same study (Dettling, Gunnar, & Donzella, 1999; Tout et al., 1998). While these sex differences might be spurious, they may also reflect differences in how emotional dispositions influence children's experiences in peer group settings. For example, we have noted that preschool girls who are popular with other girls tend to score higher on measures of negative emotionality and lower on measures of assertiveness, whereas boys who are popular with other boys tend to be more exuberant and higher in assertiveness (Sebanc, Pierce, Cheatham, & Gunnar, 2003). These findings may also reflect differences in how care providers respond to boys versus girls with different temperaments and behavioral styles (Phillips et al., 2010). Thus, the fourth goal of the study was to examine whether gender moderated the relations between child behavior and the child-care cortisol stress response.

Finally, we were also interested in how these patterns of child behavior might operate in relation to child-care quality measures in statistical models predicting the rise in cortisol over the child-care day. Both mediating and moderating relations were explored. Regarding mediating relations, the theoretical model for these relations assumed that in order for care quality to impact activity of the HPA system it must have an emotional-behavioral impact on the child. Furthermore, the aspects of behavior impacted must reflect or connect with neural systems capable of activating the HPA stress response. This model is fairly straightforward for anxious vigilance: Children displaying more anxious, vigilant behavior were expected to be experiencing more activity in cortico-limbic pathways that support fear and vigilance and which, via limbic-hypothalamic connections, converge on the HPA axis to produce stress elevations in cortisol (e.g., Rosen & Schulkin, 1998). Children in poorer quality care settings would be expected to experience more frequent periods of fear and anxiety (see also Kryzer, Kovan, Phillips, Domagall, & Gunnar, 2007) and thus should produce greater rises in cortisol at child care. The model of angry, aggressive behavior, however, is less straight-forward. Here the assumption is that these behaviors, which involve negative social interactions, result in heightened experiences of social threat which also activate amygdalar outputs to the HPA axis and thus produce stress elevations in cortisol at child care (see Dickerson & Kemeny, 2004).

Models predicting moderation assume that children's behavior at child care at least partially reflects traits that may make them more or less vulnerable to stress as child-care quality decreases. For example, Boyce and Ellis (2005) have argued that anxious, vigilant children are more sensitive to context, not only experiencing more stress and negative outcomes when conditions are poor but less stress and better outcomes than other children when rearing conditions are especially supportive. Similarly, Belsky, Hsieh, and Crnic (1998) proposed that infant negative emotionality, which includes proneness to anger, increases children's susceptibility to externalizing problems as a function of differential rearing experiences. Extrapolating from these theoretical models, both anxious, vigilant and angry, aggressive dispositions may moderate associations between care quality and cortisol stress responses.

To summarize, the purpose of this study was to develop a better understanding of the factors associated with rise in cortisol over the child-care day. There were five goals: (a) determine whether cortisol increases of the day in family day-care settings; (b) examine the extent to which structural and process measures of child-care quality are associated with the magnitude of cortisol increase over the child-care day; (c) explore whether anxious, vigilant or angry, aggressive behavior is related to the child-care cortisol stress response; (d) examine whether gender moderates child behavior–cortisol rise associations; and (e) examine whether child behavior mediates or moderates associations between process measures of child-care quality and the child-care cortisol stress response.

In conducting this study, we focused on children in family day-care homes for several reasons. First, relative to center-based care settings, there are less data on whether and to what extent cortisol increases over the day in family-based day care. Second, we were able to collect a large number of day-care homes for analysis, many more than had we tried to sample across different child-care centers, thus broadening our ability to examine relations between care qualities and HPA axis activity. Third, family-based day-care settings range widely in the number of children in care, with some including only one or two children, whereas others operate more like small day-care centers with 10 or more children and several adults, giving us the ability to evaluate the effects of group size. Finally, although we only examined licensed day-care homes, the education levels, day-care experience of the providers, and observational measures of care quality were expected to vary considerably, again allowing a broad examination of quality-related factors that might help explain variation in cortisol increases among the children.

Method

Participants

The children ($N = 151$, 54.3% girls) were recruited from family-based day-care settings in a major metropolitan area. Selection criteria were: child age 3–4.5 years ($M = 3.81$, $SD = 0.23$), full-time care (≥ 20 hr per week; $M = 40.61$ hr, $SD = 8.26$ hr), and at least 2 months attending the present *day-care* home ($M = 27.52$ months, $SD = 13.40$ months, range = 2–48 months). This last criterion was used to avoid assessing children who might still be adapting to the day-care arrangement. Of the children, 85.4% were White, 12% African American, 1% Asian, and 1% Hispanic. Demographic data were collected on the families: Ninety-six percent provided the requested information. Income before taxes was coded in $25,000 increments with mean income in the $51,000–$76,000 range. Parent education was coded as: (1) less than high school, (2) high school or general education diploma (GED), (3) some college, (4) associate's degree, (5) bachelor's degree, (6) master's degree, and (7) professional school or doctorate degree. Median level parental education was an associate's degree, with no parent reporting less than a high school or GED education. Only 4% of the children lived in single parent households. As such, we consider the sample to be low risk.

Recruitment Procedures

Children were recruited through licensed family-based child-care providers who had responded to solicitations for participation mailed directly to them or placed in the licensing agencies' newsletter. Providers were contacted to determine if they had a child in their care that met the selection criteria. Eligible providers who agreed to participate approached the parent(s) of the child to request permission to release their contact information. Parents were then contacted to request consent for their child to participate; of the parents contacted, 59% agreed to participate. Eighty-one participants were from child-care sites that contributed only a single child, whereas 70 were from 30 sites that contributed two or three participants each. Recruitment took place over multiple years, implying that children from the same site were not necessarily present at the same time in the child-care setting. Of the 30 sites with multiple participants, 36 of the 70 participants were present together at the same time. Sites contributing more than one child to the analyses tended to be the larger child-care sites, $t = 1.71$, $df = 149$, $p < .10$.

Day-Care Settings

Day-care providers completed a brief questionnaire about their setting and experience. All 120 day-care sites were licensed. The number of children present ranged from 2 to 12 ($M = 5.25$, $SD = 2.25$) and the number of adults at each site ranged from 1 to 3 ($Mdn = 1$, $M = 1.14$, $SD = 0.44$). The ratio of children to each adult who was physically present and within sight of the children averaged at the time of our observations was 1:5.38 ($SD = 2.25$, range = 1:1–1:25). Ninety-six percent of the providers classified themselves as non-Hispanic White. Providers averaged 13.84 ($SD = 7.69$) years of work as a day-care provider, and 30.7% were providing care to a child of their own who was under the age of 5 years. We note that being the child of the care provider was an *exclusion* criterion. Using the same education scale described above, the median education of the providers was some college, including 2-year degree from a technical or community college. We also examined formal child development or early childhood education course work in high school or college, 11.30% reported no such formal coursework, 52% reported some formal training but not college level, whereas 37% reported college level training.

Procedures and Measures

Care provider and child behavior measures. The children were observed on two mornings between 8:30 and 9:30 a.m. on days the provider deemed *typical* (i.e., no field trip, birthday parties, etc.). The observation inventory developed for this research project was a modification of the Observational Rating Scales of Caregiving Environment (ORCE; see NICHD ECCRN, 2000; for a complete description of the modified or M-ORCE, see Kryzer et al., 2007). Like the ORCE, the M-ORCE involves two 44-min observations (one per day), divided into four 10-min observation periods. In each 10-min period, observers alternate between 30 s observe and record frames for coding frequency counts of behavior. At the end of each 10-min period, the observer makes brief notes and tentative qualitative ratings for 2 min. This process was repeated for three 10-min periods. In the final 10-min period, the observer makes observations exclusively for the qualitative ratings. All qualitative ratings were 4-point scales. Coding of the M-ORCE was performed by six coders, one of whom was the reliability coder who trained the others. The reliability coder scored 41% of the children in the study, while the other coders contributed between 3% and 19% of the data each. Coders were trained through discussion of the codes and practice on videotapes. They then accompanied the reliability coder to practice coding sites and scored with her until they achieved Cohen's kappas of at least .80 on all scales. During data collection, coder agreement was reassessed approximately every fifth session for each coder by having the reliability coder jointly code one of the target subjects with each coder. Approximately every 6 weeks, the coders reviewed a master coding videotape and discussed discrepancies to reduce problems of coding drift.

For the present report, nine qualitative variables of care quality were examined as dimensions of the day-care environment expected to influence the stressfulness of the context. These variables were: Sensitivity, Intrusiveness, Detachment-Disengagement, Positive Regard for the Child, Negative Regard for the Child, Positive Community Building, Negative Community Building, Environmental Rating of Chaos, and Environmental Rating of Overcontrol. Sensitivity, Positive and Negative Regard, Detachment, and Intrusiveness were rated based on the provider's behavior toward the target child. Overcontrol was a rating of the care provider's structuring of the care environment, whereas Chaos reflected the general degree of unpredictability of the setting. These measures were identical on the ORCE and M-ORCE. Positive Community Building was a measure of the care provider's use of strategies to help the children understand and relate positively to one another (e.g., "Johnny is feeling sad today because his mother is in the hospital, so that is why he wants to play alone right now"). Negative Community Building was a measure of the care provider's use of strategies that created winners and losers and children pitted against one another as a discipline strategy (e.g., "Sam isn't doing what I asked, is he? We can't start the story until Sam is quiet"). These measures were developed based on work by Lewis, Watson, and Schaps (2003). As would be expected, Positive and Negative Community Building were very highly correlated ($r > .80$) and thus were combined into one scale by subtracting Negative from Positive Community Building scores.

To reduce the number of scale examined, the eight qualitative measures noted above were entered into a principal axis factor analysis. The results indicated two factors with eigenvalues > 1 that accounted together for 68% of the variance. The first factor, with an eigenvalue of 3.98, explained 49.7% of the variance and consisted of Sensitivity, Detachment (negative loading), Positive Regard, Chaos (negative loading), and the summary Community Building variable. The resulting measure was labeled Warm-Supportive Care. The second factor with an eigenvalue of 1.5 accounted for 19% of the variance and consisted of Intrusiveness, Negative Regard, and Overcontrol. We labeled the resulting measure Intrusive-Overcontrolling Care. After varimax rotation, there were no variables that cross-loaded > 0.40.

Six measures of child functioning were examined. Three were qualitative measures: Vigilant-Anxious Mood, Angry-Irritable Mood, and Belonging. Three were based on the frequency counts: Solitary Play, Positive Integration, and Negative Peer Interactions. All except Solitary Play were measures developed for the M-ORCE. Vigilant Mood (1 = *no evidence of Vigilant-Anxious behavior*, 4 = *high level of Vigilant-Anxious behavior*) described the extent to which the child engaged in such behaviors as flinching when others came near, moving quickly away from others, and continuously dividing attention between what they were doing and tracking events in the environment. Angry-Irritable Mood (1 = *no evidence of Angry-Irritable behavior*, 4 = *high level of Angry-Irritable behavior*) described the extent to which the child expressed anger and irritability in face, voice, or gesture. While such behavior might involve interactions with others, it could also reflect behavior directed toward objects (e.g., throwing down a toy). Belonging was a qualitative rating reflecting the extent to which the child acted relaxed, confident, and assured (4 = *acts highly relaxed, confident, and assured*) as opposed to anxious, tentative, and cautious (1 = *anxious, tentative, and cautious*), that is, the extent to which the child seems to "fit in" in the setting as opposed to appearing like an outsider who is not integrated into the setting. Children did not have to be involved in play with other children in order to score high on this measure, as long as their behavior was relaxed and they appeared confidently engaged in what they were doing. Solitary play was a frequency count of the number of 10-s periods when the child was playing alone computed as the percentage of intervals when the child was not engaged in physical care activities (i.e., was available for social interaction). Positive Integration assessed not only the frequency with which the child was positively engaged with others in the setting, but also the extent to which the child's role in the interaction was central to the group. A score of 4 indicated positive engagement where the child was a key player in the interactions, directing the interactions or being looked to by others while a lower score indicated positive engagement but in a role where the child was a subordinate or more peripheral actor in the activities. Thus this measure reflected not only the amount but the centrality of the child in positive social interactions. Negative Peer Interactions was a frequency count of the number of intervals in which the child was either the recipient or agent of aggressive behaviors towards other children. Aggression was scored as verbal, physical, and relational aggressive acts. Verbal acts included verbal threats of physical harm, physical acts included pushing and shoving as well as hitting and forcibly attempting to take things away from other children, while relational aggression involved threats or actions directed at harming relationships with peers (e.g., "If you don't give me that, I won't be your friend"; see Crick, Casas, & Mosher, 1997).

These child measures were also submitted to a principal component analysis to permit data reduction. The initial results with varimax rotation indicated that Solitary Play loaded greater than .40 on multiple factors and thus was removed. The resulting analysis yielded two factors with eigenvalues > 1 that accounted for 73% of the variance. The first factor had an eigenvalue of 2.52 and accounted for 50% of the variance. It consisted of Belonging, Positive Integration, and Vigilant-Anxious Mood (negative loading). The resulting measure was reverse scored to yield a measure of Anxious, Vigilant Behavior. The second factor with an eigenvalue of 1.13 accounted for 23% of the variance and consisted of Angry-Irritable Mood and Negative Peer Interactions. The resulting measure was labeled Angry-Aggressive. After varimax rotation, none of the variables cross-loaded > .40.

To examine the stability or trait-like aspect of these measures over time, we examined data on a subset of the children ($N = 108$) who were seen in these same child-care settings 6 months later. The test–retest correlations computed on these participants were: Warm, Supportive Care, $r = .49$, $p < .001$; Intrusive, Overcontrolling Care, $r = .37$, $p < .001$; Anxious, Vigilant, $r = .29$, $p < .01$; and Angry-Aggressive Behavior, $r = .30$, $p < .01$.

Salivary cortisol. Saliva was obtained for cortisol determination by having the children dip a 1.5-in. cotton dental roll into approximately .025 g of cherry flavored Kool-Aid™ mix and mouth the cotton to obtain the sweet taste. This small amount of Kool-Aid™ has not been found to significantly affect the cortisol assay (Talge, Donzella, Kryzer, Gierens, & Gunnar, 2005). Once the cotton roll was saturated, it was placed in a needleless syringe and the saliva was expressed into a 1.50-ml Eppendorf Safe-Lock microtube and sealed. At day care, samples were collected by the day-care provider on 2 days between 10:00 and 11:00 a.m. and 3:00 and 4:00 p.m. These times were chosen based on previous work showing that when four samples of cortisol are obtained (midmorning, noon, immediately postnap, late afternoon), the rise in cortisol over the child-care day can be reliably assessed at these two time points (Watamura, Sebanc, & Gunnar, 2002). Providers were asked to avoid sampling immediately before a meal, to not give the child caffeinated drinks or dairy products within an hour of sampling, and to wait until 30 min after the child got up from a nap to sample to avoid the decrease in cortisol typically seen over nap time (Watamura et al., 2002). To determine the actual time of sampling, the cotton dental rolls were supplied in a bottle with a MEMS V Track Cap™ (Aardex, Zug, Switzerland), which automatically recorded the time when the container was opened. Use of such devices allows verification of compliance with sampling protocols and also increases compliance (Kudielka, Broderick, & Kirschbaum, 2003). The care provider also completed a brief diary on each day of sampling recording timing of sample, nap times, and meal times.

The data from the MEMs cap and diary were examined to determine if the care provider had complied with the instructions. Twenty children were removed prior to assaying saliva for cortisol because the care provider deviated by more than 1.5 hr in the timing of nearly all of their samples, resulting in the child having no usable cortisol data. The 151 with usable samples are described in this report. Parents were also asked to collect samples using the same protocol on 2 days when the child did not attend day care. These measures provided a home baseline against which to judge the impact of day care on children's cortisol activity. Parents followed the same protocol as the day-care providers, including use of the MEMS V Track Cap™. There were 108 children with a sufficient number of home samples for analysis. Comparisons of child-care cortisol for those with and without home cortisol measures yielded no significant (all $ps > .10$) differences for morning or afternoon levels or for change over the day.

Once collected, day care and home samples were stored in the refrigerator and then mailed to the laboratory. These procedures have been shown not to affect cortisol data (Clements & Parker, 1998). Once in the laboratory, samples were frozen at −20 °C until assay. Assays were conducted in duplicate using a time-resolved fluorescence immunoassay. Intra- and interassay coefficients of variation were at or less than 6.7% and 9.0%, respectively, and duplicates correlated highly, $r = .997$, $p < .001$.

Both home and day-care cortisol measures were averaged within time and context over the 2 days of collection. Within each context, children needed at least one data point at each time of day to obtain a final score. Four measures were computed: Home AM, Home PM, Daycare AM, and Daycare PM. The distributions of these variables were examined and were found to be positively skewed and thus were $\log_{10}$ transformed for analysis. The raw AM values were subtracted from the raw PM values to produce Home Rise and Daycare Rise. These values had roughly normal distributions and thus were not $\log_{10}$ transformed. To examine stability in the rise in cortisol across the days, we also calculated the rise on each of the 2 days of assessment. Finally, to determine whether the levels at child care represented a biologically significant secretory response of the HPA axis for each child, we used the criteria of an increase of at least 0.10 μg/dl and 10% derived from work on previously used in adult studies (Kirschbaum, Pirke, & Hellhammer, 1993; Kirschbaum et al., 1995; Van Cauter & Refetoff, 1985).

Analysis plan and preliminary analyses

In some instances, more than one child was obtained from the same day-care setting, so we accounted for this nesting in all analyses. This was accomplished in SAS using procedures for analyzing nested data (SAS Institute, 2004). In our regression analyses (SAS Proc Surveyreg), the day-care provider was declared to be the "primary sampling unit" or PSU, while in the analysis of variance (ANOVA; SAS Proc Genmod or Proc Mixed) the day-care provider was declared to be the subject. In addition to accounting for the variance associated with children nested within day-care provider, these procedures also adjust the degrees of freedom such that they are based upon the number of day-care providers ($N = 112$) rather than the number of children.

Because some studies of child behavior relations with cortisol activity at child care have yielded evidence of associations for one sex but not the other, in all of the analyses described below we included child sex and examined possible main and interaction effects. The first analyses were conducted to determine whether cortisol rose more over the day at child care than at home. This analysis was computed using a 2 (child sex) × 2 (place: home vs. child care) × 2 (time: morning vs. afternoon) doubly repeated measures ANOVA. We also examined the day-to-day stability of the rise at child care and relied on descriptive statistics to help interpret the percentage of children exhibiting biologically significant increases over the day.

We then attempted to identify background and child-care structural quality factors that contributed to the rise at day care. This analysis included child age and sex, family demographics (e.g., family income), day-care descriptors (e.g., ratio of providers to children), and provider variables (e.g., education, years of experience). Any significant associations were then included as covariates in subsequent analyses of the association of provider behavior measures of quality with the cortisol rise at child care. Next, we examined the two care day-care observational quality measures and the two child behavior measures. Initial analyses examined possible age and sex effects for each variable. Subsequent analyses examined first the association of observed quality measures and then child behaviors with the rise in cortisol over the day-care day.

Mediation analyses require that care quality and child behavior measures were associated with the outcome (i.e., Daycare Rise) and, further, that the care quality and child behavior measures were significantly associated. To prepare for mediation analyses, we next examined whether the care quality measures were associated with the child behaviors. Finally, for the measures meeting the requirements for meditational analysis, we constructed a hierarchical regression, entering first the care quality measure(s) associated with the cortisol rise and, in the next step, the child behavior measure(s) associated with the cortisol rise. The question addressed was whether the association with care quality decreased significantly once the child behavior measures were in the equation.

Moderation analyses were computed for child behaviors exhibiting significant associations with the Daycare Rise. For such measures, hierarchical regressions were computed entering each care quality measure and then, in the interaction step, the interaction between each care quality measure and the child behavior measure. Of interest was whether the interaction term produced a significant increase in the variance explained.

Results

Cortisol Change at Day Care and Home

The 2 × 2 × 2 ANOVA of the home and day-care cortisol measures revealed that neither the effect of child sex nor interactions with child sex was significant. However, the time-of-day by place interaction effect was significant, $F(1, 107) = 5.12$, $p < .05$. Descriptive data are shown in Table 1. Tests for simple effects of time-of-day within place were computed to explicate the interaction. At home, we found no significant change from morning to afternoon, $F(1, 107) = 1.12$, *ns*, while at child care, cortisol levels increased significantly from morning to afternoon, $F(1, 107) = 29.42$, $p < .001$. In addition, cortisol levels were higher when the children were at family-based child care than home both in the morning, $F(1, 107) = 9.65$, $p < .01$, and afternoon, $F(1, 107) = 3.92$, $p < .001$, although the effect size was larger in the afternoon ($\eta^2_{\text{a.m.}} = .08$ vs. $\eta^2_{\text{p.m.}} = .24$ and $\omega^2_{\text{a.m.}} = .07$ vs. $\omega^2_{\text{p.m.}} = .23$).

To examine the day-to-day stability of the rise in cortisol at day care, we examined each day separately. At child care, the rise over the day was stable from Day 1 to Day 2, $\beta = .43$, $p < .001$, but this was not the case for the rise at home, $\beta = .04$, *ns*. We then examined the individual values to provide a more descriptive interpretation of these effects. At day care, 63% of the children showed positive (> 0) change from morning to afternoon cortisol levels; 52% showed this degree of rise on each of the 2 days of testing. For those with home data, we examined whether, relative to home baseline, the child's cortisol levels at child care met criteria for a stress response (for criteria, see Kirschbaum et al., 1993). In the morning, 10% of the children were exhibiting an HPA stress response to day care, while in the afternoon this increased to 40%. Examined across the 2 days of assessment, 20% exhibited an HPA stress level response on both of the days, while 56% exhibited such a rise on at least 1 of the 2 days.

Table 1
Means and Standard Deviations for Cortisol Data in μg/dl

Variable	*N*	*M*	*SD*
Home cortisol (10 a.m.)	113	0.12	0.14
Home cortisol (4 p.m.)	112	0.14	0.15
Daycare cortisol (10 a.m.)	151	0.13	0.11
Daycare cortisol in (4 p.m.)	151	0.19	0.18
Daycare cortisol Rise in μg/dl	151	0.06	0.14

Note. Cortisol variables are presented in a linear scale, not log10.

Rise at Day Care Related to Child Demographics and Structural Aspects of Child-Care Quality

Our next step was to relate individual differences in the rise in cortisol over the day-care day to child and caregiver factors. A hierarchical regression predicting Daycare Rise was computed. In Step 1, we included child (i.e., age, sex) and family (i.e., parental education, family income) variables, but none of these measures significantly predicted the rise (*t*s < 1.7 or > −1.7, *ns*). At Step 2, we included structural characteristics of the day-care setting (i.e., number of months at that day-care home, hours per day, group size, number of care providers, ratio of adults to children, and whether a sibling was at that day-care home, with the last entered as a dummy variable). None of these descriptive day-care measures significantly predicted the rise (*t*s < 1.0 or > −1.0, *ns*). At Step 3, we examined day-care provider information (i.e., years of experience, highest level of education, formal training in child development or early childhood education, and whether the provider had their own child under age 5 in the day care, the last coded as a dummy variable). None of the provider variables significantly predicted the rise (*t*s < 1.3 or > −1.3, *ns*). Thus, there was no evidence that any of these child, family, or day-care characteristics affected the magnitude of the rise in cortisol at day care.

We were particularly struck by the lack of effect of the number of children in care as in some of these day-care homes there were only one or two children in addition to the target child, while in others there were 10 or more children. To be sure that there was not a threshold effect of day-care size, we identified 4 children who were in care with only 1 other child (small group) and compared their rise over the day with children in care with 2–5 (medium group) and 6+ other children (large group). Examination of the medians provided no evidence of a differential rise for these three group sizes (i.e., 0.07, 0.02, 0.04 μg/dl, *Mn SD* = 0.03 μg/dl, respectively).

Sex and Age Differences in Child Behavior Measures and Observed Care Quality Measures

Prior to examining associations between process measures of quality, child behavior and cortisol increases, we examined whether these measures differed by child sex or age. Descriptive data on scales that contributed to observed quality measures and child behaviors measures are shown in Table 2. To examine possible gender differences, ANOVAs were computed on the two process measures of quality and the two child behavior measures. The results indicated that girls received more warm, supportive care than did boys (girls: *M* = 0.70, *n* = 82; boys: *M* = −0.83, *n* = 69; *z* =2.25, *p* < .05), while girls exhibited less anxious, vigilant behavior (girls: *M* = −0.47, *n* = 82; boys: *M* = 0.56, *n* = 69; *z* = 2.65, *p* < .01) and less angry, aggressive behavior (girls: *M* = −0.49, *n* = 82; boys: *M* = 0.47, *n* = 69; *z* = 3.39, *p* < .001) than did boys. There were no significant child sex differences in negative, intrusive care (*z* = 1.48, *ns*). We also examined associations with age for the child behavior measures but none were found. The pattern of gender differences supported our concern with examining whether child sex moderated any of the associations in observed measures with the cortisol rise at day care.

Table 2
Descriptive Data on M-ORCE Measures (N = 151)

	M	*SD*
Care Provider Warm-Supportive Care summary score measures		
Sensitivity	3.05	0.39
Detachment (R)	1.58	0.75
Positive Regard	2.68	0.80
Chaos (R)	1.54	0.74
Community Building	0.43	1.27
Care Provider Intrusive-Overcontrolling Care summary score measures		
Negative Regard	1.17	0.45
Intrusiveness	1.51	0.77
Overcontrol	1.55	0.73
Child Anxious-Vigilant summary score measures		
Vigilant, Anxious	1.42	0.65
Belonging (R)	3.03	0.76
Positive Social Integration (R)	31.49	10.88
Angry-Aggressive summary score measures		
Angry-Irritable	1.44	0.69
Negative Peer Interactions	1.51	2.00

Note. R indicates the measure loaded negatively on summary scale.

Day-Care Cortisol Rise Associated With Process Measures of Care Quality

We first examined whether process measures of child-care quality predicted the rise in cortisol using a hierarchical regression; we first entered child sex, then the two measures of quality, and finally the interactions between each observed measure of quality and child sex. As expected, given the null results for gender differences in the

ANOVA of the cortisol child-care rise, in the first step child sex was not significant ($t = 0.25$, *ns*, $R^2 = .00$). In the second step ($\Delta R^2 = .04$), the regression coefficient for Intrusive, Overcontrolling Care was significant ($\beta = .17$, $t = 2.17$, $p < .05$), while Warm, Supportive Care was not ($t = -0.39$, *ns*). In the final step, no interaction terms were significant ($ts < 1.0$, $\Delta R^2 = .00$). Thus, cortisol rose more over the day in family day-care homes where children received more intrusive, overcontrolling care.

Associations Between Child Behavior and Cortisol Rise

Using hierarchical regression, we entered child sex at Step 1, each of the two child behavior measures on Step 2, and the interaction between sex and each of these measures on Step 3 to predict the cortisol rise. The results, shown in Table 3, indicated child sex moderated the associations between both child behavior measures and the cortisol rise. To visualize these interactions, Daycare Rise was plotted by sex for the bottom and top quartiles of the distributions for each child behavior. As shown in Figure 1a, for girls but not boys, Anxious, Vigilant Behavior was associated with larger rises in cortisol over the day-care day. As shown in Figure 1b, for boys, Angry, Aggressive Behavior was associated with the rise in cortisol.

Associations Between Provider Quality Measures and Child Behavior

To prepare for examinations of mediation and moderation, we next examined associations between observed care quality and child behavior. We computed two hierarchical regression models, one predicting Anxious, Vigilant Behavior and the other predicting Angry, Aggressive Behavior. In each we entered child sex on Step 1, the observed care quality measures on Step 2, and the interaction of child sex and the two observed quality measures on Step 3. The results are shown in Table 4. As expected from the ANOVA analysis, Step 1 (child sex) was significant in each equation. For Anxious, Vigilant Behavior (top of Table 4), no significant interactions with sex were observed. However, the second step was highly significant and showed a significant negative association between Warm, Supportive Care and Anxious, Vigilant Behavior; no significant association with Intrusive, Overcontrolling Care was obtained. For Angry, Aggressive Behavior, the interaction step was significant. With the interactions in the equation, Warm, Supportive Care was associated with less Angry, Aggressive Behavior for both sexes, while Intrusive, Overcontrolling Care showed an interaction with child sex. Plotting the top and bottom quartile on Angry, Aggressive Behavior against Intrusive, Overcontrolling Care for each sex (see Figure 2) revealed that boys but not girls exhibited more Angry, Aggressive Behavior in association with higher Intrusive, Overcontrolling Care.

Mediational Analysis

According to Baron and Kenny (1986), we have documented three of the four steps that are required to demonstrate mediation for Intrusive, Overcontrolling Care and Angry, Aggressive Behavior for boys, but not girls. Specifically, we have shown that (a) Intrusive, Overcontrolling Care was related to Daycare Rise; (b) Intrusive, Overcontrolling Care was related to the mediator, Angry, Aggressive Behavior for boys; and (c) Angry, Aggressive Behavior for boys was related to the Daycare Rise. The interaction between Angry, Aggressive Behavior, and sex was related to the outcome (i.e., the rise in cortisol). To examine mediation we examined only the data for boys and computed another hierarchical regression, entering child sex on Step 1, Intrusive, Overcontrolling Care on Step 2, and then Angry, Aggressive Behavior and its interaction with sex on Step 3. Of interest was the decrease in the regression coefficient for Intrusive, Overcontrolling Care when the child behavior scores were in the equation. The results failed to indicate any decrease in the regression coefficient for Intrusive, Overcontrolling Care when Angry, Aggressive Behavior was in the equation; thus, there was no basis for examining whether the decrease was significant (i.e., via a Sobel test).

Moderation Analyses

Because of the gender differences in the pattern of child behavior associations with the cortisol rise, we computed these moderation analyses within sex. For girls, because Anxious, Vigilant but not Angry, Aggressive Behavior was associated with the cortisol rise, we examined whether this behavior moderated associations between observed quality measures and the rise in cortisol. A hierarchical regression was computed entering Anxious, Vigilant Behavior on Step 1, the two observational measures of care quality on Step 2, and the interaction between Anxious, Vigilant Behavior and each of the care quality measures on Step 3. In Step 3 (ΔR^2 = .02), neither the Vigilance × Warm, Supportive Care ($t = -0.26$, *ns*) nor Vigilance × Intrusive, Overcontrolling Care ($t = 1.05$, *ns*) interactions were significant. Thus, there was no evidence that Anxious, Vigilant Behavior moderated the effects of the measures of care quality for girls.

For boys, because Angry, Aggressive Behavior but not Anxious, Vigilant Behavior was associated with the cortisol rise, we examined whether Angry, Aggressive Behavior moderated the associations between observed care quality and cortisol. Again, a hierarchical regression equation was computed, entering Angry, Aggressive Behavior on Step 1, the two measures of care quality on Step 2, and the interaction of Angry, Aggressive Behavior and each care quality measure on Step 3. In Step 3, the interaction between Intrusive, Overcontrolling Care and Angry, Aggressive Behavior was not significant ($t = -0.95$, *ns*, $\Delta R^2 = .00$); however, the interaction between Warm, Supportive Care and Angry, Aggressive Behavior was significant ($t = 2.06$, $p < .05$, $\Delta R^2 = .02$). The interaction is depicted in Figure 3. Boys who were low in aggressive behavior appear to have been sensitive to variations in warm, supportive care, exhibiting larger cortisol increases when they received low levels of supportive care and smaller cortisol increases when they received more supportive care. In contrast, highly aggressive boys appear to exhibit comparable increases in cortisol regardless of the warmth and supportiveness of the provider.

Discussion

The results of the present study confirmed that even in family-based day-care settings, cortisol levels rise over the day. We also found that certain dimensions of care quality and child behavior were associated with the cortisol rise. Finally, although boys and girls did not differ in their cortisol responses to child care, the associations between child behavior, care quality, and the cortisol rise were moderated by child sex. Thus, child sex appears to be a critical factor in understanding the psychosocial processes underlying cortisol stress reactions at child care. Each of these aspects of the results will be discussed below.

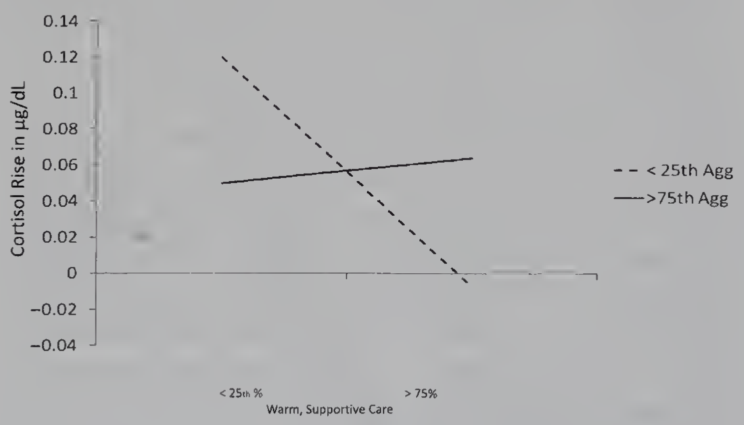

Figure 3. For boys, the interaction between warm, supportive care and angry, aggressive behavior is plotted using the 25th and 75th percentiles of each measure.

The majority of the children showed an increase in cortisol from midmorning to midafternoon at day care, while at-home levels remained relatively flat over the midsection of the day. There was no evidence of a sex difference; boys and girls exhibited similar increases in cortisol over the child-care day. Furthermore, the lack of a change from morning to afternoon in the home data was the typical diurnal basal pattern for children of this age (Watamura et al., 2004). Specifically, the basal decline from midmorning to midafternoon has been shown to emerge at home as circadian sleep patterns become more adult-like (i.e., as the child gives up the afternoon nap). In addition, the rise at day care was relatively stable across the 2 days of assessment, with over half of the children producing a rise from morning levels on each day of assessment. Because even small changes in cortisol could be statistically but not necessarily *biologically* significant, we used criteria previously used in adult studies to identify HPA stress responders. This analysis indicated that only 10% of the children exhibited a stress response in the morning at day care, while 40% could be classified as stress responders in the afternoon.

Taken together these data suggest that a substantial number of children exhibit a stress response of the HPA system over the day at day care; further, as evidenced by the day-to-day stability data, this occurs on a regular basis for a number of children. It is telling that this response is seen more clearly in the afternoon than the morning, indicating a rising pattern of cortisol over the day. This suggests that the response is not a reaction to arriving at child care in the morning, but a response that emerges over the accumulation of the day's experiences. This may explain why in half-day, preschool programs, cortisol levels are not elevated over home levels for classes that meet in the morning or for those meeting in the afternoon (Gunnar, Tout, de Haan, Pierce, & Stansbury, 1997), while these elevations are observed by afternoon in full-day programs. The question, of course, is *why*. What is it about spending a full day at child care that produces a stress response of the HPA system by the afternoon in so many young children?

We found no significant associations between any of the structural measures of care quality and the rise in cortisol at day care. Thus, there was no evidence that provider experience or training predicted this rise, nor was there evidence that the rise was related to the number of children in care or the number of adults in the setting. Our failure to find an association with group size was particularly noteworthy. Not only was no linear association found, but when we examined settings with only one or two children in addition to our target child, increases in cortisol over the day averaged the same as increases in settings with 10 or more children.

Previously we have suggested that the complexity of the demands of managing interactions with large numbers of children might account for cortisol increases over the day among children in center-based care settings (Gunnar & Donzella, 2002; see also Belsky et al., 2007, regarding the possible importance of the peer group in day-care effects). This argument was predicated on the following findings. In comparing the cortisol response over the child-care day for toddlers and preschoolers in center-based care, we did not observe elevations for children cared for in infant rooms (Watamura, Donzella, Alwin, & Gunnar, 2003). In infant rooms, activities are typically organized around the infant's schedule, which means that at any given time, only a few infants are awake and when awake, they are likely to be interacting with adults. In toddler rooms, however, the children eat, sleep and play at the same times and thus there is much more peer interaction in these rooms. Furthermore, with development over the toddler period, time spent interacting with peers increases (Hughes & Dunn, 2007). Second, when we examined changes in cortisol over nap time for preschoolers in center-based care, we noted significant decreases from before to immediately after the nap, even for children who did not appear to sleep over the nap period (Watamura et al., 2002). Because the nap period at child care is one during which children usually do *not* interact with other children, the removal of social interaction demands during this period seemed a reasonable hypothesis for why even those children who did not sleep showed decreases in cortisol over the nap period.

The fact that we observed the same cortisol rise in settings with only two or three children that we found in settings with 10 or more children strongly argues *against* the social complexity hypothesis, at least with regard to day-care settings. It still might be that center-based child-care rooms with many children and adults evoke more of a cortisol response than those with fewer children (see Legendre, 2003), given that none of our settings were that large. However, the fact that the rise in cortisol by afternoon was observed in very small settings suggests that social complexity is not the primary factor accounting for the cortisol stress response. This conclusion also is consistent with the fact that the present findings are largely consistent with previous findings for children of this age studied in center-based care. The average number of children per each preschool-aged care room in day-care centers ranges between 13.0 (at 36 months; NICHD ECCRN, 1999) and 15.4 (at 54 months; NICHD SECCYD, 2008), while the mean number of children in the family day-care homes we studied was around 5. One would have expected, therefore, that if the demands of negotiating complex social environments was the key factor, then many fewer children would have shown a cortisol stress response over the day in family-based day care than has been observed in studies of center-based care. But that was not the case.

We did obtain evidence that our measures of care provider behavior, sometimes termed *process* measure of care quality, were related to the rise in cortisol at day care. Principal factor analysis yielded evidence of two factors: warm and supportive care and intrusive, overcontrolling care. Child-care studies typically identify one dimension of quality that includes both warmth and control dimensions (e.g., NICHD ECCRN, 2000). As in many studies of parenting (e.g., Barber, Stolz, & Olsen, 2005), these dimensions were distinct in our data. It may be that the use of family day-care settings that were more home-like produced patterns of provider behavior that were more like those seen in parenting research.

Our results also showed that these two dimensions were differentially related to the rise in cortisol at day care. Specifically, although warm, supportive care was related to our measures of child behavior, it was not associated with the cortisol rise either for boys or girls (although see discussion of moderation by angry, aggressive behavior for boys, below). In contrast, intrusive, overcontrolling care was associated with larger rises in cortisol over the day-care day. This was true for both boys and girls as gender did not interact with this effect. It is not clear why intrusive, overcontrolling care was stress provoking. It may be that this dimension of care reflected a day-care environment that was structured to provide fewer developmentally appropriate experiences. Anecdotally, settings scoring high in intrusive, overcontrolling care were often ones in which the children were transitioned frequently between activities, were permitted relatively little time in free play, and spent long periods in provider-directed structured activities. In the Sims et al. (2006) study, developmentally appropriate practices related to transitions and scheduling were facets of quality associated with the rise in cortisol for children in child-care centers. It may be that when young children are required to manage a day with many structured activities and transitions, this overtaxes their coping capacities as the day progresses. Notably, however, although intrusive, overcontrolling care accounted for statistically significant variance in the cortisol rise, there was still a good deal of individual variation that was not explained by this process dimension of quality.

Some of this unexplained variance was associated with child behavior patterns at day care. As expected, two dimensions of behavior were identified. The first dimension involved variation in anxiety and vigilance and in social integration. Children scoring high on this dimension were more anxious and vigilant and were less socially integrated in the setting. The second dimension involved variation in angry mood and negative interactions with peers. Both anxious vigilance and angry, aggressive behavior were observed more in boys than girls. Given the association with the cortisol rise, this would suggest that boys might have experienced more stress at child care than girls. However, as noted above, we found no gender difference in cortisol at day care. Rather, we found that gender moderated the associations of behavior and rise in cortisol over the day. For boys, larger cortisol increases were associated with more angry, aggressive behavior, while for girls it was associated with more anxious, vigilant behavior.

Other studies of child care have also noted gender differences in associations between child behavioral dispositions and HPA activity. For example, Dettling et al. (1999) found that parent-reported surgency positively predicted the cortisol rise for boys but not girls, while parent-reported effortful control negatively predicted the rise for girls. Why associations might differ for boys and girls is unclear. By adulthood, there are clear differences in reactivity of the HPA axis to stressors, as well as evidence that the type of stressors that most strongly affect men differ from those that are most provocative for women (for a review, see Dedovic, Wadiwalla, Engert, & Pruessner, 2009). For both men and women, threats to the social self stimulate the HPA axis, but for women the most salient threats to the social self appear to be ones that threaten relationships, while for men they appear to be ones that threaten social status and agency (see also Stroud, Salovey, & Epel, 2002).

While these gender differences in stress provocation appear to emerge most clearly after childhood (see Stroud et al., 2009), the present results are consistent with the adult findings. That is, larger cortisol increases were observed for the girls who, in addition to being anxious and vigilant, were also less socially integrated into the day-care setting. Our scoring of positive social integration was based on whether the child was central to the action, such that if the child left the activity or decided to change the activity then the other children would follow or play would stop. When combined with anxious, vigilant behavior, our summary score may have reflected anxiety over threats to goals of having and maintaining relationships with peers. If by this young age social relationships are beginning to emerge as a more central goal for girls than boys, then this might explain its greater association with the cortisol rise for girls at day care. Note that this argument is consistent with evidence that by preschool age, girls use somewhat more relational aggression or actions that threaten relationships than do boys (Crick et al., 1997).

This argument does not explain why we obtained a significant association between angry, aggressive behavior and the rise in cortisol for boys but not girls. As noted, our finding for boys was consistent with the meta-analysis of aggressive, undercontrolled behavior that provided evidence that while such behavior is associated with low cortisol for school-aged children, among preschool-aged children it is associated with higher cortisol levels (Alink et al., 2008). What was noteworthy was the gender difference in the association of care quality with angry, aggressive behavior. For both sexes, this behavior was observed more when children were receiving less warm and supportive care, but only for boys was angry, aggressive behavior associated with higher levels of intrusive, overcontrolling care. In fact, as suggested in Figure 2, it was at high levels of intrusive, overcontrolling care that the gender differences in angry, aggressive behavior were most pronounced. This suggests that not only the frequency but the social meaning and function of angry, aggressive behavior may have differed for boys and girls. For boys it may have been a reflection of salient threats to agency, which, even at this age, may be a more central goal for boys than girls. Indeed, this would be consistent with evidence that as early as 1 year of age, loss of control (agency) over a loud, noise-making toy elicits more negative affectivity in boys than girls (e.g., Gunnar, 1980), as well as evidence of gendered differences in adulthood in the role of fighting and asserting dominance or control versus seeking relationships in coping with threatening situations (Taylor et al., 2000).

The data for angry, aggressive behavior and stress for boys, however, were even more nuanced than gendered association with intrusive, overcontrolling care would suggest. Specifically, in the moderation analyses we found that among boys, angry and aggressive behavior moderated the association between warm, supportive care and the cortisol rise. Specifically, we found that it was the boys who scored low on this measure whose cortisol rise at child care was associated with the degree of warm and supportive care they received. Under conditions of low warmth and support they showed large increases in cortisol over the day, while under conditions of high warmth they show small increases that were well within the norm for cortisol changes over the day at home. Boys scoring high on angry, aggressive behavior did not show any modulation of the cortisol response to child care in relation to care provider warmth and support. This moderation effect was the opposite of that predicted based on arguments that children who are more vulnerable to behavior problems (e.g., externalizing-type problems in this case) might be more sensitive to variations in care quality. However, as boys were more aggressive than girls, it may be that boys scoring low on angry, aggressive behavior may have had more difficulty managing play with other boys and thus may have been more dependent on the degree of warm, supportive care they were receiving from the care provider.

We recognize that our explanations for the gender differences in cortisol-behavior associations are speculative and that these findings will contribute to continued uncertainty about how behavior in peer settings is associated with activity of the HPA axis in young children. However, they should also encourage researchers to consider the role of gender differences in future studies of child-care stress. Our findings suggest that even when boys and girls do not differ in their physiological stress reactions to complex social situations, they may differ in how emotional-behavioral dispositions and patterns of action relate to their stress responses in those contexts. Furthermore, it seems likely given our pattern of results that these gender differences reflect the gendered aspects of children's social worlds and socialization experiences. As noted above, by adulthood there is good evidence for gender differences in stress reactivity and regulation (Dedovic et al., 2009; Taylor et al., 2000); thus, an increased focus on gendered patterns of stress-behavior-context associations during development is needed.

One of the challenges of interpreting the present findings is that the associations we found accounted for only modest amounts of the variance in the cortisol rise. For example, our measure of intrusive, overcontrolling behavior only accounted for 4% of the variance in the cortisol rise, while in combination the child behaviors and their interaction with sex explained 10% of the variance. It is likely that our methods limited the amount of variance that we could explain. First, cortisol and behavior were measured on different days, and there was likely error in our measures such that behavior on one the days of observation was not exactly the behaviors we would have observed had we measured on the days of cortisol assessment. Unfortunately, the M-ORCE, like the ORCE, requires summating over the 2 days of observation; thus, we do not have a measure of day-to-day variability in either our two process measures of quality or our two measures of child behavior. For the cortisol rise, although we observed a significant correlation across the 2 days of assessment, the rise on day one explained only 16% of the variance in the rise on Day 2. Thus, limitations in the method likely limited the magnitude of the associations we could hope to find. Nonetheless, the effect sizes we observed were consistent with others often reported in child-care studies, and it has been argued that such effect sizes should not be dismissed in considering the import of findings for child-care policy and practice (McCartney & Rosenthal, 2000).

Our findings provide added impetus to the effort to understand whether and how HPA stress responses at child-care impact children's development. Although early life stress is typically viewed as a risk factor for healthy development, recent studies in both nonhuman primates and in human populations raise questions about this type of blanket assessment of early life stressors. For example, Lyons and Parker (2007) have examined the impact of repeated, 1-hr separations in infant squirrel monkeys. As in the work on cortisol responses to full-day child care, these separations in squirrel monkey infants produced marked and repeated activations of the HPA axis. However, followed into the late juvenile and early adult age, animals exposed to this form of early life stress were found to be less fearful, to produce lower rather than higher cortisol responses to stressors, and to show more optimal development of prefrontal regulatory brain circuits; consistent with these findings, they also performed better on tests of executive functioning. Thus, at least for this animal model, repeated separation stress early in life fostered a form of resilience.

In studies of human populations, most of the work on early maltreatment and risky family patterns has been conducted on adults with various affective disorders. Here, the evidence is that early life stress produces hyper-reactivity of the HPA axis, consistent with views that early life stress enhances the neural substrate underlying vulnerability to affective disorders (e.g., Heim, Plotsky, & Nemeroff, 2004). However, in recent studies, researchers have sought to examine the associations between early life stressors and HPA reactivity among adults who are free of significant internalizing pathology. These studies are showing hypoactivity of the HPA axis compared to healthy adults without early life stressors (Carpenter et al., 2007; Elzinga et al., 2008). These findings are also consistent with recently reported evidence that teenagers who experienced more full-time, center-based day care under the age of three produce lower than average levels of cortisol early in the morning at the peak of the diurnal cycle (Roisman et al., 2009). We clearly need to continue to be cautious about interpreting the implications of cortisol elevations in day care. Nonetheless, evidence that this rise is associated with anxious, vigilance (i.e., internalizing) behavior for girls and anger, aggression (i.e., externalizing) behavior for boys should not make us sanguine about its potential implications for children's development.

Several limitations in this study also should be noted. First, although we included family demographic factors in our analyses, we did not examine the quality of parent–child relations and their associations with the day-care cortisol rise. As in other studies of child-care effects, it is possible that issues in the children's families carry more of the weight in predicting how the child responds to child care than issues within the child-care setting (Ahnert & Lamb, 2003; Love et al., 2003; Phillips et al., 2006). Although we did not attempt to pre-select for parents with fairly high educations, incomes, and marital status, the variation in family characteristics was quite narrow, reflecting fairly advantaged and low-risk segments of the U.S. population. It may well be the case, as has been found in prior research (Loeb, Fuller, Kagan, & Carrol, 2004; NICHD ECCRN, 2001, 2003), that quality of child care matters more for low-income children and may thus play a stronger role as an influence on cortisol elevations for children from disadvantaged backgrounds. We were not able to randomly assign children to day-care homes, and thus selection factors could not be controlled in our analyses. We only included licensed day-care homes in our analyses, and thus cannot generalize to effects in the many unlicensed settings used for day care. Finally, although we worked to increase our racial-ethnic variation, the sample was still predominantly White and of European heritage. This again limits generalizability.

With these limitations, however, we have clearly documented that, similar to children in center-based care, many children in family day-care settings show a substantial rise in cortisol over the day, and they do not show this rise when at home. We have found that this rise is observed even in care settings with only two or three children, thus arguing against the hypothesis that social complexity is a major factor underlying increasing activation of the HPA stress response. We also noted associations between intrusive, overcontrolling care and the rise in cortisol for both boys and girls and between warm, supportive care and the cortisol rise for less angry, aggressive boys. These findings may help refine our attempts to understand aspects of child care that promote increases in cortisol in young children. Finally, the gendered differences in associations we noted should focus attention on understanding how boys and girls may differentially process and experience stressors in child-care settings.

Children's Sleep and Adjustment Over Time: The Role of Socioeconomic Context

Mona El-Sheikh, Ryan J. Kelly, Joseph A. Buckhalt, and J. Benjamin Hinnant
Auburn University

Relations were examined between children's sleep and their externalizing and internalizing symptoms. Longitudinal relations were examined when children were in 3rd (T1) and 5th (T2) grades, and cross-sectional relations were assessed at T2. Participants included 176 children at T1 (M = 8.68 years) and 141 children at T2 (M = 10.70 years). Sleep was examined via subjective reports and actigraphy. Children reported on anxiety, self-esteem, and depression symptoms, and parents reported on children's externalizing and internalizing symptoms. Cross-sectionally and longitudinally, sleep problems were associated with worse adjustment outcomes; African American children or those from lower socioeconomic status homes were at particular risk. Findings highlight the importance of adequate sleep for children's optimal development, especially in the context of ecological risk.

The significance of children's sleep to their developmental outcomes is receiving increased attention in the child development literature. Rapidly developing evidence links children's sleep problems within the normative range and their adjustment outcomes. Behavioral problems (Paavonen et al., 2002) and internalizing symptoms (Gregory et al., 2005) have been associated with shorter sleep duration and worse sleep quality in elementary-school-aged children. Nevertheless, many open scientific questions remain regarding relations between sleep disruptions and child developmental outcomes. Notably, few studies have investigated these associations with objective sleep measures, samples of typically developing children, multiple informants of adjustment outcomes, multiple response domains, or longitudinal designs. The main objective of this study is to assess relations between sleep disruptions (amount, quality, schedule) and children's adjustment both cross-sectionally at T2 and longitudinally with two waves of data. This investigation builds on the existing literature by examining sleep problems both objectively via actigraphy and subjectively via child and parent reports in a large community sample utilizing a longitudinal design. Mothers', fathers', and children's reports of child adjustment are used for a better explication of child functioning in the context of sleep disruptions. Further, we explore the role of race, socioeconomic status (SES), and gender in moderating relations between sleep and adjustment outcomes.

For all children, acquisition of adaptive socioemotional behaviors is a primary developmental task with immediate and long-term consequences. Sleep has only recently been related to a number of outcomes in this domain, and indications are that sleep plays a vital role in healthy development. In community samples, restricted or disrupted sleep has been associated with externalizing behaviors, including aggression, conduct problems, and delinquency (Aronen, Paavonen, Fjallberg, Soininen, & Torronen, 2000; Chervin, Dillon, Archbold, & Ruzicka, 2003). Similarly, sleep problems in childhood have been associated with internalizing problems, primarily symptoms of anxiety and depression (Chorney, Detweiler, Morris, & Kuhn, 2008; Gregory & Eley, 2005), which may persist to adolescence and adulthood (Gregory & O'Connor, 2002; Gregory et al., 2005). Theory to guide research in this domain is in an emergent stage, but Dahl (1996) hypothesizes a role for the prefrontal cortex (PFC) in the association of sleep problems and emotional dysregulation. Sleep deprivation in adults is known to disrupt behaviors mediated in the PFC,

including executive processes necessary for controlling cognition and emotion (Muzur, Pace-Schott, & Hobson, 2002).

The term *sleep problems* as used here does not refer to clinically diagnosed sleep disorders (e.g., sleep apnea). Sleep problems were examined in typically developing children, are conceptualized along a continuum, and are indicated by shorter average sleep times, sleep characterized by higher activity or several extended night wakings, or sleep schedules that are more variable from night to night, relative to other participants. Arguably, chronic sleep insufficiency and erratic sleep schedules may be the most prevalent forms of sleep problems in otherwise typically developing children, and assessment of sleep problems along the normative continuum is critical for clarifying developmental outcomes for many children in the population.

With the present sample, cross-sectional data collected in the first wave, when children were in third grade, supported relations between sleep problems and children's externalizing and internalizing symptoms (El-Sheikh, Buckhalt, Cummings, & Keller, 2007). This study reports cross-sectional findings from the second wave of data when children were in fifth grade, as well as longitudinal data over the 2 years of assessment. Multiple child outcomes (externalizing and internalizing symptoms) were examined.

One study objective is the assessment of child race and SES as moderators of the link between sleep problems and child adjustment. Research with adults indicates higher rates of clinical sleep disorders (for a review, see Durrence & Lichstein, 2006) and more restricted sleep (Stamatakis, Kaplan, & Roberts, 2007) in African Americans (AAs) in comparison with European Americans (EAs). Fewer studies have examined race- and SES-related effects in children's sleep, and in the majority that did, clinical samples were used. For example, evidence indicates that AA children have higher rates of asthma and sleep-disordered breathing, less-reported sleep duration, and poorer sleep quality (Crosby, LeBourgeois, & Harsh, 2005; Rosen et al., 2003). Further, in comparison with EA children, AA children are more likely to have later bedtimes, earlier wake times (Adam, Snell, & Pendry, 2007), less consistent bedtime routines, and to cosleep with siblings, even after controlling for SES factors (Milan, Snow, & Belay, 2007). In our own research with the first wave of data obtained with the present sample, controlling for SES, EA children slept longer, had lower levels of disrupted sleep, and reported fewer sleep problems in comparison with AA children (El-Sheikh, Buckhalt, Cummings, et al., 2007; El-Sheikh, Buckhalt, Keller, Cummings, & Acebo, 2007). Additionally, controlling for race, children from higher SES backgrounds slept longer and had fewer sleep problems than children from lower SES backgrounds (El-Sheikh, Buckhalt, Keller, Cummings, et al., 2007).

Although examining differences in sleep parameters between AA and EA children is informative, explication of developmental outcomes for children in various cultural contexts requires the testing of the racial-cultural milieu as a moderator of effects. Very few studies have undertaken such assessments in the context of child sleep and development. One objective here is to examine the role of race (AA, EA) and family SES as moderators of the link between sleep problems and child adjustment. In two of the previous studies with the present sample at T1, we found that race and SES moderated relations between sleep and cognitive and achievement tasks (Buckhalt, El-Sheikh, & Keller, 2007; El-Sheikh, Buckhalt, Keller, Cummings, 2007). In a recent follow-up of children in this sample, longitudinal relations between children's sleep and cognitive functioning were examined (Buckhalt, El-Sheikh, Keller, & Kelly, 2009). Disrupted sleep was associated with poorer cognitive performance 2 years later primarily for AA children and those with less educated fathers. These findings are supportive of the health disparities view (e.g., Carter-Pokras & Baquet, 2002) in that minorities and individuals of lower SES are likely exposed to chronic stress and have an increased burden of many adverse conditions. Under adverse conditions, disruptions of a primary biological regulation system like sleep may have a greater deleterious effect. However, we are not aware of any studies that investigated SES, ethnicity, or race as moderators of the link between children's sleep and their socioemotional functioning cross-sectionally or longitudinally.

Several studies have reported gender-related sleep differences among school-aged children; however, findings have been inconsistent. Some studies found that girls had better sleep quality (Buckhalt et al., 2007; El-Sheikh, Buckhalt, Mize, & Acebo, 2006; Sadeh, Raviv, & Gruber, 2000) or longer sleep durations (El-Sheikh, Buckhalt, Cummings, et al., 2007; Fredricksen, Rhodes, Reddy, & Way, 2004). Other research has reported that boys sleep more than girls (Gau & Soong, 1995), and as girls near early adolescence, sleep–wake times become significantly earlier than boys' wake times (Lee, McEnany, & Weekes, 1999). However, there have been no published studies of gender as a moderator of effects in the sleep–child development link. Further, few of the studies that have documented gender-related mean differences in sleep parameters were based on actigraphy, which warrants further investigation to determine gender-related effects in boys' and girls' sleep patterns and their effects on developmental outcomes (Sadeh et al., 2000). We examined gender as a moderator of effects in the association between sleep and child adjustment.

To summarize, the main objective was to examine relations between sleep disruptions (amount, quality, schedule) and children's externalizing and internalizing symptoms cross-sectionally at T2 and longitudinally (T1 and T2). At T1, children were in third grade; at T2 they were in the fifth grade. Building on T1 cross-sectional evidence (El-Sheikh, Buckhalt, Cummings, et al., 2007), we expected that reduced sleep amount, less-optimal sleep quality, and an inconsistent sleep schedule would be associated with increased adjustment problems at T2. Longitudinally, we expected that T1 sleep problems would be associated with more adjustment problems, after controlling for autoregressive effects. Thus, longitudinal analyses examined sleep as a predictor of *changes* in adjustment outcomes over time, controlling for T1 child adjustment. Multiple objective and subjective sleep measures were examined for a better clarification of relations between sleep and child adaptation (Sadeh, 2008).

A second objective was to examine moderators of effects in the link between sleep disruptions and child adjustment: SES, race, and gender. Based on prior empirical evidence (El-Sheikh, Buckhalt, Cummings, et al., 2007) and the health disparities view (Carter-Pokras & Baquet, 2002), we anticipated that the link between sleep disruptions and child adjustment would be more robust for either AA children or children from lower SES homes. SES and race were examined as cross-sectional (T2) and longitudinal moderators. Given the lack of conceptual or empirical guidance in the literature, we had no specific hypotheses regarding the role of gender in the sleep–adjustment link.

Method

Participants

Children in third grade were recruited from public schools in the Southeastern United States. Parent contact information was obtained from the schools. To participate, children had to satisfy the inclusion criteria, which included living in a two-parent home, and having no history or diagnosis of a sleep problem, attention deficit hyperactivity disorder, chronic or acute physical illness, mental retardation, or a learning disability. T1 participants included 176 children (78 boys, 98 girls) with an average age of 8.68 years ($SD = 0.36$), along with their parents. Mothers' reports on the Puberty Development Scale (1 = prepubertal, 2 = early pubertal, 3 = midpubertal, 4 = late pubertal, 5 = postpubertal; Petersen, Crockett, Richards, & Boxer, 1988) indicated that the majority of boys ($M = 1.25$, $SD = 0.23$) and girls ($M = 1.45$, $SD = 0.34$) were prepubertal.

For SES classifications, families were categorized based on Hollingshead's (1975) criteria. Specifically, 28% were classified as Level 1 or 2 (e.g., unskilled workers), 41% were in Level 3 (e.g., skilled workers), and 31% were in Level 4 or 5 (e.g., minor professional or professional).

Racial identity of the child was identified by the parent according to 2000 U.S. census categories. All parents selected a sole category of "White" or "Black or AA" with the following result: 69% EA, 31% AA. The sample constitution is very similar to the racial and SES composition of the school district from which it was drawn, which includes 75% White and 22% Black or AA. We oversampled to include a wide range of SES from both AA and EA families with a resulting low but still significant association between race and SES ($r = -.24$, $p < .01$ for SES raw score; $r = -.19$, $p < .05$ for SES level; note that race coding used 1 for AAs and 0 for EAs). In this study, the term *race* rather than *ethnicity* is used. Much attention has been given to the proper use and measurement of race and ethnicity in scientific research (e.g., Entwisle & Astone, 1994), and we elected to use race.

Approximately 2 years later, 142 of the families returned for a second wave of data collection (T2; 81% of the original sample). Attrition occurred due to moving out of the study area, inability to be located, disinterest in continuing study participation, and a busy schedule. At T2, 80 boys and 61 girls (70% EA, 30% AA) participated. Children's average age was 10.70 years ($SD = 0.55$) at T2. Average puberty status at T2 was 2.06 ($SD = 0.55$) for girls and 1.49 ($SD = 0.42$) for boys, corresponding with an early pubertal status for girls and prepubertal status for boys (Petersen et al., 1988).

Independent samples t tests and χ^2 analyses were used to determine whether differences existed between children who participated in one or two waves. In comparison with children who participated during both waves, children who did not participate in the second wave came from families with less income, $t(162) = -2.18$, $p < .05$, and lower SES status, $t(174) = -3.46$, $p < .001$. There were no gender, race, age, pubertal stage, externalizing, internalizing, or sleep parameter differences between retained and missing participants, with the exception that children who dropped out were reported by their parents to have more sleep-related difficulties, $t(171) = 2.16$, $p < .05$. No differences in objective sleep measures were found.

Procedure

A research assistant instructed parents to place an actigraph on the child's nondominant wrist just prior to bedtime for seven consecutive nights. To help ensure typical sleep patterns, actigraphic data collection occurred only during the regular school year, excluding holidays, and only data from medication-free nights were used for analyses (for more detail regarding procedures, see Buckhalt et al., 2009; El-Sheikh, Buckhalt, Keller, Cummings, et al., 2007).

Typically, children came to our university laboratory with their mothers and fathers following the last day of data collection. Each parent and the child completed subjective sleep and child adjustment measures. Children were administered each measure via interview by a research assistant, whereas parents used self-report. Child height and weight were measured in the lab to compute body mass index (BMI), based on Must, Dallal, and Dietz's (1991) criteria. The study was approved by the University Institutional Review Board and parents and children provided informed consent and assent. Procedures and measures at T1 and T2 are the same unless otherwise indicated.

Measures

Socioeconomic status. Two different markers were used to determine SES: parents' combined annual family income and SES classifications based on Hollingshead's (1975) criteria. For annual income, families were classified into one of the following categories: (a) \$10,000–\$20,000, (b) \$20,000–\$35,000, (c) \$35,000–\$50,000, (d) \$50,000–\$75,000, or (e) more than \$75,000. Because annual income and Hollingshead SES classifications were correlated at T1 ($r = .46$, $p < .001$) and T2 ($r = .49$, $p < .001$), they were composited at each time point to reduce the number of analyses and to create an overall SES score. Reference to SES in the remainder of this study refers to the composite.

Parent report of children's sleep. Mothers and fathers completed the 35-item Children's Sleep Habits Questionnaire (CSHQ; Owens, Spirito, & McGuinn, 2000), which has good validity and reliability for community and clinical samples. The CSHQ assesses several sleep domains, including bedtime resistance, sleep onset delay, sleep duration, sleep anxiety, parasomnias, night awakenings, sleep disordered breathing, and daytime sleepiness, during the last week. For each item, response options are *zero to one time* (1), *two to four times* (2), and up to *five to seven times* (3). All items were combined to form a total score. Mothers' and fathers' reports were associated ($r = .55$ at T1; $r = .40$ at T2; $ps < .01$), and were averaged to derive a parent reported sleep problems composite (coefficient αs = .90 at T1 and .95 at T2). At T1, 95% of mothers and 81% of fathers completed the CSHQ, and at T2, 94% of mothers and 74% of fathers completed the measure. When one reporter's data were missing, the other's data were used in the analyses. At T1 and T2, scores ranged from 37 to 89, and 35 to 79, respectively.

Child self-reports of sleep. The Sleep Habits Survey (Wolfson & Carskadon, 1998) was used to obtain subjective self-reports of children's sleep, and has been shown to be reliable and valid for children as young as 6 years (e.g., El-Sheikh & Buckhalt, 2005). Two subscales were pertinent: the 10-item Sleep–Wake Problems scale (coefficient αs = .71 at T1 and .79 at T2) and the nine-item Sleepiness scale (coefficient αs = .77 at T1 and .67 at T2). Items on the Sleep–Wake Problems scale assessed irregular sleep times, staying up past bedtime, and oversleeping. For each item, response options ranged from *never* (1) to *everyday/night* (5), with a higher number indicative of increased problems. At T1 and T2, scores on the Sleep–Wake Problems scale ranged from 10 to 34, and 10 to 40, respectively. Items on the Sleepiness scale asked whether participants unintentionally fell asleep during nine daily activities, such as in class, watching TV, or while riding in a car; one item regarding feeling sleepy while driving was not administered. Children answered each item using a 5-point response format that ranged from *never* (1) to *everyday/night* (5), with higher scores, reflecting increased problems. At T1, total scores on the Sleepiness scale ranged from 9 to 27; at T2, scores ranged from 9 to 24.

Objective measurement of sleep. Children wore actigraph bracelets, which were roughly the size and weight of a wristwatch, between bedtime and wake time for seven consecutive nights. Actigraphy has been frequently used as a proxy for sleep duration and quality, and has demonstrated good reliability, especially when worn for several consecutive nights (Acebo et al., 1999; Sadeh, Gruber, & Raviv, 2002). To help ensure reliability among actigraphic recordings, parents completed daily sleep logs to cross-check child bedtime and wake times. Actigraphs were Octagonal Basic Motionloggers (Ambulatory Monitoring Inc., Ardsley, NY) and measured body motion in 1-min epochs using the zero crossing mode. Children were considered to be awake or asleep based on Sadeh's scoring algorithm (Sadeh, Sharkey, & Carskadon, 1994). The actigraph and analysis software have demonstrated reliability and validity when compared with polysomnography (Sadeh et al., 1994). Actigraphy was used to derive the following sleep parameters: (a) sleep duration—the total amount of time between sleep onset and wake time, and (b) sleep efficiency—percentage of motionless sleep and generally accepted in the sleep literature as an index of sleep quality. Further, to capture the variability in sleep schedule over the week of actigraphic assessment, variability in sleep onset and variability in wake time were computed, using the mean-centered coefficient of variance statistic (Snedecor & Cochran, 1967), and were composited to create (c) variability in sleep schedule.

For sleep duration and sleep efficiency, scores were generated by computing an average score across all available nights. Intraclass correlations indicated that each sleep variable exceeded Acebo et al.'s (1999) recommended stability level of .70: sleep duration αs = .78 at T1 and .86 at T2; sleep efficiency αs = .87 at T1 and .92 at T2. These coefficients indicate that children's sleep parameters were stable across the various nights of sleep assessment.

Overall, 75% of children had valid actigraph data across all seven nights at T1. In some instances, actigraph recording did not occur on all nights. Reasons for missing data included the use of allergy medicine, mechanical actigraph problems, and forgetting to wear the actigraph. Consequently, at T1, the actigraph was worn an average of 6.59 nights (SD = 0.85), and 14% of the children had data for six nights, 8% had data for five nights, and 3% had data for four nights or fewer. For T2, 56% of participants had data for all seven nights, 25% had data for six nights, 14% had data for five nights, and 5% had data for four nights or fewer (M = 6.30, SD = 0.95). The rates of valid actigraphy data in this study satisfied Acebo et al.'s (1999) recommendations.

Parent reports of child externalizing and internalizing symptoms. Both mothers and fathers reported on child adjustment using the 280-item Personality Inventory for Children (PIC; Wirt, Lachar, Klinedinst, & Seat, 1990). For this study, two scales were used. The Externalizing scale assesses aggression, impulsivity, disruptive behavior, delinquency, and noncompliance. The Internalizing scale measures depression, anxiety, fear, worry, and psychosomatic problems. The PIC has very good psychometric properties (Wirt et al., 1990). Mother and father reports of child externalizing (r = .77 at T1, and .63 at T2, ps < .001) and internalizing symptoms (r = .73 at T1, and .45 at T2, ps < .001) were correlated, and were averaged to derive an externalizing and an internalizing symptoms composites. For externalizing symptoms, αs = .89 at T1 and .93 at T2; for internalizing symptoms, αs = .80 at T1 and .90 at T2.

Child report of internalizing symptoms. Children completed the 28-item Revised Children's Manifest Anxiety Scale (RCMAS; Reynolds & Richmond, 1978). The RCMAS is frequently used to measure child anxiety and has demonstrated test–retest reliability (Wisniewski, Mulick, Genshaft, & Coury, 1987) and concurrent validity (James, Reynolds, & Dunbar, 1994). For this study, α = .89 at T2. Further, children completed the Self-Perception Profile for Children questionnaire (SPPC; Harter, 1982, 1985), which assesses children's perceived competence and has demonstrated test–retest reliability and validity (Harter, 1982). For this study, children's reports on the 6-item Global Self-Worth subscale were used. At T2, the SPPC α = .84. Children reported on depression symptoms using the Children's Depression Inventory (CDI; Kovacs, 1985), which contains 27 items; one item regarding suicidal ideation was not administered. The CDI has demonstrated good test–retest reliability and discriminant validity (Kovacs, 1985). At T2, CDI α = .77.

Bivariate correlations revealed that children's anxiety was associated with depression (r = .49 at T2, p < .001) and self-esteem scores (r = −.42 at T2, p < .001). Further, self-esteem was associated with depression (r = −.47 at T2, p < .001). To reduce the number of analyses, the children's anxiety, self-esteem, and depression scores were composited to create a total child report of internalizing symptoms score. Self-esteem scores were reverse-coded, and children's anxiety, self-esteem, and depression scores were standardized using z scores prior to compositing each measure. Because the child-report internalizing score is a standardized composite, it is likely not an appropriate measure for our longitudinal analyses (Singer & Willett, 2003). Thus, this measure is only included in cross-sectional analyses at T2.

Results

Analysis Plan

In preliminary analyses, descriptive statistics and correlations among variables were examined. Next, a series of cross-sectional and longitudinal path models were estimated: First, demographic characteristics were entered (child gender, race, age, pubertal status, BMI, and SES). Next, main effects of children's T2 sleep parameters (parent-reported sleep problems, child-reported sleep–wake problems or sleepiness, *or* actigraphic measures of sleep duration, efficiency, or variability in sleep schedule) were entered in the models as predictors of children's T2 adjustment (see Figure 1 for an example of a cross-sectional model). This resulted in two distinct models of prediction: one for subjective reports and one for objective actigraphy measures. Within these models, all relevant sleep variables were entered simultaneously to evaluate their relative contributions to prediction while controlling for other sleep characteristics. To avoid potential shared method bias with the models involving subjective reports, only child-reported subjective sleep measures were used to predict parent-reported child adjustment. Similarly, only parents' reports of child sleep were used to predict child-reported internalizing symptoms. Finally, interactions between children's sleep and the potential moderators (race, SES, and child gender) were added to the models.

To predict residual change, longitudinal path models were estimated in which children's sleep at T1 was examined as a predictor of children's adjustment at T2, while controlling for the respective adjustment measures at T1. Controlling for T1 levels of the predicted variable reduces bias in parameter estimates, permits conclusions regarding change in the predicted variable over time, and provides information about the direction of effects between model variables (Cole & Maxwell, 2003). The same analytic process used to evaluate the cross-sectional data was used to evaluate the longitudinal data (see Figure 2 for an example of a longitudinal model). As noted in the Method section, child-reported internalizing symptoms were not analyzed longitudinally. In order to decrease the likelihood of Type I error, moderation effects were only reported and interpreted if the specific moderator was significant at least 10% of the time. For example, 10% of the possible interactions including SES as a moderator between sleep and

$^*p < .05$. $^{**}p < .01$. $^{***}p < .001$.

adjustment outcomes would have to be significant in order to be reported.

Path analysis (Amos 16.0; Arbuckle, 2007) was used because of the benefits it has regarding missing data: using maximum likelihood estimation and thus utilizing a larger sample size and more relaxed assumption that data are missing at random than multiple regressions (Little & Rubin, 2002). Exogenous variables were allowed to correlate, resulting in saturated models. Fit indices were not produced because all models were fully saturated. Within each model, all continuous variables were mean-centered.

Path model findings are reported first for cross-sectional analyses and then for longitudinal analyses and are ordered according to the dependent variable as follows: externalizing symptoms, parent-reported internalizing symptoms, and child-reported internalizing symptoms. The prediction of each dependent variable is reported in the following format: (a) demographic characteristics, (b) main effects of subjective or objective sleep, and (c) interactions (if any) between sleep characteristics and moderators. Although gender was tested as a moderator in the link between children's sleep and their adjustment, no statistically significant interactions involving gender were detected for either the cross-sectional or longitudinal associations. Thus, no such moderation effects are reported.

Aiken and West's (1991) criteria were used to interpret interaction effects; Preacher's interaction utility was used to plot significant interactions (Preacher, Curran, & Bauer, 2006). Representative significant interactions were plotted at high (+1 *SD*) and low (−1 *SD*) levels of the predictor and moderator. Slopes representing the association between the predictor and outcome variables were examined to determine if they were significantly different from zero. Of note is that a significant interaction term denotes that the association between the predictor and outcome variables is different for children at higher and lower levels of the moderator (i.e., the plotted lines are significantly different from each other).

Descriptive statistics and associations among variables. Means, standard deviations, and bivariate correlations are provided in Table 1. Children averaged 8 hr 53 min (*SD* = 37 min) of sleep per night at T1 and 8 hr 33 min (*SD* = 38 min) per night at T2. Notably, at T1 and T2, AAs had a shorter sleep duration (*r*s = −.22 and −.24, respectively) and tended to have more subjective sleep-related problems (*r*s = .16–.25). At T1 and T2, SES was positively associated with sleep duration (*r*s = .17 and .19, respectively), such that higher SES children had longer sleep. Several associations between children's sleep and adjustment outcomes were also observed. At both time points, more parent- and

**p* < .05.

child-reported sleep problems were associated with elevated levels of parent- and child-reported externalizing and internalizing problems (*rs* = .18–.52). Regarding objective reports of sleep, more sleep efficiency was associated with less parent-reported externalizing and internalizing symptoms at T1 (*rs* = −.25 and −.30 respectively). At T2, longer sleep duration was negatively correlated with parent-reported internalizing problems (*r* = −.18), and more variability in sleep schedule was positively associated with more child-reported internalizing symptoms (*r* = .34). Also of note, subjective reports of sleep tended to be correlated over time (*rs* = .19–.58), as were sleep duration (*r* = .47) and sleep efficiency (*r* = .41).

Cross-Sectional Prediction of Child Adjustment

Externalizing symptoms. Demographic characteristics accounted for 11% of the variance in externalizing symptoms. Race (β = −.21; *p* = .02) and SES (β = −.29; *p* = .002) were significantly related to externalizing symptoms; AA children were reported as having fewer externalizing symptoms and as SES increased, externalizing symptoms decreased. Child-reported daytime sleepiness, sleep–wake problems, or their interactions were not related to externalizing symptoms, although sleep–wake problems approached significance (β = .16; *p* = .08). No other R^2 is reported because no variable beyond demographics accounted for a significant additional amount of variance in externalizing symptoms.

In predicting externalizing symptoms from objective sleep actigraphy measures, no main effects emerged for sleep duration, efficiency, or variability. One significant interaction was observed between sleep efficiency and SES (β = .33; *p* < .001). For children of lower SES, as sleep efficiency increased, externalizing symptoms decreased significantly (*p* = .01), but for children of higher SES, as sleep efficiency increased, externalizing symptoms increased significantly (*p* = .01; Figure 3A). Importantly, no differences in externalizing symptoms were observed between higher and lower SES children when sleep efficiency was high. However, at lower levels of sleep efficiency, children from higher SES homes had fewer externalizing behaviors than their lower SES counterparts. This interaction accounted for 10% of variance in externalizing symptoms beyond demographic or main effects.

Parent-reported internalizing symptoms. Both child age (β = .22; *p* = .009) and SES (β = −.19; *p* = .03) were associated with parent-reported internalizing symptoms; older children were reported as having more problems, and as SES increased, internalizing symptoms decreased. Demographic characteristics accounted for 11% of variance in internalizing symptoms.

Sleep–wake problems reported by children were positively associated with internalizing symptoms (β = .24; *p* = .009) and accounted for 5% of unique variance. This main effect was qualified by an interaction with SES (β = −.19; *p* = .05) that accounted for 2% of unique variance, which indicated that although sleep–wake problems were unrelated to internalizing symptoms for children from higher SES families, they were positively related to symptoms for children from lower SES

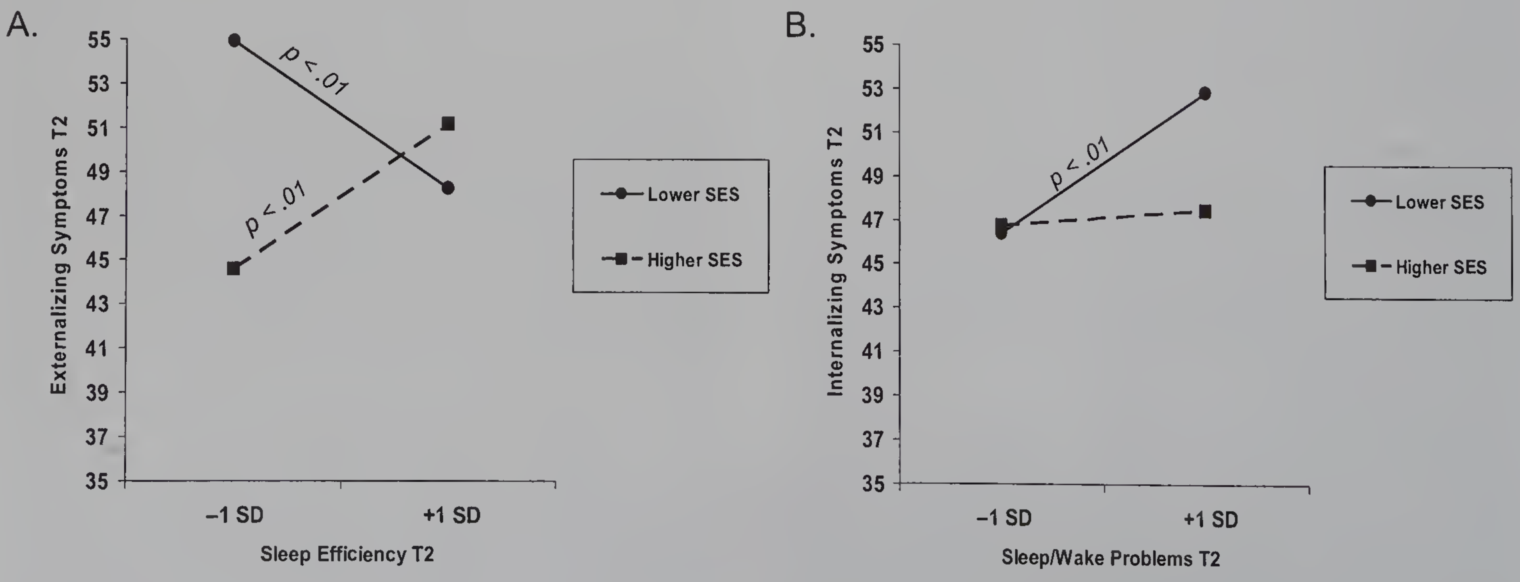

Figure 3. Cross-sectional interactions between socioeconomic status (SES) and children's sleep in association with parent-reported externalizing and internalizing symptoms.

families ($p = .01$; Figure 3B). At lower levels of sleep problems, predicted means for internalizing symptoms were almost identical for children from higher and lower SES families. Conversely, at higher levels of sleep problems, children from lower SES families had higher predicted means for internalizing symptoms than their higher SES counterparts. We found no evidence for the prediction of internalizing symptoms by objective measures or their interactions.

Child-reported internalizing symptoms. None of the demographic characteristics were significant predictors of children's self-reported internalizing symptoms and, taken together, accounted for 6% of variance. Parent-reported sleep was not a significant predictor of internalizing symptoms. Of the actigraphy measures, sleep schedule variability was positively related to internalizing symptoms ($\beta = .32$; $p < .001$) and accounted for 10% of variance beyond demographics. As children's sleep schedules become less regimented and predictable, they report more internalizing symptoms. No interactions were found to qualify this result.

Longitudinal Prediction of Child Adjustment

Externalizing symptoms. Prior externalizing symptoms ($\beta = .69$; $p < .001$), race ($\beta = -.20$; $p = .003$), and SES ($\beta = -.21$; $p = .003$) were related to T2 externalizing symptoms. Demographic characteristics and the autoregressive effect accounted for 52% of the variance. Children's subjective reports of sleep were not directly related to externalizing symptoms; however, one interaction was detected between children's sleep–wake problems and race ($\beta = .21$; $p = .03$). AA children's externalizing symptoms did not change significantly along with changes in sleep problems but as EA children experienced more sleep problems they decreased on externalizing problems ($p = .05$; Figure 4). Notably, when sleep–wake problems were low, both EA and AA children had similar amounts of externalizing symptoms. However, when sleep–wake problems were high, AA children had more symptoms. This finding accounted for 2% of unique variance.

In using objective measures of sleep to predict externalizing symptoms, only sleep efficiency was significant ($\beta = .18$; $p = .008$). Surprisingly, increases in sleep efficiency predicted increases in externalizing symptoms and accounted for 2% of variance beyond demographics. No interactions were found in predicting externalizing symptoms from objective measures.

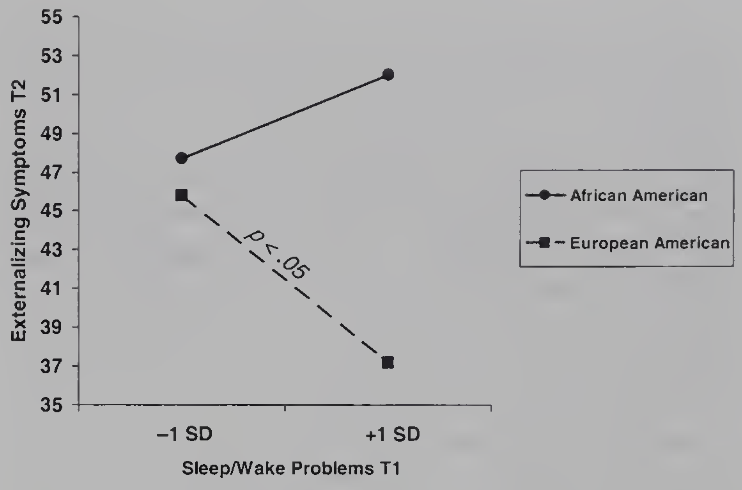

Figure 4. The interaction between race and sleep–wake problems at T1 in the prediction of parent-reported externalizing symptoms at T2.

Parent-reported internalizing symptoms. Prior internalizing symptoms ($\beta = .61$; $p < .001$), race ($\beta = -.20$; $p = .03$), and gender ($\beta = .15$; $p = .04$) were related to T2 internalizing symptoms. This meant that EA children and boys had higher parent-rated internalizing symptoms than AA children and girls, respectively. Demographic characteristics and the autoregressive effect accounted for 41% of the variance. Neither subjective report of sleep was related to internalizing symptoms. There was an interaction between sleep–wake problems and race ($\beta = .20$; $p = .05$), indicating that slopes for AA and EA children were significantly different from one another; however, neither slope was different from zero. This interaction accounted for only a very small amount of unique variance (1%), had no significant slopes, and resembles Figure 4 in terms of directions of slopes, and is not depicted. Importantly, and similar to the interaction evident for externalizing symptoms (Figure 4), predicted means for internalizing symptoms for AA and EA children were very similar at lower levels of sleep–wake problems. However, at higher levels of sleep problems, AA children appeared to have higher predicted means for internalizing symptoms in comparison to their EA counterparts.

None of the actigraphy sleep measures were directly related to internalizing symptoms. One interaction was found in which the link between sleep efficiency and internalizing symptoms was moderated by race ($\beta = .21$; $p = .02$). Sleep efficiency was unrelated to internalizing symptoms for EA children but was positively related to internalizing symptoms for AA children ($p = .01$). This interaction accounted for 2% of unique variance and is depicted in Figure 5.

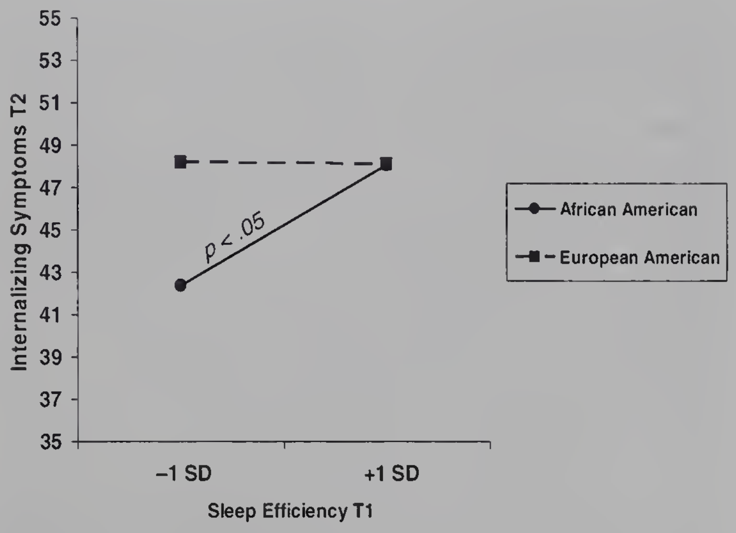

Figure 5. The interaction between race and sleep efficiency at T1 in the prediction of parent-reported internalizing symptoms at T2.

Discussion

A complex picture has emerged from predicting children's concurrent adjustment and changes in adjustment from both subjective reports of sleep from parents and children, objective actigraphy measures of sleep, and interactions between sleep and either race or SES. Some direct associations were observed between sleep characteristics and child adjustment. Further, different patterns of relations (i.e., moderation effects) were seen for children of different race and SES backgrounds. Interactions testing the study hypotheses accounted for relatively small but significant amounts of variance in children's internalizing and externalizing symptoms, ranging between 1% and 10%. These findings build on the literature and indicate that disruptions in children's sleep have a negative impact on multiple developmental processes over time and may depend on race and ecological context (e.g., Buckhalt et al., 2009; Gregory et al., 2005). In addition to establishing cross-sectional and longitudinal links between sleep and adjustment, the findings are unique in demonstrating that race and SES functioned as moderators of relations between children's sleep and adjustment. Results suggest that health disparities (Carter-Pokras & Baquet, 2002) need to be taken into account when examining child adaptation, and illustrate that certain populations may be more negatively impacted by adverse conditions (Foundation for Child Development, 2008). In this study, sleep was associated differentially with child adjustment based on the child's cultural or economic milieu. We found no evidence, however, for our exploratory hypothesis that gender may also moderate associations between sleep and adjustment. Importantly, in investigating the role of race and SES as moderators, any predictive ability of race also controlled for SES and vice versa.

Children's sleep was stable over 2 years: *r*s = .47 for sleep duration; .41 for sleep efficiency; .58 for parent-reported sleep problems; .40 for self-reported sleep–wake problems; and .19 for self-reported sleepiness. A few studies have documented that sleep problems persist across childhood (Jenni, Fuhrer, Iglowstein, Molinari, & Largo, 2005). In a 12-year longitudinal study of subjective measures of sleep, Gregory and O'Connor (2002) reported that sleep problems at age 4 persisted through childhood into midadolescence. Our findings parallel earlier findings and further highlight the stability of objective and subjective sleep parameters over 2 years of development, which has important implications for prevention and intervention considering associations between sleep and adjustment difficulties.

In original cross-sectional assessments when children were in third grade (El-Sheikh, Buckhalt, Cummings, et al., 2007), direct associations between various sleep parameters and child behavioral and emotional problems were found. The present results show that associations are still present 2 years later. Strengthening these findings is the fact that child-reported sleep problems were associated with parent-reported outcomes, indicating that these results are not due to mono-informant effects.

Importantly, the longitudinal results are novel and demonstrate the important role of sleep at T1 in predicting *changes* in child adjustment outcomes over 2 years, while controlling for T1 outcomes. The use of multiple reporters of children's adjustment, stringent control criteria, and assessments of objective and subjective sleep parameters increase confidence in our findings. In another report with the present sample (Buckhalt et al., 2009), sleep was a robust predictor of changes in children's cognitive and academic functioning examined through a comprehensive and standardized test battery (Woodcock–Johnson III Tests of Cognitive Abilities; Woodcock, McGrew, & Mather, 2001) and standardized achievement tests (Stanford Achievement Test [SAT], 2005). The pattern of effects in these studies illustrate that the negative effects of sleep disruptions are more pronounced for either AAs or children from lower SES homes across multiple domains of child development. A similar finding has been reported recently in which the link between adolescents' sleepiness and parent-reported executive functioning was more pronounced in the context of lower caregiver education (Anderson, Storfer-Isser, Taylor, Rosen, & Redline, 2009).

Race and SES moderated several associations between children's sleep and adjustment cross-sectionally. In relation to adjustment outcomes, AA and lower SES children tended to be more negatively influenced by sleep disruptions in comparison with EA and higher SES children. The most consistent pattern of moderation occurred cross-sectionally with SES. Children at lower levels of SES were well above average for externalizing symptoms, especially when they were also lower on sleep efficiency. As sleep efficiency increased, however, lower SES children dropped into more normative levels of externalizing symptoms. A similar result was seen with SES and child-reported sleep–wake problems; at higher levels of sleep–wake problems, parents of lower SES children reported more child internalizing symptoms. These moderated influences may not have long-lasting consequences, as we failed to find them when predicting future adjustment, although it should be noted that in this study the cross-sectional aspect of our study was conducted at T2 rather than T1; nevertheless, cross-sectional findings from T1 are supportive of this general pattern of SES-moderation effects.

When predicting future adjustment, the picture is slightly more mixed. It was evident that when child-reported sleep–wake problems were high, it was AA children who were reported by their parents as having the highest levels of externalizing and internalizing symptoms. In contrast, however, it was when objectively measured sleep efficiency was lowest that parents of AA children reported the lowest levels of internalizing symptoms. This finding is important for considering discrepancies between subjective and objective measures of sleep. Discrepancies between these categories of measures have been frequently noted by sleep researchers, and the general consensus is that we should continue to explore their different associations with outcome measures (Sadeh, 2008). Overall, effect sizes for moderation analyses were small to moderate, and interpretations of moderation showed a pattern of consistency cross-sectionally for SES and across time for race.

These findings suggest that negative outcomes associated with disruptions in a fundamental biological regulation system are exacerbated in the context of economic adversity or racial and ethnic minority status. The implication is that prevention and intervention efforts for children need to be tailored based on the family's resources and the challenges facing them. Periodic or chronic problems in children's sleep may have different associations with multiple outcomes depending on the family's circumstances. More generally, any single new problem facing a minority or low-SES family, such as illness of any member or a new financial challenge (to name but a few), may be enough to act as a "tipping point" toward broad dysfunction that may have various manifestations, including academic or behavioral problems in children. Alternatively, for families with more material and social resources, a single new challenge may have a lower level of impact. It is in this sense that the present findings are consistent with what others have termed the health disparities view (Carter-Pokras & Baquet, 2002).

Findings need to be interpreted within the study's particular context and limitations. Although sleep was examined objectively, via actigraphy, and subjectively, via both parent and child reports, these measures have limitations (Sadeh, 2008) including the inability to detect various sleep stages. Another study feature was the assessment of children's sleep and adjustment when they were in third and fifth grades. Assessments over other developmental periods may yield a different pattern of effects, and it is imperative for future research to examine developmental trajectories of child adaptation and sleep at various ages. Whereas we did not find gender-related moderation effects, such effects may be found in older children and adolescents. Although the present longitudinal study with two assessments is an advance in this new discipline of inquiry, full explication of developmental trajectories requires up to four assessments for the analysis of linear and nonlinear effects over time. Further, the causal relations between sleep problems and children's well-being appear to be bidirectional (e.g., Sadeh & Gruber, 1998). Just as sleep could be a symptom of child psychopathology or a significant stressor in a child's life, psychopathology could result from or be exacerbated by insufficient sleep and consequent fatigue and sleepiness, and establishing directionality of effects is a very important empirical question. It is also possible that the directionality of effects is different for children in various developmental periods, and thus models that test these various possibilities over a larger age span, and investigate alternative explanations, are critical. Furthermore, the current sample only included AA and EA children from the rural Southeast United States, and it is possible that regional customs with regard to sleep influenced the results. In addition, although we examined race and SES as moderators, there are still many questions to answer regarding the underlying processes by which they influence children's adjustment.

In summary, the current study's primary contribution is in demonstrating cross-sectional and longitudinal relations between various sleep parameters and externalizing and internalizing symptoms in a community sample of children. Findings highlight the importance of sleep quality and consistency of sleep schedule for children's optimal adjustment. The moderation effects of race and SES are intriguing and deserve continued attention. Interventions to improve sleep may yield significant benefits, and although benefits may accrue to all children, they may be especially valuable for children who are at greater risk for maladjustment and underachievement.

Experience-Based and On-Line Categorization of Objects in Early Infancy

Marc H. Bornstein and Clay Mash
Eunice Kennedy Shriver *National Institute of Child Health and Human Development*

What processes do infants employ in categorizing? Infants might categorize on line as they encounter category-related entities; alternatively, infants might depend on prior experience with entities in formulating categories. These alternatives were tested in forty-four 5-month-olds. Infants who were familiarized in the laboratory with a category of never-before-seen objects subsequently treated novel objects of the same category as familiar—they categorized on line—just as did infants who were exposed to objects from the same category at home for 2 months leading to their laboratory assessment of object categorization. Infants with home experience also recognized novel category objects as familiar from the outset—that is, prior experience with category exemplars was brought to bear in laboratory tasks.

One of the central challenges of object identification and categorization is the ability to recognize and organize category-related objects independent of their orientation, where they appear in the visual field, and so forth. For object perception and cognition to proceed with any degree of organization, order, or coherence, both biological and environmental variation must be transcended. Categorization constitutes a critical and adaptive solution to the challenges posed by both biological instability and environmental diversity. Categories refer to shared representations of like, but (usually) discriminable, entities and are in evidence when organisms treat (discriminably) different entities equivalently. Categorization allows generalization across experience, because categorization relates experienced entities to one another and to their mental representation. Categories mediate our interactions with the world in many ways (Bornstein, 1984; Harnad, 1987; Rakison & Oakes, 2003; Rosch, 1975; Smith, 1989; Smith & Medin, 1981). They structure and clarify perception and cognition, facilitate the storage and retrieval of information, and supply a principle of organization by which new information is banked efficiently in memory. An entity that is encountered for the first time could be treated as unique or, if categorization is brought to bear, in the same way as previously encountered entities that it resembles. Categorization is also used to generalize about newly encountered entities from the same category (Furrer & Younger, 2008; Gelman, 1988; Kalish & Gelman, 1992; Lin & Murphy, 2001; Proffitt, Coley, & Medin, 2000). Knowledge about a category affords expectations about novel entities in toto as well as about features of novel entities (Baldwin, Markman, & Melartin, 1993; Greco, Hayne, & Rovee-Collier, 1990; Mandler, 1998, 2000; Needham, Cantlon, & Ormsbee Holley, 2006). Categorization is thus a fundamental process by which the brain assigns meaning to sensory stimuli, and categorization is critical for rapidly and appropriately selecting behavioral responses (Freedman & Assad, 2006).

Little wonder, then, that the primate visual system has evolved such that single neurons respond selectively and quickly to complex object categories, such as faces and hands (Bruce, Desimone, & Gross, 1981). The activity of even tiny populations of neurons (on the order of approximately 100 randomly selected cells) over very short time spans (as brief as 12.5 ms) process accurate and robust information about both an object's identity and its category, and that category information generalizes over a range of object orientations, locations, and scales, even for novel objects (Freedman, Riesenhuber, Poggio, & Miller, 2001; Hung, Kreiman, Poggio, & DiCarlo, 2005; Schwarzlose, Swisher, Dang, & Kanwisher, 2008). Notably, specific category-related brain activity has been

observed in young human infants (Quinn, Westerlund, & Nelson, 2006).

Given the significance of categorization, surprisingly little is understood about the conditions required or the time course over which categorical representations are first formed in infancy. After all, infants are limited in the universe of objects to which they are exposed as well as in their cognitive capacities. Examining categorization processes in infancy can inform about factors that influence the nature and origins of categorization and the earliest accumulation of category-relevant knowledge (Furrer & Younger, 2008; Rakison & Oakes, 2003).

In a typical categorization study, infants are familiarized with discriminable exemplars of a category, and they are then tested with novel exemplars from the familiar category and from a contrasting different category (e.g., Arterberry & Bornstein, 2002; Behl-Chadha, 1996; Bornstein, Kessen, & Weiskopf, 1976; Quinn, Eimas, & Rosenkrantz, 1993). To show that they categorize, infants must include discriminably different novel exemplars of the category in the representation they have and simultaneously exclude contrasting novel exemplars from outside the category. Operationally, generalization of familiarization to a novel exemplar from the familiar category, coupled with heightened responsiveness to a novel exemplar from the novel category, is taken as evidence of category formation. For example, 5-month-olds who were habituated to varying facial expressions from one category (smiles) responded to a novel test image from the habituation category as if it were familiar, but responded differently to a novel (fearful) expression from a different category (Bornstein & Arterberry, 2003).

Routinely in infancy studies of object categorization, images or replicas of real-world objects are used, such as animals or vehicles or furniture, which are known and with which infants normally have experience. Visual-fixation studies have shown that infants as young as 3–4 months distinguish between categories such as animals and furniture, and even subcategories within animals and furniture such as cats, dogs, fish, and horses (Eimas & Quinn, 1994; Eimas, Quinn, & Cowan, 1994) or chairs, beds, sofas, and tables (Behl-Chadha, 1996). In these common cases, infants may categorize on the basis of their experience seeing exemplars in the course of the study or on the basis of experience they have in real life or from picture books, videos, television, and the like. Thus, it is unclear whether infants' categorization performance is based on preexisting familiarity with objects or categories, or, instead, if infants form categories during the (usually highly structured) experimental familiarization period. This circumstance leaves open key questions of whether and how infants actually construct categorical representations of objects they experience during fleeting encounters in routine daily life. Answers to these questions are important to fully understand human learning and how it develops.

Are object category representations in infants constructed before an experiment, or are they formed during the course of an experiment? If infants form category representations before being brought to the laboratory, it is probable that infants recognize experimental exemplars as representations of objects in the world with which they are already familiar and for which they may have some existing category knowledge. On this view, the familiarization phase of the familiarization/novelty-test procedure presumably serves to prime the knowledge that infants have already acquired outside the laboratory. If infants initiate category construction during the course of familiarization, then the familiarization/novelty-test procedure is better understood in terms of category formation. Infants presumably construct a category representation as they see exemplars from the familiar category. However, from the extant literature, it is difficult to completely rule out the possibility that prior experience or knowledge does not influence infant categorization. For most experiments designed to study categorization, it is possible that young infants recruit from their preexisting knowledge base in a way that, at least in part, determines their subsequent categorization behavior (Quinn, 2004).

In the present study, categorization was called *on line* when infants appeared to rely only on their immediate perceptions of the given experimental entities to form an object category within the familiarization period. Categorization was called *experience based* when infants could refer to some already existing experience, knowledge, or representation that was activated by perceptions of given entities but included properties other than those corresponding to the physical attributes of the experienced material. This study investigated whether infants younger than 6 months of age show on-line or experience-based categorization using an object-examination paradigm and objects that infants could never have seen before; therefore, the study controlled experience and eliminated preexisting knowledge from explaining infant object categorization performance.

Infants might show on-line categorization, or infants might show experienced-based categorization.

To take these two main options in reverse order, the second possibility holds that categorization in infants is experience based if infants refer to already existing knowledge representations that are being reactivated. By the middle to end of the 1st year (to take a common age span at which object categorization studies are performed), infants are already experience rich and perceptually competent, and so could easily be expected to take full advantage of opportunities to categorically structure their interactions with objects. There are three ways that preexisting experience could then affect categorization in the laboratory. One is that previous experience with the category is used during the familiarization phase of a categorization task and influences the acquisition or nature of the category representation. Another is that experience might be recruited during categorization judgments after the familiarization phase has ended. Familiarization might serve as a reminder that countervails forgetting by priming or reactivating an available but otherwise inaccessible category in memory (Tulving & Thomson, 1973), thereby facilitating access to that memory at the time of the subsequent test (Spear, 1973, 1978). In infants, reminders are effective in counteracting forgetting after retention intervals as long as 1 month (Fagen & Rovee-Collier, 1983; Rovee-Collier, Sullivan, Enright, Lucas, & Fagen, 1980; Sullivan, 1982). Last, of course, infants could use existing knowledge in both ways.

For example, asymmetries in young infants' categorization have been attributed to infants' relatively greater experience with one or another category (Quinn, 2002). Preliminary evidence for the role of previous experience in categorization was provided by Quinn, Yahr, Kuhn, Slater, and Pascalis (2002). Using a visual familiarization task, they found that 3- to 4-month-old infants with female primary caregivers formed an exclusive category of relatively unfamiliar male faces (i.e., a category that excluded female faces) but remembered individual exemplars from the more familiar category of female faces. Using an object-examining task, Pauen (2002) observed that 10- to 11-month-old infants responded to the distinction between furniture and animals both when between-category exemplars shared several perceptual properties and when they shared few. Pauen reasoned that on-line (perceptual) processes could not account for these results, and therefore infants' responding must reflect accumulated knowledge. Likewise, it has been suggested that categorization of cats and dogs differs for infants who do or do not have pets in their home. Kovack-Lesh, Horst, and Oakes (2005) reported that infants whose parents rated them as being highly interested in dogs performed best on a pattern-learning task involving pets.

Thus, experience and experience-dependent preferences seem to play a role in categorization performance (Needham et al., 2006, discuss related findings), and preexisting representations may help to explain categorization in young infants. More generally, these findings suggest that infants' experiences outside the laboratory can affect their categorical responding in the laboratory (Bar-Haim, Ziv, Lamy, & Hodes, 2006; Kelly et al., 2005, 2007).

However, other data cast some doubt on exclusively experienced-based interpretations of infant categorization. If infant categorization of nonhuman animals in the laboratory is assisted by their real-world experiences with nonhuman animals occurring before arrival at the laboratory, Quinn (2004) argued, one might expect having home pets to facilitate infants' animal categorization performance. Two studies compared animal categorization by infants who had been exposed to pets at home and infants who had not, and neither revealed a facilitative effect of home pets on categorization performance. Data from 3- to 4-month-old infants tested in Quinn's Experiment 1, and 6- to 7-month-old infants tested in his Experiment 2, offered no evidence that categorization of cats or dogs as measured in the laboratory was influenced by the presence of a home pet. Similarly, whether or not infants had a pet dog at home was not a significant predictor of their category task performance, nor did it correlate with infants' reported interest in dogs in Saffran, Pollak, Seibel, and Shkolnik (2007). "These null results thus fail to support the suggestion that infant categorization of nonhuman animals in the laboratory is assisted by real-world experience with nonhuman animals occurring prior to arrival at the laboratory" (Quinn, 2005, p. 113).

On the first possibility, then, infant categorization might not (solely) reflect their prior accumulated experience. Categorization might take place on line if infants rely on their immediate experiences with given stimuli to form categories. Even if infants possess some categorical knowledge, some infant categorization performance might still be best explained by spontaneous category learning (Mareschal, French, & Quinn, 2000; Mareschal & Quinn, 2001). For example, infants presented with the contrast between replica animals and people did not categorize in the first half of the task but gave evidence that they did in the second half (Oakes, Plumert, Lansink, & Merryman, 1996).

Infants in this study seemed to discover a categorical distinction as they actively explored the experimental objects. Younger and Fearing (2000) provided evidence for infant on-line category formation by showing that infants form categories at multiple levels that depend on similarities among the entities presented during the experiment. Presented with cat versus dog contrasts manipulated by changing featural (although not categorical) characteristics of the stimuli, infant responsiveness varied, suggesting that they formed categories during familiarization (and that category boundaries could be manipulated depending on the information presented during familiarization; see also French, Mermillod, Quinn, & Mareschal, 2001). The authors reasoned that if infants were tapping into category representations that were fixed and established before their participation in this task, infant responsiveness would not differ with featural variation in the category information presented. Together, these findings suggest that categorization performance in infancy can be attributed to active on-line processing and within-task learning.

Finally, infant performance need not be one (on line) or the other (experience based), but both. Four-month-olds' previous experience with dogs, cats, or both and their on-line looking behavior during learning an adult-defined category of cat in a visual familiarization task jointly determined whether or not infants categorized (Kovack-Lesh, Horst, & Oakes, 2008). Infants were divided by whether they had a pet at home and how much they shifted their gaze back and forth between stimuli during familiarization. Infants in a pet/high-switching group showed significantly greater novelty preference than did infants in a no-pet/high-switching group and infants in a pet/low-switching group. In this study, infants who had a pet at home and who engaged in relatively high levels of stimulus comparison demonstrated the highest level category functionality—they remembered individual items and they recognized commonalities among items from within the same category. Infants in other groups did not respond either to the category or to the individual items. One problem with this pattern of results, however, was that infants in the most advanced pet/high-switching group did not differ in novelty preference from infants in the least advanced no-pet/low-switching group.

The common use of real or familiar stimuli in these infancy studies restricts the analysis of performance contrasts and the important deductions that can be made from them. Even if young infants have not observed the exact stimuli in categorization experiments prior to their participation, they have been exposed to related stimuli that may be sufficient to build up representations that could influence learning within those tasks (Needham & Baillargeon, 1998, and Quinn & Eimas, 1998, discuss relations between real-world experience and within-task learning). It could also be that parents with pets treat their infants differently than do parents who do not have pets. In either case, infants might differ in their attention and learning in general. Investigating infants' categorization abilities, some researchers have used novel stimulus materials such as meaningless dot patterns and unusual creatures (e.g., Bomba & Siqueland, 1983; Younger & Cohen, 1983). However, dot patterns are simplified stimuli and hardly ecologically representative of 3-D objects that have affordances for action and serve functional roles, and hybrid animal-part studies depict familiar parts and/or part–whole relations that enable (or specifically draw on) linkages to previous experience. Many factors influence the ease of representation of the input and facilitate categorization, and one obvious factor is familiarity; elements similar to those that have been encountered previously can be expected to be easier to represent, maintain in memory, and perhaps categorize (Saffran et al., 2007). Thus, materials that infants can readily represent, such as animals, vehicles, and furniture, might facilitate categorical task performance. Finally, one can expect natural variation in infants' experiences and, in consequence, infant performance in any natural experiment through unsystematic exposure to materials and images.

How then do infants categorize objects? To address this question, task performance is best examined independently of differing levels of stimulus experience and familiarity. Here, we investigated infant object categorization by directly examining infants' learning of entirely new object categories both with and without previous experience with object exemplars of those categories. Experience was controlled through the development and use of purpose-constructed never-before-seen objects and categories, and whether or not infants were shown the objects preceding their participation in a laboratory categorization task. If infants with no possible experience with such an object category and its exemplars form a categorical representation during a laboratory task, then previous, cumulative experience must not be requisite for object categorization, and infants can categorize "on the fly." If infants with no experience with the object category and its exemplars cannot form a categorical representation during a laboratory task, then previous, cumulative experience may be requisite for object categorization. If infants having such previous, cumulative experience with the object category and its exemplars form a categorical representation during a laboratory task, then that experience would appear to define a milestone of experience-dependent sufficiency for learning new categories and subsequently categorizing novel exemplars. Thus, along with its control of experience with the object stimuli, this study offers an experimental vantage point from which to examine infants' developing categorization abilities. In this experiment, we contrasted laboratory object categorization in young preverbal infants given prior home experience with unique and entirely novel objects to laboratory object categorization in infants given no such experience.

Method

Infants

Nineteen normal and term infants (5 girls) were 3.15 months (*SD* = 0.26) when they began the home experience condition; they were 5.38 months (*SD* = 0.39) at the laboratory assessment. (One additional infant was recruited, but the family moved during the home experience phase.) Twenty-five normal and term 5.12-month (*SD* = 0.42) infants (13 girls) participated in the no home experience condition. (An additional 3 infants were recruited, but their data were not included due to fussiness or experimenter error.) There were no differences in sociodemographic characteristics of infants or families in the two conditions.

Stimuli

Never-before-seen objects were constructed to comprise two novel categories (Figures 1A and B) for infants. The objects were each made of three wooden pieces assembled in unique configurations. Individual parts were painted with a total of eight different colors, four used for each category. Each category exemplar represented a unique combination of part configuration and color. Both within and between categories, the parts of each object were assembled in a similar way, but each varied with respect to the exact positioning of parts. Each category contained a total of eight unique

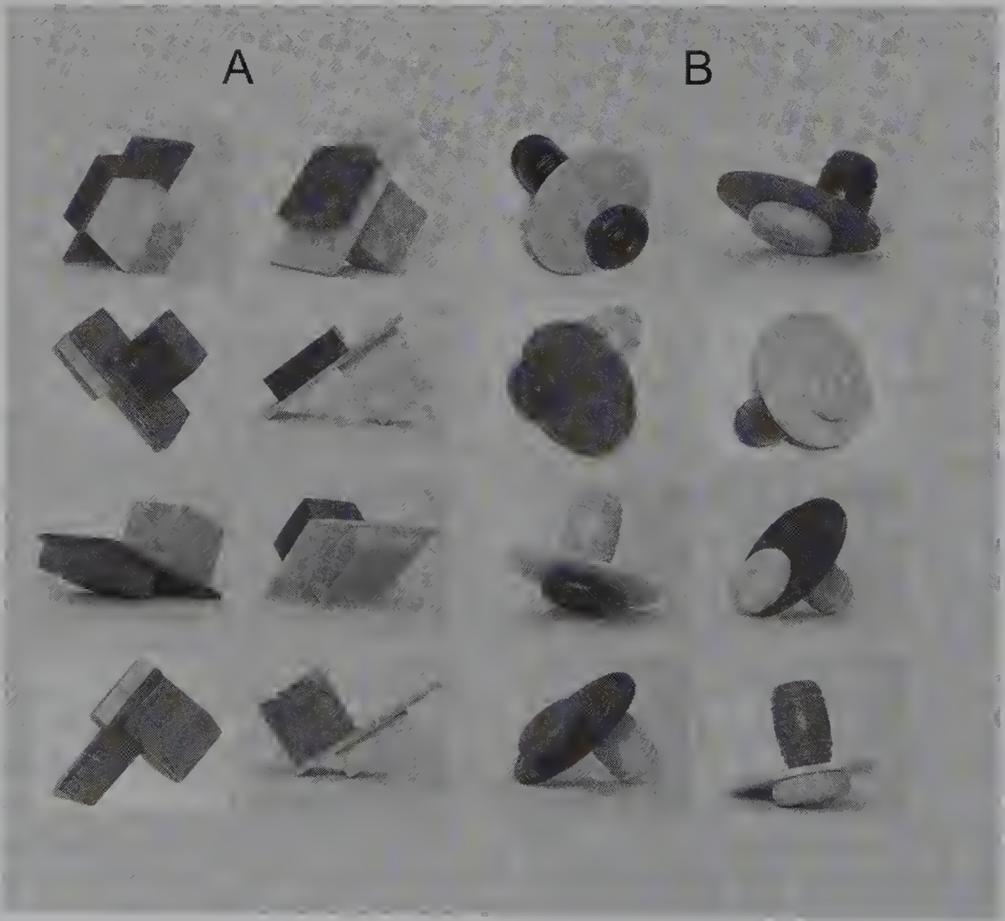

Figure 1. Examples of Categories A and B.

exemplars. Each object was painted with three colors (one per part), and the colors did not overlap across categories. Thus, the two categories were similar in size, complexity, part configuration, and the distribution of color boundaries but differed in the parts and colors of the objects. Curved versus linear edge features were distributed over the entire object for each exemplar and category. The familiarization exemplars were depicted in numerous and varied orientations and viewpoints, so edge composition did not provide a single, location-invariant feature for discrimination between images.

Home Experience Procedure

At the 3-month laboratory visit, parents of infants in the home experience condition received materials and training for conducting stimulus exposure sessions at home. They were provided with a booklet containing 20 photographs, four pictures each (differing in orientation) of five randomly selected exemplars from one category. The images were 10.2 cm × 15.2 cm and printed on standard size plain white paper, which was then laminated. Parents were instructed to show their infants the pictures once per day on a daily basis until they returned to the laboratory for the experimental task. They were provided with a timer and were instructed to pace presentations so that the entire stimulus set was shown over the course of 2 min. Parents were telephoned on a weekly basis to evaluate compliance with the procedures. Mothers were accommodating in conducting the stimulus exposure sessions at home, reporting successful administration of 5.54 sessions/week on average (*SD* = 1.04) throughout the 2-month home-experience period. They reported no significant problems with administration. Missed sessions were distributed uniformly over participants, most typically resulting from competing household demands and minor illness.

Laboratory Object Examination

Object examination procedure. To test preference, discrimination, and categorization, an object-examination procedure was used following established conventions (Oakes & Tellinghuisen, 1994; Ruff, 1986). Actual objects were presented directly to infants. The data of primary interest from object examination are the amounts of time infants spend in focused examination of objects while handling them. Oakes and Tellinghuisen (1994) have argued that focused examination provides a more sensitive index of information processing than traditional measures of looking time. Each session was videorecorded, and infants' examination of stimulus objects was coded from the videorecords. All coders were blind to the hypotheses of the study and condition assignment of the infants. Reliability of coding was established by calculating agreement between coders. All together, 35% of sessions were coded twice, with high agreement, $r = .91$.

Stimulus preference and discrimination. To assess baseline stimulus preference and within-category exemplar discrimination, an independent sample of 14 normal and term infants participated in a fixed-trials familiarization/novelty-preference task (*M* age = 5.23 months, *SD* = 0.26; 6 girls). (Two additional infants were tested, but their data were not included due to fussiness and inattention.) Infants participated in two different sessions, one involving each of the two different object categories. For each session, a single exemplar of one category was randomly selected and presented repeatedly over the course five 20-s familiarization trials. At the end of each trial, the experimenter retrieved the object from the infant, removed it from view, then re-presented it to begin the next trial. Two discrimination trials were then administered in the same fashion. In one trial the same object was presented again, and in the other trial a randomly selected novel member of the same category was presented. The order in which the discrimination trials were administered (novel exemplar first or second) was counterbalanced across infants. The order of sessions for the two categories was also counterbalanced.

To assess infants' baseline preference, infants' object examination was compared between categories within the first 20 s of exposure during the familiarization phase. Examination times did not differ between categories (A: $M = 2.88$ s, $SD = 4.37$ vs. B: $M = 3.66$ s, $SD = 4.80$), $t(13) = 0.70$, *ns*. Infants' discrimination of exemplars within categories was examined in an analysis of variance (ANOVA) utilizing category (A vs. B) and discrimination trial (familiar exemplar: $M = 2.05$ s, $SD = 1.65$, vs. novel exemplar: $M = 3.50$ s, $SD = 2.01$) as within-infants factors. Only the discrimination trial contrast was significant, $F(1, 13) = 6.10$, $p = .028$, with infants examining the novel exemplars longer than the familiar ones. In brief, infants had no a priori preference for one category over the other and could discriminate among same-category exemplars.

Categorization. All infants participated in the same laboratory categorization task. The categorization procedure comprised a familiarization phase and a test phase. Five objects from one (or the other) category were randomly assigned for familiarization. Using a fixed-trials procedure (Ruff, 1986), each object was examined twice over the course of 10 familiarization trials in an order uniquely randomized for each infant. During familiarization, the experimenter presented one object at a time to the infant, using a count-down timer to mark an elapsed time of 20 s per trial. At the end of each trial, the experimenter retrieved the object from the infant and then presented the next object. Except for the one being presented, the remaining objects were hidden from the infant's view. Two test trials were then administered in the same fashion. In one test trial a novel previously unseen member of the familiar category was presented, and in the other test trial a randomly selected member of the novel category was presented. The order in which the test trials were administered (novel category first or second) was counterbalanced over infants.

In summary, infants in the home experience condition and infants in the no home experience condition came to the laboratory at 5 months. At that laboratory visit, infants were familiarized to five objects—for infants in the home experience condition, they were the same objects as those depicted in the picture booklet the infants saw at home—and then tested with two previously unseen objects (one from each category). Half of each sample was familiarized to each category, after which every infant received both a familiar-category novel test trial and a novel-category novel test trial. Laboratory visits and data analysis were conducted in exactly the same manner for infants in the home experience and no home experience conditions.

Results

Infants' laboratory object-examination categorization was analyzed in two mixed-model ANOVAs utilizing familiar category (A vs. B) as a between-infants factor and a series of planned trial contrasts as within-infant factors. Planned comparisons examined effects of (a) familiarization (mean of first two familiarization trials vs. mean of last two familiarization trials), (b) category generalization (mean of last two familiarization trials vs. the familiar-category novel-object test trial), and (c) category discrimination (mean of last two familiarization trials vs. the novel-category novel-object test trial). Preliminary analyses revealed no effects of test condition order or gender, so subsequent analyses excluded those factors.

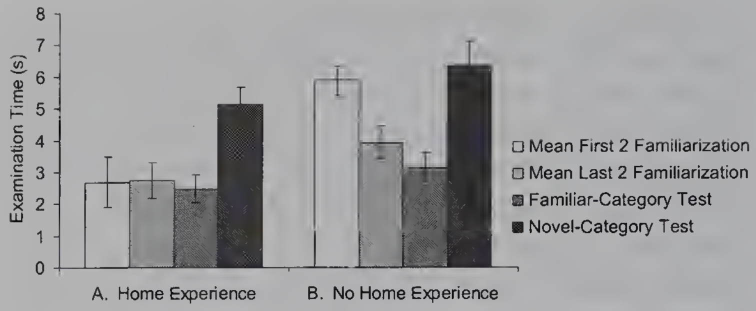

Figure 2. Mean examination time (in s ± 1 *SEM*) at the start of familiarization, at the end of familiarization, for the test of the familiar-category novel exemplar, and for the test of the novel-category novel exemplar: (A) home experience condition and (B) no home experience condition.

Familiarization, Category Generalization, and Category Discrimination Following Prior Home Experience

The familiarization and category generalization contrasts were not significant, *F*s(1, 18) = 0.009 and 0.334, *ns*, but the category discrimination contrast was significant, *F*(1, 18) = 14.05, *p* = .001, partial η^2 = .438 (Figure 2A).

Familiarization, Category Generalization, and Category Discrimination Without Prior Home Experience

The familiarization contrast was significant, *F*(1, 24) = 5.73, *p* = .025, partial η^2 = .193; the category generalization contrast was not significant, *F*(1, 24) = 1.21, *ns*; and the category discrimination contrast was significant, *F*(1, 24) = 7.92, *p* = .010, partial η^2 = .248 (Figure 2B).

Familiarization Differences and Similarities Between Experimental Conditions

To examine whether their home experience modified infants' familiarization (encoding) during the laboratory task, three additional analyses compared object examination times between the two groups. First, the means of the first two familiarization trials differed across conditions, *M* = 2.69 s (*SD* = 2.09) in the home experience condition versus *M* = 5.88 s (*SD* = 4.91) in the no home experience condition, *F*(1, 42) = 7.01, *p* = .011, partial η^2 = .143. Second, a main effect of condition emerged over the start through the end of familiarization, *F*(1, 42) = 5.02, *p* = .030, partial η^2 = .107, with infants in the no home experience condition examining objects longer ($M = 9.80$ s, $SD = 6.92$) than infants who had previous home experience ($M = 5.44$ s, $SD = 3.53$). Additionally, trial interacted marginally with condition, $F(1, 42) = 3.59$, $p = .065$, partial $\eta^2 = .079$. As noted earlier, a significant decrement was observed in the no home experience condition but not in the home experience condition. Third, the average duration of object examination per individual look throughout familiarization was significantly longer in the no home experience condition ($M = 2.48$ s, $SD = 1.96$) than in the home experience condition ($M = 1.41$ s, $SD = 1.07$), $F(1, 42) = 4.64$, $p = .037$, partial $\eta^2 = .099$.

To assess infants' general orientation to the task and its demands during familiarization, two additional analyses were conducted. First, the total duration of casual looking toward the stimuli—that is, general visual regard not limited to focused examination—was calculated across familiarization trials and compared between groups. Mean looking did not differ between infants in the home experience ($M = 12.10$ s, $SD = 2.58$) and no home experience ($M = 10.54$ s, $SD = 4.64$) conditions, $t(42) = 1.32$, *ns*. Additionally, general interest in the stimulus objects was independently rated for each trial using a 5-point Likert-type scale from 1 = *no interest* to 5 = *extremely interested*. Fifteen percent of the sessions were rated by a second coder, and ratings correlated $r = .94$ between coders. Ratings did not differ between infants in the home experience ($M = 3.75$, $SD = 0.50$) and no home experience ($M = 3.76$, $SD = 0.88$) conditions, $t(42) = 1.32$, *ns*. Together, these findings indicate that infants' general engagement in the task did not differ between conditions and therefore cannot account for the differences observed in infants' processing of the stimulus objects during familiarization.

Discussion

At 3 months, infants were randomly assigned either to a home experience condition that consisted of their parents showing them images of exemplars of a novel, never-before-seen category of objects or to a no home experience condition. At 5 months, all the same infants participated in a laboratory categorization study with objects from those same categories. Infants in the home experience condition did not decline in looking at objects over the course of laboratory familiarization, they generalized from the end of familiarization to presentation of a novel within-category object, and they examined a novel-category novel object longer than they examined objects at the end of familiarization. Infants in the no home experience condition declined in looking over the course of familiarization to the objects, they generalized from the end of familiarization to the presentation of a novel within-category object, and they examined a novel-category novel object longer than they examined objects at the end of familiarization. These findings were not ascribable to infants' differential engagement with the stimuli or to differential preferences for or failure to discriminate among the stimuli.

Two Lessons Learned

This study of infant categorization of ad hoc, unfamiliar objects eventuated in two main sets of findings. First, 5-month infants with no prior experience with a completely novel category of never-before-seen objects categorized them on line at the time of an experimental session, just as infants would presumably do in encountering category-related objects in everyday life. Second, infants with prior experience also categorized the objects at the time of an experimental session, and home experience with completely novel objects in a novel object category also influenced infant behavior at the time of the later experimental laboratory session.

Infants familiarized to exemplars of a never-before-seen object category during an experimental session generalized examination time to a novel object exemplar from the same category, while discriminating one from a contrasting category. Because otherwise equivalent infants showed no baseline preference for exemplars of one category over the other, and demonstrated an ability to discriminate exemplars within both categories, the no home experience infants' performance clearly reveals their ability to categorize objects on line, that is as never-before-seen objects in a category are encountered. Because infants participating in the no home experience condition had never previously experienced exemplars of the novel stimulus categories, their representations could only have formed during the task itself. These findings affirm the position that young preverbal infants' responses during laboratory tasks incorporate and reflect experience during the task. This study indicates that infants can formulate categorical representations of objects entirely within the confines of a few short minutes exposure. Infants appear to have learned an object category during familiarization. It may be that mere exposure on the task of comparing different exemplars of the same category over time leads to the extraction of a category

(Gentner & Medina, 1998). In adults, categorization experience with stimuli analogous to those used in testing attunes the individual and the brain to relevant dimensions of a stimulus (Baker, Behrmann, & Olson, 2002; Goldstone, Steyvers, & Larimer, 1996; Jiang et al., 2007; Schyns, Goldstone, & Thibaut, 1998).

This is not to imply that prior experience plays no role in infant cognition. The second question of whether infants construct categorical representations over their encounters with objects as they arise in everyday life and later call on that information was examined in the complementary home experience condition. These infants were exposed to pictures of novel objects every day (for just a few seconds each) over the course of 2 months. When these infants participated in the same laboratory categorization task, they too demonstrated categorical representations during the test phase of the task, but no evidence of learning during the familiarization phase. On the convention that attention during familiarization reflects active encoding (Bornstein, 1985; Colombo, 1993), experience at home clearly exerted a direct effect: More encoding occurred when prior opportunity for encoding was absent. This finding underscores the conclusion that infants utilized stimulus representations they had constructed at home, bringing them to bear on their categorization performance in the laboratory. Because the category exemplars were novel and unique to this research program, infants must have constructed categorical representations of the stimulus objects over the course of their distributed home experience, brought this information with them to the laboratory, and then used this information during the laboratory task. The fact that infants in the home experience condition (a) treated stimuli at the beginning and end of the laboratory familiarization the same and (b) treated stimuli at the start of familiarization differently from infants in the no home experience condition provides additional evidence that infants carried their knowledge of the category from previous home experience into the laboratory. (Checks verified that the two groups did not differ overall in engaging the stimuli.) This finding is consistent with the positions that infants can construct stable categorical representations of objects they experience and that those representations can guide the systematic generalization of familiarity and knowledge to novel entities. The different patterns of familiarization between groups for objects that were previously experienced versus those that were not indicate that prior representations (based on experience) exerted a more dramatic influence on property extensions than did in-task modeling.

Furthermore, young infants in the home experience condition had to transfer knowledge from pictures to objects, and from looking to looking and handling. These differences are nontrivial and require intersensory and mental generalization. This deduction accords with previous research that revealed the abilities of infants in this age range to detect equivalences between objects and their photographs (e.g., DeLoache, Pierroutsakos, & Uttal, 2003). Real-life exposure to images of objects appears to influence infants' responses to categories of the same three-dimensional objects in the laboratory.

Object Representation: Items or Prototypes?

On what basis do infants learn object categories? One approach to answering this question starts from the nature of infant representation in category development. Object categories may be represented by individual exemplars of the category or by a summary representation (perhaps a prototype or rule) of the category (e.g., Medin & Schaffer, 1978; Nosofsky, 1984). Item-based approaches tend to rely on (sometimes large) mnemonic stores of previous experience; prototype or rule-based approaches usually rely on simpler criteria and presumably do not require extensive memory. In adults, when the number of stimuli is small, categorization may be mediated by individual items, but when the number of stimuli exceeds some capacity, categorization is presumably handled by prototypes or rules rather than by individual exemplars (Ashby & Ell, 2001). It has been asserted that infants form categories both as collections of individual items (e.g., Hayne, Rovee-Collier, & Perris, 1987; Quinn et al., 2002; Younger, 1993) and as organized around prototypes (e.g., Bomba & Siqueland, 1983; Bornstein, 1982; Younger, 1985). Which infants do appear to depend on their age, the task at hand, or other factors. Younger (1990) reported that 13-month infants use specific-item information in categorization, but younger babies do not. Quinn (2002) proposed that experience with exemplars from a particular category changes infants' categorization from forming a summary representation (prototype) of exemplars to remembering each individual exemplar as well as maintaining a summary representation. Horst, Oakes, and Madole (2005) also reported results that support infants' learning individual exemplars and forming a summary representation. Perhaps after extensive experience with a limited number of items in a category, infants can both maintain a summary representation or prototype and remember individual items. In light of the constancy in infants' home experience in our study—seeing the same five objects each in a limited number of orientations every day—it is possible that infants stored and retained each exemplar individually and compiled a summary representation (prototype) of the category. If so, home experience infants' flat familiarization profile could reflect individual item recognition or common reference to a previously developed category (prototype) representation. It is impossible to discern from the present familiarization data which format infants used to encode their home experience and applied during laboratory familiarization.

That said, any related ambiguity with respect to infants' familiarization performance in no way undermines our interpretation of infants' test phase performance where both groups provided clear evidence for categorical representations. Because the home experience infants in this present study demonstrated categorization of familiar-category novel exemplars in the test, and there was no evidence for their learning during familiarization, we deduce that infants acquired a categorical representation prior to the laboratory task (i.e., over the course of home experience) and used it during the test. It is possible that infants in the home experience condition formulated specific memories of each individual image or stimulus object and showed reduced examining during familiarization because they recognized individual stimuli instead of recognizing the category. On closer inspection, however, this interpretation is not consistent with the evidence available. First, infants in the laboratory task had to bridge their home experience with pictures into their responses to objects over significant differences in setting, context, and presentation mode. More critically, however, if infants simply recognized individual objects during familiarization, they would not have generalized examination time to either test stimulus. Because infants in a separate task discriminated among members of both categories, the familiar-category novel-object test stimulus would have been discriminated if infants relied on item recognition alone. As reported earlier, however, this is not what happened. Infants in the home experience condition, like their no home experience counterparts, generalized looking from familiarization to the familiar-category novel object.

Object Representation: Features or Configurations?

Another approach to the basis of infant object categorization turns on the question of what about objects and object categories constitute critical criteria. Infants in our study treated discriminably different same-category novel objects in the test equivalently to the objects in the familiarization set and discriminated different-category novel objects. Some investigators contend that infants younger than 1 year of age form categories based on knowledge about causal and functional similarities of objects (Gelman, Durgin, & Kaufman, 1995; Mandler, 2000, 2004; Mandler & McDonough, 1993; McDonough & Mandler, 1998; Van de Walle, 1999). The object stimuli used in the present study lack causal or functional relations as such, and so these bases of categorization are ruled out. Thus, novel objects were presumably categorized or discriminated by their similarity of appearance to familiar ones. Such comparisons could refer to (a) similarity of critical features or (b) similarity of a configuration of features. In a sense, the answer to this question further specifies the nature of the infant's representation of the object category.

Perhaps infant object representations are holistic, based on an object category's overall configuration or appearance without selective attention to individual features, dimensions, or attributes. Using sequential touching, Rakison and Butterworth (1998) deduced that infants under 2 years attend, not to individual object parts per se, but to the structural configuration of the parts perceived as a whole, and Träuble and Pauen (2007) found that 1-year-olds categorized objects on the basis of their overall similarity and not their part similarity. Elsewhere, infants have been shown to rely on overall shape similarity as a basis of object categorization (Graham, Kilbreath, & Welder, 2004; Welder & Graham, 2001). Later, infant categorization could become more analytic, with selective attention paid to features, dimensions, or attributes (Shepp, 1978). There is evidence, too, however, that young infants discriminate and categorize on a so-called partonomic bias. Tversky and Hemenway (1984) contended that children first form categories based on partonomies rather than taxonomies (see also Mash, 2006; Rakison & Butterworth, 1998; Rakison & Cohen, 1999). This means that infant categorization refers to a focus on specific parts rather than the entire object (Booth & Waxman, 2002; Madole & Cohen, 1995; Mash, 2006). Parts are known to be highly relevant for object discrimination and categorization in adults as well as in children

(Biederman, 1993; Hummel & Biederman, 1992; Madole & Cohen, 1995; Saiki & Hummel, 1996; Tversky & Hemenway, 1984; Younger, 1990). Younger and Cohen (1983, 1986) found that 10-month-olds recovered attention on the basis of correlations among stimulus features, whereas 4- and 7-month-olds recovered attention on the basis of individual stimulus features. Children graduated over age from processing features (parts of animal pictures) independently at 4 months to processing correlations among features (the animal as a whole) at 10 months. Well into their 2nd year of life, infants seem still to reference prominent perceptual features of objects. Infants between 1 and 2 years categorize unmodified cars from unmodified cows (Rakison, 2000). However, 14-month-olds fail to categorize cows from cars when object parts (legs and wheels) are removed, and 14- and 18-month-olds fail to categorize cows from cars when the same object parts are possessed by all exemplars.

The stimuli in the present task held configural relations constant between categories (i.e., part attachment positions and angles), whereas the shape and color of local parts differed. Thus, for infants to categorize our stimuli, they had to compare the objects on the basis of part features (shape, color, or both). Because the familiarization and test objects in this study had similar perceptual features, infants' choice of object following familiarization likely reflects a perceptual match of the test object to the familiarization exemplars (Rakison, 2005; Rakison & Hahn, 2004; Rakison & Poulin-Dubois, 2001). It is also possible of course that local part differences give rise to overall shape differences if separate parts enter equally into visual analysis and memory. Thus, the perceptual basis of object categorization—features or configurations—appears still an open question.

Future Directions and Conclusions

Infants in a home experience condition saw a variety of objects for approximately 100 min in total (or 20 min per object image), which was apparently sufficient to influence their later laboratory familiarization behavior. Future research might be directed at quantifying exposure times more precisely and determining relations between amount and kind of exposure (e.g., massed vs. distributed practice) and the development and robustness of infants' resulting categorical representations. Questions about whether it is the amount, kind, or schedule of experience can be addressed in training studies similar to this one in which infants are assigned parametrically programmed protocols to determine the critical experiences for formation and use of object category knowledge. Extensive experience with items from a particular category likely help infants form relatively strong and stable category representations. Further comparisons could be made between visual only, manual only, and visual–manual experiences to determine whether intersensory information confers category construction advantages over single sensory experience alone (Iachini, Borghi, & Senese, 2008). Additional research might be directed to uncover how infants come to regard novel objects as familiar, what information they store about objects, and how object categories arise even earlier in life. Is experience with particular objects or with categories of objects critical? Metacognitively, an effect of experience need not be specific to a particular categorical contrast or set of stimuli; experience outside the laboratory with one set of categories might influence infants' responding to a new category in the laboratory.

The categories we used here were ad hoc and unfamiliar, and babies' reactions to them reveal a basic category abstraction mechanism in infancy that does not seem to require a deep understanding of any specific object domain. We note, too, that just because the stimuli are simple and abstract, it does not automatically follow that these results are generalizable. Nonetheless, an impressive category extraction mechanism seems to be at work in the first half-year of life that gives infants the wherewithal and flexibility to learn new categories on the fly as well as retain and apply those categories they have previously experienced. These findings articulate with, and bring to a functional behavioral level, evidence showing that distinct neural signals correspond with category learning and representation in infants as young as 6 months.

Mexican-Heritage Children's Attention and Learning From Interactions Directed to Others

Katie G. Silva, Maricela Correa-Chávez, and Barbara Rogoff
University of California, Santa Cruz

The study builds on ethnographic research noting an emphasis in many Indigenous communities of the Americas on learning through keen observation of and participation in ongoing community activities. Forty-four U.S. Mexican-heritage 5- to 11-year-old children whose families likely have experience with Indigenous ways more frequently attended to and learned from a toy construction activity that was directed to another child, compared to 36 U.S. Mexican-heritage children whose mothers had extensive experience with Western school (and related European American practices). The results support the idea that children whose family history emanates from Indigenous communities of México may be especially oriented to learning by observing ongoing events, and that this method of learning may be less commonly used by children whose families have extensive experience with schooling (and related Western practices).

This study investigates cultural variation in children's attentiveness to a nearby toy construction demonstration that was not directed to them. We examined this "third-party attention" and resultant learning of U.S. Mexican-heritage children whose families likely varied in experience with Indigenous practices and with Western schooling (and related practices).

Third-party attention can provide children with important information regarding, for example, their community's cultural values and how to interpret ambiguous situations (Lewis & Feiring, 1981; Mitchell-Kernan & Kernan, 1975; Repacholi & Meltzoff, 2007). They can learn new words and the appropriate use of language through listening in on conversations not directed to them (Akhtar, 2005; Barton & Tomasello, 1991; Ochs, 1988; Oshima-Takane, Goodz, & Deverensky, 1996; Schieffelin, 1991; Ward, 1971).

Although keen observation of events directed to others may be helpful to everyone, it may be more common among people with experience of Indigenous practices of the Americas than among people whose experience heavily involves Western schooling and related practices. Ethnographic research in Indigenous communities of the Americas shows that children are integrated in a wide range of their community's activities and encouraged to keenly observe the events around them (Cancian, 1964; Corona & Pérez, 2005; de Haan, 1999; de Leon, 2000; Gaskins, 2000; Greenfield, 2004; Modiano, 1973; Morelli, Rogoff, & Angelillo, 2003; Whiting & Edwards, 1988). For example, Chamoux (1992) reported that Indigenous children in Central Mexico gain a great deal of knowledge through keen observation of ongoing events and understanding of Indigenous explanatory theory by listening in on conversations among adults.

The cultural learning tradition in which children observe and pitch in to ongoing events of importance in their community has been labeled "learning through *intent community participation*" (Rogoff, Paradise, Mejía Arauz, Correa-Chávez, & Angelillo, 2003; Rogoff et al., 2007). As "legitimate peripheral participants" in community events (Lave & Wenger, 1991), children can observe and contribute when they are ready. Indeed, they may not only be given the opportunity to learn by observing ongoing events but they may be expected to spontaneously

---

We greatly appreciate the participation of the children, and the permission of their parents and teachers from Gault School and Starlight School. For able assistance, we thank Mayra Moreno, Anna Corwin, Irma Núñez, Isaí Baltézar, and Carly Bliman. We appreciate the helpful comments of Nameera Akhtar, Maureen Callanan, Amy Dexter Roberts, and Megan Luce on this manuscript. We are grateful for support to KGS from the Center for Informal Learning and Schools (NSF Grant ESI-0119787) and from NIH Graduate Trainee Fellowship T32 HD046423, and for support to M.C.C. from an AERA/IES post-doctoral fellowship. We are also grateful for support from the UCSC Foundation Professorship in Psychology to B.R. Maricela Correa-Chávez's work on this study occurred at University of California, Santa Cruz and at University of California, Los Angeles; she is now at Clark University.

Correspondence concerning this article should be addressed to Katie Silva, 277 Social Sciences 2, University of California, Santa Cruz, CA 95064. Electronic mail may be sent to ksilva@ucsc.edu.

do so throughout their day (Chavajay, 1993; Philips, 1972).

Learning through intent community participation may be present everywhere but less common in communities in which children are seldom included in a wide range of community activities. In middle-class communities where schooling is prevalent, children are commonly segregated from the range of activities of their communities. Much of their days are spent in school and they are otherwise restricted from the work and mature social activities of their communities (LeVine & White, 1992; Morelli et al., 2003; Rogoff, 2003; Zelizer, 1992). As such, they have limited opportunities to learn by watching or listening to events that are not directed to them. Instead, adult-child interactions often involve child-centered lessons directed to children, utilizing formats common in Western schooling (Harkness, 1977; Heath, 1983; Martini, 1996; Ochs & Schieffelin, 1984; Rogoff, Mistry, Göncü, & Mosier, 1993). Frequently, middle-class parents attempt to manage their children's attention, unlike the expectation in some Indigenous-heritage communities where children are expected to attend keenly on their own (Chavajay, 1993; Dixon, LeVine, Richman, & Brazelton, 1984; Rogoff et al., 1993).

Systematic Cultural Comparisons of Observation and Attention

Although ethnographic studies often have implied a contrast with Western middle-class ways of teaching and learning, systematic cultural comparisons of patterns of attention and observation are rare. One comparative study examined attention when children were directly instructed and found that U.S. Mexican-heritage children from Indigenous regions of México (whose mothers had only basic schooling) more frequently observed an origami demonstration and their peers' efforts to fold the figures, without pressing for more information, compared with both European heritage and Mexican-heritage U.S. children whose mothers had extensive school experience (Mejía Arauz, Rogoff, & Paradise, 2005). The authors related this difference to community emphasis on learning through observation versus experience with the lesson formats of schooling and other Western practices.

Several studies have found cultural differences in simultaneity of attention to multiple surrounding events. Children whose families came to the United States from Indigenous regions of México often skillfully attended to several events simultaneously, without interrupting their attention to one event as they attended to another. They did so more often than European American middle-class children and U.S. Mexican-heritage children whose mothers had extensive school experience, who more often attended to one event at a time, interrupting each in rapid alternation (Correa-Chávez, Rogoff, & Mejía Arauz, 2005). Similarly, Guatemalan Maya toddlers and their mothers more often simultaneously attended to several events at once compared to middle-class European heritage toddlers and mothers, who tended to alternate their attention between events (Chavajay & Rogoff, 1999; Rogoff et al., 1993). These authors speculated that attending simultaneously to several events would facilitate learning by observing, in that it would allow monitoring of possibly important surrounding events without interrupting the activity at hand.

To our knowledge only two studies have systematically examined cultural variation in children's attention to surrounding events that were *not* directed to them. Spontaneously attending to surrounding events can be key to learning in communities where children have opportunities to be present during the range of community interactions. The two studies, with children living in two Indigenous communities (Navajo and Guatemalan Maya), found differences in children's attention to third-party interactions that may relate to experience with Indigenous ways as well as to experience with Western schooling.

In one study, children were on the periphery as one child taught a game to another. Middle-class European American children were more often off task and distracted than Navajo children, who more often maintained attention to the game and the instruction (Ellis & Gauvain, 1992).

In the other study, children were present when an adult showed their sibling how to make a toy. Guatemalan Maya children from families with many traditional Maya practices (and little or no Western schooling) attended more keenly to the interaction that was directed to their sibling than did middle-class European American children and Guatemalan Maya children whose mothers had extensive experience with Western schooling (Correa-Chávez & Rogoff, 2009). The Maya children from more traditional families also demonstrated greater learning—they needed less assistance when they unexpectedly had the chance to make the toy they had had the opportunity to observe being made a week earlier.

Both studies are consistent with ethnographic work showing that learning through keen observation to events that involve others is important in Indigenous communities of the Americas. Both of the prior studies examined Indigenous children's attention in communities that are structured as and identify as Indigenous (Navajo in the United States and Mayan in Guatemala).

The present study examined the attention of children whose families were *not* living in Indigenous communities but whose families are likely to have experience with practices emanating from Indigenous communities of prior generations in México, although they currently live in a predominantly European American setting, with a distinct structure of learning opportunities. We examined whether similar patterns of attention would be seen among children in families that had emigrated to the United States from rural regions of México that formerly had extensive Indigenous populations and who were likely to have experience with some Indigenous practices, compared with children from families from the same region of México but with extensive experience in Western schooling and related practices.

Thus, although much cultural research treats national origins as homogeneous, our study focuses on cultural practices that vary within two groups with the same national origin (Mexican) and the same residence (California). Our focus is on experience with cultural ways, rather than on ethnic identity per se.

The present study also differs from the prior two studies in extending to the practices of distinct Indigenous groups—those of West Central México rather than of the United States and Guatemala. (The Indigenous population of the region of México from which most of our sample emigrated has been largely P'urepecha in addition to a few smaller groups—all of which are culturally and linguistically very distinct from both Navajo and Mayan.)

The practices of Indigenous communities and of Western schooling appear to be widespread features of constellations of cultural practices that are important for many U.S. immigrant children, as well as U.S. and Canadian Native children and children in many communities of Mexico and Central America. However, the generality across these national and cultural groups needs to be investigated, not assumed. (We limit our speculations regarding generality of the patterns to North and Central America in the interest of caution, given that we have less knowledge of the extent to which the pattern appears on other continents.)

Identifying Experience With Indigenous Practices of the Americas and Western Schooling

A large portion of the Mexican immigrant population in central California has come from rural areas in México that have been considered Indigenous in the recent past, such as in Michoacán. People of some rural *pueblos* in this region of México consider themselves to be Indigenous. Many others consider themselves *mestizos* (mixed race), but in earlier generations many of their ancestors lived as Indigenous people in *pueblos* that were often organized according to recognizably Indigenous practices (Bonfil Batalla, 1996; Frye, 1996; Vigil, 1998). These pueblos have had little access to Western schooling. Therefore, we presume that experience with Indigenous practices is likely among families that have immigrated to the United States from such regions of México if they have limited schooling.

Our presumption of historical connection with Indigenous practices is supported by a study in a West Central Mexican town that was considered Indigenous a generation ago. Residents of this town have little involvement in Western schooling and participate in some Indigenous practices that can be traced back centuries; highly schooled residents of nearby Guadalajara who have lived in the city for only a generation engage in Indigenous practices in an attenuated form, whereas families with generations of extensive schooling and residence in Guadalajara do not engage in these Indigenous heritage practices (Najafi, Mejía Arauz, & Rogoff, 2007).

Similarly, in a Nahua town in Central México, people usually do not identify themselves as Indigenous (except to claim or request something from the government). They may simply refer to themselves as "Mexicans," although they refer to people in nearby towns as Indigenous. However, they continue to pass down key traditional Mesoamerican Indigenous practices and beliefs across generations, including stories, moral values, and cosmological concepts (Lorente y Fernández, 2006; personal communication, June 2007).

Luis Urrieta (2003) reflected on the Indigenous identity of people from the West Central Mexican region from which many California immigrant families come. His father's *pueblo* in Michoacán had once been "a culturally *P'urhépecha* village. . . . But due to the proximity of the *hacienda* there were many cultural shifts that diluted the strength of Indigenous identity" (p. 155). In his youth, Urrieta found references to being Indian confusing:

> I heard older relatives in Los Angeles and Michoacán saying, "When we were Indians," while at other times, "When we were more Indian." This was also made more confusing when referring to people of nearby *pueblos* in the Pátzcuaro region as being *mas indios*, or "more Indian," as if being "Indian" was something that could be diluted, lessened, or changed. (p. 149)

Indigenous identity underwent some changes around the time of the Mexican Revolution in the early 1900s, when many Indigenous *pueblos* transformed from Indian to *campesino*, in a process promoted in part by schooling (Urrieta, 2003). Only recently has extensive schooling become widespread, extending from the United States and Europe to Indigenous communities in Mesoamerica (Meyer, Ramirez, & Soysal, 1992). One of the goals of mass schooling in México was to "modernize" the mostly Indigenous countryside, and to suppress Indigenous ways (Bonfil Batalla, 1988; Stavenhagen, 1988).

With experience in particular cultural institutions, such as school, people may adopt approaches resembling practices associated with those institutions in other parts of daily life (Gutiérrez & Rogoff, 2003). Mothers' experience with schooling in such communities often relates to their use of teaching approaches that coincide with teaching models often used in Western schooling (Chavajay, 2006; Chavajay & Rogoff, 2002; Dunn, Griggs, & Price, 1993; Laosa, 1980, 1982; Moreno, 2000; Rogoff et al., 1993). Mexican-heritage U.S. children whose mothers had completed at least 12 grades observed an Origami demonstration in ways that resembled those of U.S. European-heritage children whose mothers had also completed at least 12 grades. Both backgrounds relied less on observation as a source of information and less often attended simultaneously to ongoing events compared with Mexican-heritage U.S. children whose mothers averaged six grades of school (Correa-Chávez et al., 2005; Mejía Arauz et al., 2005).

Although we argue that experiences with school practices provide familiarity with particular ways of teaching and learning (along with LeVine, LeVine, & Schnell, 2001), we do not regard schooling as a solitary "active ingredient" in community differences. Rather we regard the extent of experience with Western schooling in Indigenous-heritage communities of México and Guatemala as part of a constellation of associated characteristics—such as migration, urban experience, occupations requiring school credentials, few children in a family, and limited involvement of extended family—that may also relate to teaching and learning approaches (Chavajay & Rogoff, 2002; Rogoff & Angelillo, 2002; Rogoff, Correa-Chávez, & Navichoc Cotuc, 2005; Rogoff et al., 2007). Thus, family experience with Western schooling may contribute, along with many associated practices, to community practices surrounding learning.

The Present Study

Our primary question was whether U.S. Mexican-heritage children whose families likely had greater familiarity with Indigenous practices (and little experience of Western schooling) would use more sustained attention while their sibling is shown how to construct a toy, compared with U.S. Mexican-heritage children whose mothers had extensive experience with school. In addition, we examined the children's learning, by coding the ease with which the children of the two backgrounds constructed the toy their sibling had been shown how to make, when they were given an unexpected opportunity to make it a week later. We also examined whether the children's extent of sustained attention to the third-party interaction in the first session was related to their subsequent ease of constructing the toy that they had had the opportunity to observe.

The current study also examined differences in children's attempts to direct attention toward themselves when they were not included in the interaction. Children who are accustomed to being directly addressed may disrupt interactions that are addressed to others by calling attention to themselves. European American middle-class children more often interrupted and sought attention when adults were occupied than did Efe or Maya children (Correa-Chávez & Rogoff, 2009; Rogoff et al., 1993; Verhoef, Morelli, & Anderson, 1999). In ethnographic reports, children in several Indigenous Mexican communities rarely tried to garner attention to themselves (de Haan, 1999; Gaskins, 2000; Paradise, 1996). Both Guatemalan Mayan children from traditional families and those whose families had extensive experience with Western schooling seldom tried to divert attention to themselves when they were not addressed (Correa-Chávez & Rogoff, 2009).

Method

Participants and Their Communities

Eighty children between the ages of 5 and 11 years old participated in the study (see Table 1

Table 1
Maternal Schooling, Gender, and Age of Focal Child

	Pueblo Basic Schooling (*n* = 22 pairs)	Mexican Hi Schooling (*n* = 18 pairs)
Average maternal schooling	6.4 grades (range = 0–9)	12.6 grades (range = 12–16)
First nonaddressed child (observing mouse construction)		
Gender	7 girls, 15 boys	11 girls, 7 boys
Average age of focal child	6.8 years (range = 5–10 years)	6.4 years (range = 5–9 years)
Second nonaddressed child (observing frog construction)		
Gender	9 girls, 13 boys	11 girls, 7 boys
Average age of focal child	9.0 years (range = 6–11 years)	9.1 years (range = 7–10 years)

for ages, gender, and grades in school for children). Children were Mexican-heritage sibling pairs recruited through two public elementary schools in neighboring California towns where immigrant populations from México have often come from rural areas of the state of Michoacán, attracted by the agricultural industry. Siblings were used to ensure that the children working together had similar family schooling histories, to provide a familiar partner, and to provide a reasonable excuse for making the children ''wait'' for another child.

In the first of the two sessions, participants were 44 children from ''Pueblo Basic Schooling'' families that likely had familiarity with Indigenous practices from the pueblos of México and had little experience with Western schooling (average maternal grade = 6, range = 0–9 grades) and 36 children from ''Mexican Hi Schooling'' families (average maternal grade = 13, range = 12–16 grades). In the second session, 37 of the children whose families were from the Pueblo Basic Schooling background and 35 of the children from Mexican Hi Schooling families participated. (Some children who participated in the first session were not able to participate in the second session 1 week later due to absence from school.)

Maternal experience with school was divided at high school completion because completion of high school is an important milestone in both México and the United States that can often lead to different occupations and income, and often accompanies differences in family life such as fewer children and more school-like interactions of parents with children. Maternal schooling experience was thus a proxy for a constellation of cultural practices that seem to be indicative of Indigenous experience for families who come from rural areas of México to California for agricultural work. The labels ''Pueblo Basic Schooling'' and ''Mexican High Schooling'' represent not only differences in extent of the children's mothers' experience in Western schooling but also many other related features such as their fathers' and grandparents' schooling, parental occupations, and family size.

Of the 44 children from Pueblo Basic Schooling families, most (32) were born in the United States, 6 were born in México, and parents declined to give birthplace information of 6 of the children. Almost all (21) of the 22 Pueblo Basic Schooling mothers were born in México and 1 was born in California; almost all (20) had attended school in México, 1 had attended school in both México and the United States, and 1 had not attended school. Of the fathers, almost all (20) were born in México and 2 of their birthplaces were not reported; they averaged 7 grades of schooling. In both backgrounds, mothers' and fathers' schooling was highly correlated, $r = .66$, $p < .01$. Grandparents' schooling was limited to primary grades: Most (65%) had completed 0–3 grades, and some (23%) had completed 4–6 grades; information was not available on the remainder. The Pueblo Basic Schooling families averaged 3.3 children.

Of the 36 children from Mexican Hi Schooling families, almost all (33) were born in the United States, 1 was born in México, and parents declined to give information about the birthplace of 2 children. Half (9) of the 18 Mexican Hi Schooling mothers were born in the United States and half (9) were born in México; almost all (16) had attended school in the United States, 1 had attended school in México, and 1 had attended school in both countries. Of the fathers, about half (7) were born in the United States, 8 were born in México, and 3 of their birthplaces were not reported; they averaged 13 grades of schooling. Grandparents' schooling ranged broadly: 0–3 grades completed (33%), 4–6 grades (11%), 7–9 grades (6%), 10–11 grades (11%), and 12 or more grades (18%). The Mexican Hi Schooling families averaged 2.4 children.

Procedure

One of two bilingual female research assistants ("Toy Ladies") who were blind to the hypotheses and goals of the study worked with the siblings in a vacant section of an elementary school classroom. Both Toy Ladies worked with children from both groups and were not informed of the background of the children with whom they were working. Comparison of sessions from the two Toy Ladies ensured that differences between Mexican Hi Schooling and Pueblo Basic Schooling groups were not due to the different Toy Ladies who worked in different schools.

The procedure was based on Correa-Chávez and Rogoff's (2009) study with Mayan and European American children, for comparability across the different cultural communities. In Session 1, each sibling had a chance to make a toy; our interest was in each child's attention when they were not addressed. The first nonaddressed child was always the younger child (waiting while the sibling made a toy mouse that runs via a spool and rubber band) and the second nonaddressed child was always the elder (waiting while the sibling folded an Origami paper frog that jumps). Thus, the children's age, order of making a toy, and which toy they had a chance to observe being constructed were purposely not counterbalanced. Hence we do not compare age, order, or toy differences. We note, however, that the pattern of the younger child who observed the mouse construction first was similar to that of the older child who observed the frog construction second. In Session 2, the children came back individually 1 week later to pick up the toys they had made, and were unexpectedly invited to construct the toy that their sibling made the week before.

Session 1: Observing sibling's toy construction. The Toy Lady led the sibling pairs into a child-friendly classroom with two tables. The main table had a chair for the Toy Lady and one for the child constructing the toy. A side table, 16 in. away, had a chair for the nonaddressed sibling to sit in while "waiting." The nonaddressed child's chair was parallel to and slightly forward of the sibling's chair, to give a cue that the nonaddressed child was not expected to participate in the activity of their sibling. The position required the nonaddressed child to turn to watch, which also meant that coders could clearly see when the child was attending to the construction activity (see Figure 1). All interactions were videotaped.

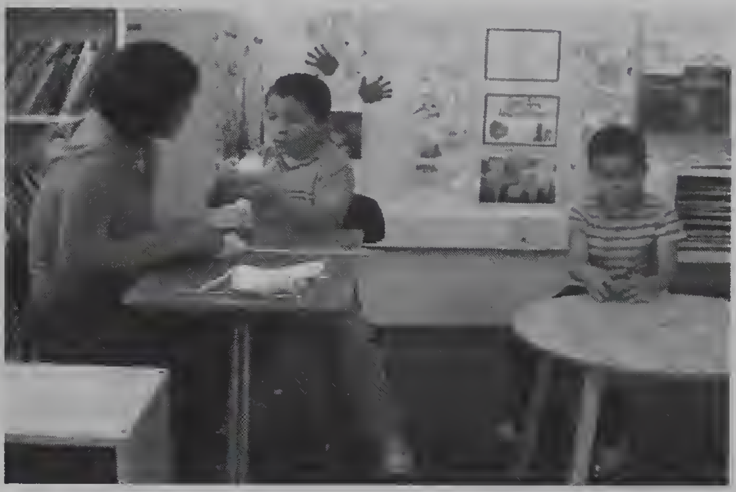

Figure 1. Setup for Session 1.
Note. The Toy Lady and a child make the mouse at the rectangular table while the nonaddressed sibling sits at the round table with the distracter.

The session was designed for the nonaddressed child to know that they would make a different toy than their sibling and thus would be unlikely to think that attending to their sibling's mouse construction would help for making their own toy. The Toy Lady greeted the children and introduced herself and told them that she was going to help them make a toy. She led the younger child to wait in the seat at the side table saying, "I'm going to start with your big brother/sister, and he/she is going to make a mouse, and when he/she's done you can make a frog" (referring to the models of each toy in view on the main table). The Toy Lady handed the nonaddressed sibling the distracter toy saying, "While he/she does that, how about you sit here and you can play with this." The distracter toy was a "do-nothing" machine—a wooden block with a crank to turn. This toy was chosen because it does not require much focused attention to manipulate it and it is attractive but is not interesting for long.

After settling the nonaddressed child, the Toy Lady then sat with the older sibling at the main table and put two sets of the materials used to make the mouse toy on the table (one set for the child and one for herself). She addressed only the child making the mouse: "I'm going to be making one and you are going to be making one. You can watch me and do what I do."

After the mouse was completed, the Toy Lady asked the siblings to switch seats. The child who constructed the mouse now sat at the nearby table and was given the distracter toy and told, "You can play with this while you wait if you want." The previously nonaddressed child sat at the table with the Toy Lady and constructed an origami jumping frog. The Toy Lady said, "Okay (addressed child), now it's your turn." The Toy Lady followed a script similar to the one used while constructing the mouse.

At the end of the session, the Toy Lady had the children put their names on a bag for her to keep their toys in for a week (to prevent other children in the school from studying them and to justify Session 2). She told the children "We are going to keep your toys for a few days until all of the kids have a chance to make one. You can come back next week to pick them up." Session 1 lasted about 8 min in total for both children to construct their toy.

The Toy Lady followed a script in all interactions to ensure that she taught and interacted with all children in a similar way. The script limited the Toy Lady's extent of explanation of steps in the toy construction (avoiding explicit verbal instructions and instead saying, e.g., "put this through here") to ensure that the nonaddressed child would need to watch the toy construction in order to learn from it.

The script also provided the Toy Lady with guidelines on how to react if the nonaddressed sibling sought involvement and/or attempted to enter into the construction of the toy: She gently discouraged the nonaddressed sibling's participation by reminding the child that she/he would soon have the chance to make the origami frog. The script also included instructions for how to interact if the nonaddressed child tried to disrupt the construction activity. For example, if the nonaddressed child began to talk about something extraneous such as an upcoming vacation, the Toy Lady would either ignore the child or say, "oh that's nice" and turn back to the child she was working with and begin the next step, making it clear that she was only addressing the child at the table.

The Toy Lady was not told about the second session until she had completed Session 1 with all of the children, to further limit the possibility of her encouraging attention from the nonaddressed child. The Toy Lady was not told about our interest in the nonaddressed child's attention (or about our interest in the children's backgrounds). She was informed that we were interested in how children learn to make toys and what the nonaddressed children do naturally when waiting for their turn to make a toy.

A procedural check was conducted on 25% of the Session 1 data in order to ensure that the Toy Lady was consistent in her treatment of the nonaddressed child and her adherence to the script. Most important, the Toy Ladies did not address the nonaddressed child or encourage that child to attend to the toy construction in any sessions; they interacted almost exclusively with the child constructing the toy.

Session 2: Nonaddressed siblings' learning. Each child returned to the classroom individually, approximately 7 days later, to pick up the toy that they made a week before. The Toy Lady unexpectedly gave them the opportunity to make the toy that their sibling had made the previous week, saying, "I have some extra material and I thought that you might like to make a [frog/mouse] this time."

The Toy Lady put all of the materials that the child needed on the table and said, "Here are all the materials that you will need to make a [frog/mouse]. I have a project to do right now so you can get started and let me know if you need help." The Toy Lady then picked up a notebook and started writing, seemingly absorbed in her project, so that the child would not expect her to give instructions and so that the Toy Lady would have reason not to respond immediately if the child requested help (see Figure 2). The Toy Lady sat at the same table as the child but with her chair slightly pushed away from the table, working on her project and sitting back in her chair, to create distance from the child and the toy construction.

To measure learning, we examined the extent of help needed by the child to construct the toy, based on a set of graduated, scripted hints. (A similar series of hints was specified for each step in the mouse and the frog.) As she worked on her project, the Toy Lady inconspicuously monitored the progress of the child and at the beginning of each step of the toy construction, the Toy Lady waited approximately 5 s for the child to attempt to get started on

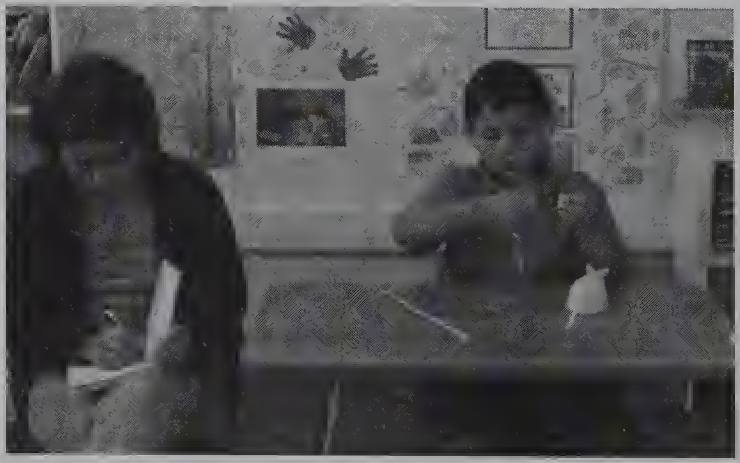

Figure 2. Setup for Session 2.
Note. The Toy Lady acts busy at work on her project while the child attempts to construct the mouse toy.

the step. After the 5 s, if the child did not spontaneously complete the step, or if they asked for help (either verbally or nonverbally) or began to do the step incorrectly, the Toy Lady started off giving them a small hint specifying what step to do (e.g., "The body is first") or what material to begin with (e.g., "Try starting with the string"), then went back to her work and waited another 5 s. If the child continued to have trouble, the Toy Lady gave the child a bigger hint about what to do with the materials (e.g., "Fold this," pointing to the portion of the paper the child needed to fold). If the child needed more help, the Toy Lady demonstrated a bit of the step to the child, and finally if the child could not do the step, the Toy Lady completed the step for them and then went back to her work and told the child to go ahead. A procedural check conducted on 25% of the Session 2 data showed that the Toy Ladies did not differ in adherence to the script, time lapse before giving children hints, or order of hints given.

On completion of the toy, the child was given both toys. (All participants in the same school completed Session 1 before Session 2 began, so that children would not anticipate making their sibling's toy at the time they participated in Session 1.) Each child's second session took an average of 7 min.

Coding of Session 1: Children's Attention to the Construction Activity Plus Disruption and Attempts to Become Involved

Our primary interest was the attention of the nonaddressed child to the construction activity, which was coded in 5-s segments by a coder who was blind to the goals of the study and to the children's maternal schooling. The child's predominant form of attention during each 5-s segment was coded as either sustained attending to the construction, briefly glancing at the construction, or not attending to the construction activity, based on the children's gaze, posture, gestures, and other visual and verbal cues.

Sustained attending to the construction consisted of energetically watching the construction activity, with attention devoted to it for most of the segment. During sustained attending, children sat still and actively attended to the toy construction activity, with their eyes fixed on the construction activity and with an alert body posture. Children could break their attention to the construction momentarily or simultaneously work the distracter toy, but their attention to another activity was minor within the segment.

Glancing involved sporadic interest in the construction activity for a brief portion of a segment, without seemingly being engaged by the construction activity; most of the segment involved attending to something other than the construction activity. In the few instances when both sustained attending and glancing occurred in the same 5-s segment, the segment was counted as sustained attending. (There was no difference between the two backgrounds in the percentage of segments in which children equally used both sustained attending and glancing in the same 5-s segment.)

If children stretched or strained or moved their chair closer to get a better view of the toy construction activity while engaged in sustained attention or glancing, straining to observe was also coded within those 5-s segments.

If the child was not attending to the construction activity, we recorded what else they were attending to. Often, this involved working the distracter toy, but it also sometimes involved looking at objects in the room such as posters and books, or daydreaming.

We also examined the time segments in which the nonaddressed child tried to disrupt the construction activity, trying to divert the attention of the Toy Lady or their sibling to themselves (e.g., by playing loudly in an insistent repetitive way, talking to the sibling or Toy Lady about a topic extraneous to the toy construction, or grabbing materials to get attention). Disruptions were not mutually exclusive with the attentional categories; however, they did not often occur in the same 5-s segment with sustained attention or glancing.

In addition, we coded whether the nonaddressed child showed attempts to collaborate in the construction activity of the Toy Lady and the sibling, verbally and/or nonverbally. Attempts to collaborate included picking up the materials to try to become involved in the construction (not to disrupt it), attempting to help build the toy, nodding to verify the information the Toy Lady was giving about how to make the toy as if they were part of the interaction, asking "Can I do it?" or commenting on the ongoing activity (e.g., "Wow, that looks really cool").

Coding Session 2: Children's Learning: Unexpected Toy Construction

Session 2 was coded by a blind coder for the amount of assistance that the child needed from the Toy Lady in each step of the construction. A different blind coder was used than in Session 1 so that the coder would not know the children's extent of observing in Session 1. The coder tallied the level of hints the child needed to complete each step: completing the step with no assistance (0 points); a small hint about the step or the materials to use for the step (1 point); a bigger hint about what to do with the materials (2 points); showing the child a bit of the step (3 points); or doing the entire step for the child (4 points). The maximum score for the four steps of the mouse was thus 16 and for the five steps of the frog the maximum was 20; no help needed was scored 0.

Reliability. A bilingual coder, blind to the hypotheses of the study, coded the Session 1 videotapes. A second coder coded 40% of the data. Intercoder reliability was calculated by means of Pearson's correlations between the two coders: percent of segments with sustained attention $r = .95$, glances $r = .84$, straining to observe $r = .91$, not attending $r = .99$, disruptions $r = .97$, and attempts to collaborate $r = 99$.

For the Session 2 data, a different bilingual research assistant coded 40% of the data. Intercoder reliability was examined by means of Pearson's correlations between the blind coder and the first author for amount of help needed by the children, $r = .99$. Disagreements in both sessions were resolved by the coders reviewing the segment together and coming to consensus.

Results

We first examine cultural differences in Session 1 in children's attention to an interaction that is directed at others, attempts to disrupt, and attempts to collaborate in others' activities. We then compare the children's learning in Session 2 (i.e., the amount of help they needed to construct the toy that they had the opportunity to observe being constructed a week before). Finally, we examine the relation between attention in Session 1 and learning in Session 2. We employed planned comparisons (a conservative test) for the key analyses for which we had clear predictions.

Attention, Disruption, and Attempts to Collaborate by the Nonaddressed Child (Session 1)

Because the length of sessions varied among individual children, the proportion of time segments was used to analyze the data. However, there was no systematic difference in the length of sessions of the two cultural backgrounds.

Table 2

Mean Percent (and Standard Deviation) of Segments in Which Nonaddressed Children Attended to the Construction

Form of attention	Pueblo Basic Schooling	Mexican Hi Schooling
First nonaddressed child (observing mouse construction)		
Sustained attention	40.2 (19.9)*	28.0 (20.4)*
Not attending	43.8 (19.1)*	53.8 (21.2)*
Brief glancing	16.0 (9.1)	18.1 (11.6)
Second nonaddressed child (observing frog construction)		
Sustained attention	40.5 (32.5)*	19.2 (20.0)*
Not attending	44.6 (24.5)**	62.7 (19.2)**
Brief glancing	14.9 (12.7)	18.0 (11.6)
All siblings combined		
Sustained attention	40.4 (27.0)**	23.6 (20.0)**
Not attending	44.2 (21.7)**	58.3 (20.4)**
Brief glancing	15.4 (10.9)	18.1 (11.0)

*$p < .05$. **$p < .005$.

Third-party attention. Children observing first and those observing second showed the same patterns of attention in both backgrounds, so we focus on the combined data. (Note that any difference between siblings was not interpretable in terms of age, birth order, nature of the toys constructed, or order effects, as these were purposely not counterbalanced.) There were not systematic gender differences in the children's attentional patterns. Table 2 shows the means and standard deviations for Session 1 analyses, separately for each child and then combined.

As expected, U.S. Mexican-heritage children from Pueblo Basic Schooling families used more sustained attention than the U.S. Mexican-heritage children from Mexican Hi Schooling families, in an average of 40% versus 24% of the time segments, $t(78) = 3.18$, $p < .001$ (see Table 2). Straining to observe their sibling's toy construction activity was not common but, as expected, children from Pueblo Basic Schooling families strained to observe more often than did Mexican Hi Schooling children, in an average of 3.9% versus 1.6% (*SDs* = 5.7 and 3.0) of the segments, respectively, $t(78) = 2.39$, $p < .01$.

Also as expected, children from Mexican Hi Schooling families spent more time not attending to the construction compared to children from Pueblo Basic Schooling families, in 58% versus 44% of the time segments, $t(78) = 2.96$, $p < .002$. We had no prediction for differences between the backgrounds in briefly glancing at the construction activity, and analysis showed none, $t(78) = 1.08$, $p = .28$.

When the children were not attending to the construction, they were mostly attending to the distracter toy (in 78% of the nonattention segments). They attended to a made-up activity or game in 16% of the nonattention segments, attended to extraneous activities of the Toy Lady or their sibling in 5% of nonattention segments, and stared into space in 1% of the nonattention segments. There were not differences between the backgrounds in how often their nonattention involved one activity or another.

Nonaddressed sibling's attempts to disrupt or collaborate in the construction. As expected, disruptions were rare among the U.S. Mexican children from both backgrounds, and there was no significant difference between them. Children in the Pueblo Basic Schooling group attempted to disrupt in 2% of the segments, as did children in the Mexican Hi Schooling group (*SD*s = 0.05, 0.04). These rare instances of disruption were in segments in which children were not attending to the toy construction activity, and there were no gender differences. These findings are similar to Correa-Chávez and Rogoff's (2009) findings with two Guatemalan Mayan backgrounds varying in experience with traditional Mayan ways and with Western schooling; they found that disruption was more frequent among European American children.

We expected that if there were differences in attempts to collaborate in the construction activity, children from the Pueblo Basic Schooling background would do so more often. Indeed, the children from Pueblo Basic Schooling families attempted to collaborate in the construction activity more than the children from Mexican Hi Schooling families, in an average of 6.9% of the segments versus 0.7% of the segments (*SD*s = 15.0, 2.2), respectively, $t(78) = 2.70$, $p < .01$. There were not systematic gender differences. The children's attempts to collaborate occurred when they were attending to the activity, suggesting that these attempts were motivated by interest and not by boredom. The greater attempts to collaborate in the construction among nonaddressed children whose families likely had more experience with Indigenous practices than among children whose families had more experience with schooling may relate to observations that Indigenous communities emphasize learning through *intent community participation* (Rogoff et al., 2003; Rogoff et al., 2007), with children pitching in collaboratively with other children and adults in ongoing events.

Learning: Amount of Help Needed in the Unexpected Toy Construction (Session 2)

We present the comparisons separately for the children constructing the mouse and those constructing the frog, because across the two backgrounds, children who constructed the mouse in Session 2 needed less help than children who constructed the frog toy (even though these were the younger siblings), $t(70) = 4.73$, $p < .001$. Much of the information about how to construct the mouse was contained in the materials themselves. For example, even without having watched, a child might assume that the string needed to be wrapped around the spool, and do this without help. It would be more difficult to infer a correct fold for the origami frog. Indeed, Correa-Chávez and Rogoff (2009) found significant differences in amount of help needed only for constructing the frog, among Guatemalan Mayan and European American children.

The scores for amount of help needed were converted to percentages, because the maximum scores differed for the two toys (due to the differing numbers of steps needed to construct them). Planned contrasts were used to test for differences between the two backgrounds in the amount of help needed to construct each toy after having had the opportunity to observe their sibling construct it a week earlier.

The children in the Pueblo Basic Schooling group needed less help than the children in the Mexican Hi Schooling group to construct both the mouse toy and the frog toy: $t(32) = 2.20$, $p < .02$ for the mouse; $t(36) = 1.87$, $p < .04$ for the frog. There were no significant gender differences. Table 3 shows the means and standard deviations for Session 2 analyses.

Children who engaged in more sustained attention to the toy construction in Session 1 needed less help when unexpectedly given the chance to construct their sibling's toy in Session 2. (This was primarily the case for younger children from Pueblo Basic Schooling background constructing the mouse and older children from Mexican Hi Schooling background constructing the frog. It is not clear why the correlations for the other two situations were not significant; we did not expect differences in the extent of correlation across the four cells of Table 3.) Combining across the two cultural backgrounds, $r = -.34$, $p < .02$ for the mouse and $r = -.30$, $p < .04$ for the frog. There were no significant correlations between brief glances and the amount of help needed to construct either toy.

Table 3

Mean Percent (and Standard Deviations) of Help Children Needed to Construct the Toy, and Correlations With Session 1 Sustained Attention

	Pueblo Basic Schooling ($n = 22$ pairs)	Mexican Hi Schooling ($n = 18$ pairs)
First nonaddressed child (observing mouse construction)		
Help needed (% of the available hints)	26.8 (14.8)$_a$	38.6 (16.4)$_a$
Relation of sustained attention and help needed	$r = -.40$*	$r = -.13$
Second nonaddressed child (observing frog construction)		
Help needed (% of the available hints)	46.5 (18.3)$_b$	56.1 (12.6)$_b$
Relation of sustained attention and help needed	$r = -.06$	$r = -.66$**

Note. Subscript letters indicate significant differences across columns with the same letter at *$p < .05$, **$p < .005$.

The cultural differences in how much help the children needed in Session 2 were directly related to the differences in how much sustained attention they showed in Session 1. This was determined by an analysis of covariance (ANCOVA, with cultural background as a fixed factor and amount of sustained attention as a covariate) showing that sustained attention was a significant covariate in how much help the children received, $F(1, 72) = 4.69$, $p < .05$. After controlling for sustained attention, cultural background became a nonsignificant main effect, $F(1, 52) = 2.43$, $p = .12$. These results suggest that other possible cultural differences (such as possible differences in dexterity) did not contribute significantly to the children's learning.

Discussion

This study found cultural differences in children's attention and learning during interactions directed to others in two Mexican-heritage communities living in the United States. The findings extend research indicating that learning through keen attention to surrounding events is emphasized in Indigenous communities of the Americas. The two cultural backgrounds of this study both involved families that had emigrated from regions of México that formerly had extensive Indigenous populations and limited Western schooling. We inferred that the families that have limited parental schooling in the current generation are likely to have experience of Indigenous practices of México, although they do not now live in Indigenous communities. Mexican-heritage families with extensive experience in Western schooling are likely to have less involvement with Indigenous practices, and of course they have more experience with potentially conflicting Western school and related practices.

As predicted, U.S. Mexican-heritage children from families that likely had experience with Indigenous practices and had little experience with formal school attended more keenly to an interaction that was not addressed to them and more often strained to observe it than U.S. Mexican-heritage children whose mothers had extensive experience in Western schooling (and related practices). U.S. Mexican-heritage children whose mothers had extensive experience with school instead often played with the distracter toy, daydreamed, and looked at other items in the room.

The U.S. Mexican-heritage children from families with likely experience of Indigenous practices also learned more about how to construct the toy they had had the opportunity to observe being constructed than the U.S. Mexican-heritage children whose mothers had extensive school (and related) experience. Indeed, sustained attention seemed to have helped the children learn about constructing the toy—children who showed more sustained attention often needed less help when given an unexpected opportunity to construct the toy.

The findings suggest that Indigenous ways of learning may be maintained among families that do not live in Indigenous communities and have left regions where Indigenous practices may be sustained among communities that do not at present identify as Indigenous. Cultural practices may be resilient among populations whose cultural identity is no longer explicitly tied to prior communities from which the practices emanate. In particular, families may continue to structure children's learning in line with the practices of communities that they no longer live in. Our findings regarding attentiveness to surrounding events support the idea that some practices related to the cultural tradition of organizing learning through intent community participation may be sustained among Mexican-heritage families coming from regions where Indigenous communities have been common and Western schooling has been rare.

Generality Across Times and Places

Our study thus suggests some generality in the pattern of cultural differences in children's attention to surrounding events, across populations residing in different nations and with historical or with current ties with Indigenous communities. The families of the present study, who likely have some experience with Indigenous practices of México but who live as newcomers in a largely European American region, not in Indigenous communities, show a pattern similar to that found in two comparative studies performed in Indigenous communities (Correa-Chávez & Rogoff, 2009; Ellis & Gauvain, 1992). Taken together, the three studies support the idea that children from families that have experience with Indigenous practices of the Americas, whether or not they live in or identify with Indigenous communities, are more likely to be alert to and learn from surrounding events than children from families with little or no experience of such practices. In addition, our study extends the pattern to a different Indigenous heritage, involving P'urepecha and other groups of West Central México, which are culturally and linguistically quite distinct from both the Maya of Guatemala and the Navajo of the United States.

Although we feel confident assuming that maternal schooling experience can be a proxy indicator of Indigenous experience in our participant communities given their histories, in this study we did not have specific information on family experience with Indigenous ways. In future research with immigrants from México, it will be helpful to examine experience with Indigenous practices of the Americas directly, instead of relying on information about the historical and demographic location from which the families have immigrated to infer their extent of experience with Indigenous ways. This would require more in-depth contact with the children's families and communities than was possible in the present school-based study.

It would also be valuable to further examine the generality of keen attention to surrounding events to examine its prevalence among Indigenous people on other continents. Ethnographic studies report that learning through observation is valued in many other communities around the world without a long history of schooling (Harkness, 1977; Mitchell-Kernan & Kernan, 1975; Ochs & Schieffelin, 1984; Ward, 1971). Systematic comparative studies focused on third-party attention in other cultural settings around the world would allow examination of the generality of the patterns, and their relation to communities' histories and people's participation in their communities' traditions and institutions.

It would also be fruitful to examine the community organization and practices that encourage learning by being aware of ongoing activities. Learning by observing surrounding activities depends on being present when notable events occur. What else is involved in allowing or encouraging attention to one's surroundings? And to what extent do the approaches of the children and families vary across settings (e.g., home, community, and school) that differ in their organization and practices?

The Role of Schooling (and Related) Approaches

Our findings also support the idea that family experience with the forms of interaction and learning common in Western schooling may compete with ways of organizing learning valued in many Indigenous-heritage communities of the Americas. Schooling experience appears to be an important feature of a cluster of practices that may relate to how children approach learning (Rogoff & Angelillo, 2002). For example, greater maternal schooling has been associated with smaller family size and thus fewer opportunities to learn by observing others, as well as differences in occupation, language, and other cultural practices (LeVine, 1987; LeVine et al., 2001; Najafi et al., 2007; Rogoff et al., 2005).

Experience with Western school has been related to the ways that parents interact with their children in the home (Crago, Annahatak, & Ningiuruvik, 1993; Laosa, 1980, 1982; Richman, Miller, & LeVine, 1992; Rogoff, 2003). Like in school, where the teacher often "orchestrates" individual and group attention (O'Connor & Michaels, 1993, 1996), mothers with extensive experience with school are more likely to interact with children in school-like ways, such as managing children's attention and participation (Chavajay & Rogoff, 2002; Rogoff et al., 1993). Children from families with extensive schooling may rely more on having their attention directed by adults, and muster less attention when no one is telling them to attend, as in our activity.

In future research, it would be fruitful to examine whether in supportive circumstances, people may be able to fluently use multiple approaches to learning, or whether schooling experience necessarily or usually competes with ways of organizing learning in Indigenous-heritage communities of the Americas. Understanding the circumstances that promote expansion of people's repertoires (rather than replacement of one approach by another) would be important information for supporting teaching and learning for immigrant and other populations.

Conclusions and Implications

Our research supports the idea that children whose families have experience with practices of Indigenous-heritage communities of the Americas may be especially keen observers of events occurring around them. Such keen observation may be an important way to approach learning in communities where children are integrated in the range of activities of the community and pitch in when they are ready, in the tradition of learning through *intent community participation* (Rogoff et al., 2003; Rogoff et al., 2007).

The study underlines the importance of focusing on children's community practices as a way of understanding cultural variation, and not just relying on nationality or ethnicity as homogenous categories of culture. Had this study combined the children of the two backgrounds because they are both of Mexican descent, we would have missed important differences in approaches to learning. Rather than assuming that all Latinos or all Mexicans have the same characteristics, it is important for research to examine empirically the extent to which communities within such broad categories differ from as well as resemble each other. This is facilitated by consideration of cultural practices as ways of organizing life, rather than reducing cultural research to simply comparing national or ethnic categories.

Recognizing various ways that children approach learning activities can help in the organization of schools. Children come to school already familiar with practices in their communities that guide them in what is important to learn and how to learn. In addition, teachers come with their own values and methods of teaching influenced by their communities and their own history of involvement in Western school.

Children from communities with Indigenous roots may have to integrate several methods of learning into their repertoires in order to succeed in school. This may be both a challenge and an opportunity for the children as well as for schools, because being able to learn in several ways is likely to be useful in later life and other circumstances. Schools could make use of a likely propensity for keen observation among children with familiarity with Indigenous practices, along with teaching them how to engage in the adult-directed attentional management common in schools.

More broadly, observing ongoing interactions in which one is not involved may be beneficial to all children as a method of learning and being involved in community life. Indeed, schools could make greater use of children's observation of others as a pedagogical tool that may benefit all children's learning.

Children's Understanding of Social-Cognitive and Social-Communicative Aspects of Discourse Irony

Eva Filippova and Janet Wilde Astington
University of Toronto

To bridge the social-reasoning focus of developmental research on irony understanding and the pragmatic focus of research with adult populations, this cross-sectional study examines 5-, 7-, and 9-year-olds' ($n = 72$) developing understanding of both social-cognitive and social-communicative aspects of discourse irony, when compared with adults ($n = 24$). Although 5-year-olds lag behind the other age groups in their reasoning about the speaker's meaning, belief, intention, and motivation, adults are consistently superior to children of all ages on these social-cognitive measures. In contrast, limited age-related differences were found in participants' judgment of the social-communicative function of irony (how nice, mean, and funny irony is). The findings help to reconcile previous discrepant claims as to the age when children come to understand irony.

Discourse irony is a crafty strategy for the negotiation of meaning in social contexts and for carrying on social relationships. All forms of irony—whether sarcasm, humorous bantering, jocularity, understatement, overstatement, and so on—involve indirectly communicated beliefs and attitudes that constitute a speaker's implied meaning. For instance, an ironist can say "what a gracious dive" to comment on a friend's landing on the pool surface with her belly. The listener must substitute the intended meaning for the literal one uttered. In addition, an appreciation of irony entails the listener's recognition of the speaker's motivation for such meaning substitution. For instance, the use of "sarcasm" is motivated by a desire to ridicule someone while elevating one's own position whereas the use of "jocularity" is motivated by the speaker's wish to convey group solidarity (e.g., Gibbs, 2000).

Full appreciation of irony involves an appreciation of the social-cognitive as well as the social-communicative aspects of irony. Although the former refers to an assessment of the mind of the speaker, the latter refers to the pragmatic function of irony, that is, what the use of irony achieves for the speaker in a conversation. Within the field of children's theory of mind, researchers have used irony as a means of investigating the development of higher order social-cognitive abilities (e.g., Happé, 1993, 1995; Sullivan, Winner, & Hopfield, 1995; Winner & Leekam, 1991). In contrast, studies examining social-communicative aspects of irony have primarily examined adults' appreciation of irony's pragmatic function, without exploring what cognitively underlies this appreciation (e.g., Clark & Gerrig, 1984; Grice, 1975; Kreuz & Glucksberg, 1989; Kumon-Nakamura, Glucksberg, & Brown, 1995; Searle, 1979; Sperber & Wilson, 1995). However, a complete understanding of irony involves an appreciation of both social-cognitive (i.e., theory of mind) and social-communicative (i.e., pragmatic-functional) aspects. The present study examines both of these facets of irony interpretation within the same research paradigm. In so doing, our study unites the social-cognitive focus of the developmental research and the pragmatic focus of irony research in adults in a single developmental investigation in order to reveal developmental perspectives on both aspects of irony understanding.

Investigating particularities in the development of understanding of these different aspects of irony may help reconcile claims that 5- and 6-year-olds understand some aspects of irony (e.g., Dews et al., 1996, for irony muting function; Harris & Pexman,

2003; Sullivan et al., 1995; Winner & Leekam, 1991) and the counterclaim that even children in middle-school years do not understand irony (e.g., Demorest, Meyer, Phelps, Gardner, & Winner, 1984; Demorest, Silberstein, Gardner, & Winner, 1983, for conflation of irony and deception). Indeed, even young children may perceive the meanness of a sarcastic comment or appreciate the humor of a counterfactual assertion without explicitly figuring out that the speaker has said something he or she believes to be untrue and does not intend the listener to believe it to be true.

The Present Study

Children's understanding of both the social-cognitive and social-communicative aspects of irony was expected to improve through the early- to middle-school years. Tracing development of understanding of each of these aspects was the main goal of this study. Children heard stories in which a character made an ironic statement and were asked (a) to make judgments about the speaker's mental states (belief, intention, attitude) and (b) to evaluate the pragmatic function of the statement (how nice, mean, funny it was). Thus, we can reveal any differences in the development of understanding of the social-cognitive and social-communicative aspects of irony (a and b, respectively). We may show that before children explicitly conceptualize speakers' beliefs and intentions, they can perceive meanness and humor in nonliteral statements. We operationalize and refer to these statements as ironic, while acknowledging that in some cases children may not have conceptualized them as irony based on their judgment of speaker beliefs and intentions.

Children's comprehension of counterfactual assertion is documented to emerge around the age of 6 years (e.g., Ackerman, 1983; Andrews, Rosenblatt, Malkus, Gardner, & Winner, 1986; Dews et al., 1996; Harris & Pexman, 2003; Winner & Leekam, 1991; Winner et al., 1987). Although these studies systematically tested irony in the form of counterfactual statements (i.e., statements in which the implied meaning is the exact opposite of the expressed meaning), the task in the present study also incorporates irony in the form of noncounterfactual statements. As deliberately exaggerated statements (hyperbole) are also considered ironic (Gibbs, 2000; Leggitt & Gibbs, 2000; Winner et al., 1987), the present study uses hyperbole as a contrasting form to counterfactual statements. In other words, although counterfactual statements communicate the opposite valence to that uttered, hyperbolic statements communicate the same valence as that uttered. All the forms of irony used in this study—counterfactual praise or "jocularity," counterfactual criticism or "sarcasm," and hyperbole—are the most frequently occurring types of irony in everyday adult discourse (e.g., Gibbs, 2000). Additionally, all these types of utterances are less dependent on direct echoing of previously mentioned thoughts (i.e., explicitly referring to something said earlier; Gibbs, 2000). The present design complements Hancock, Dunham, and Purdy's (2000) study that revealed a bias to detect ironic criticism before praise, to the latter of which echoing contributes significantly. Our task omits the explicit echoing to reveal any underlying aspects of implicit reference to social norms or expectations. Thus, the design of the task enables a direct comparison of children's and adults' interpretation of critical and praise forms of irony occurring in two types of statements—counterfactual statements and noncounterfactual exaggerated statements (i.e., hyperbole).

Along with our primary developmental focus on understanding irony, our study examines whether forms of ironic criticism are understood before forms of ironic praise (Hancock et al., 2000). It also explores whether counterfactual assertions are understood before noncounterfactual assertions, a hypothesis based on the pronounced saliency of counterfactual statements (i.e., opposite of the logically expected statement) in contrast to the less salient noncounterfactual statements (Creusere, 2000; Demorest et al., 1983). Thus, an inclusion of critical *and* praise valence of irony in the form of counterfactual *and* noncounterfactual assertions enables an exploration of the documented asymmetry in understanding different kinds of discourse irony.

Further, different types of ironic statement serve different pragmatic functions and communicate different moods and attitudes. Our study also explores the understanding of social-communicative (i.e., pragmatic) functions of irony identified by children and adults. As hyperbolic criticism (HC) is a directly offensive type of statement, we expected it to be judged as the meanest statement of all. We expected counterfactual criticism (CC), due to its muting critical tone relative to exaggerated critical comments, to be judged as the second meanest type of statement, followed by counterfactual praise (CP), itself followed by hyperbolic praise (HP). The reverse order was hypothesized for the rating on the niceness scale. Lastly, as humor is one of the goals of irony (e.g., Creusere, 2000; Dews et al., 1996; Gibbs, 2000; Kumon-Nakamura et al., 1995; Pexman, Glenwright, Krol, & James, 2005), we expected the statements to be judged as funny, especially in the counterfactual types of statements where the context–utterance discrepancy and ambiguity are more salient than in hyperbole.

Method

Participants

Children of three different ages (*n* = 72) participated in the study: twenty-four 5-year-olds (11 boys and 13 girls; age range = 5.2–6.2, *M* age = 5.8), twenty-four 7-year-olds (13 boys and 11 girls; age range = 7.2–8.1, *M* age = 7.7), and twenty-four 9-year-olds (11 boys and 13 girls; age range = 9.1–10.1, *M* age = 9.7). All the children came from middle- to upper-middle-income areas of a major Canadian city and were at the same school. Children were recruited through their class teachers. Due to the nature of projected follow-up comparative research with different language groups, the present sample was ethnically and linguistically homogeneous, consisting of monolingual English speakers only.

In addition, 24 adults (11 men and 13 women; age range = 23–63, *M* age = 32) participated in the study. The adult sample consisted of 10 monolingual English speakers, 13 speakers of more than one language whose maternal tongue was English, and 1 speaker with English as a second language yet fully proficient in English. The adult participants were from a range of educational and professional backgrounds. They were recruited through friends and acquaintances of colleagues of the investigators.

Materials and Design

The task consisted of eight short stories, each describing an everyday interaction between a child and another person, and ending with an ironic comment made by the other person to the child. Each story was illustrated by one picture, in which the other person was depicted from behind, facing the child, to eliminate any mediation of interpretative cues through facial expressions (see the Appendix for an example of story and illustration).

Each of these eight stories had two possible kinds of ending—a positive and a negative—to accommodate the valence of the ironic comment in the form of ironic praise and ironic criticism, respectively. Further, the form of the ironic comment at the end of each story was of two possible types: either a counterfactual assertion or a non-counterfactual, hyperbolic assertion.

The two factors (i.e., valence and type) were crossed to yield four different versions of the eight unique scenario types (32 stories in total). Each participant's protocol consisted of one version of each scenario type, for a total of eight different stories (i.e., no protocol repeated the same story content with a different ending or different ironic comment). Each protocol included two CCs, two HCs, two CPs, and two HPs (see Table 1 and story example in the Appendix). All the statements of all eight stories were completely counterbalanced, as was their order across the testing protocols.

Following each irony scenario, there were two comprehension questions followed by two sets of test questions: the first set assessed social-cognitive understanding (i.e., the detection of the meaning, the speaker's first-order belief, third-order intention, and the speaker's motivation and/or attitude); the second set of questions examined participants' judgment of the social-communicative function of the statement (i.e., how nice, how mean, and how funny the statements were) on a scale from 0 (*not at all*) to 3 (*very very*; see the Appendix for an example of story and questions).

Procedure

Children were interviewed individually in two sessions, taking place on two different days in a quiet room on their school premises. The procedure was identical for all participating children. At the beginning of the first session, children were trained on how to use the rating scale, depicted as four glasses with an increasing amount of liquid (*not full at all*, for not nice/mean/funny at all, to *very very full*, for very very nice/mean/funny).

Children were presented with four stories per session, with one CC, one CP, one HC, and one HP in each session. In addition to the task reported here, children also received advanced theory-of-mind, language, memory, and prosody tasks, as

Table 1
Conditions of the Irony Task

	Valence	
Type	Criticism	Praise
Counterfactual	CC	CP
Hyperbolic	HC	HP

Note. CC = counterfactual criticism; CP = counterfactual praise; HC = hyperbolic criticisms; HP = hyperbolic praise.

reported in Filippova and Astington (2008). Thus, another type of task was administered between each irony story. Each session lasted for up to 40 min.

During the administration of the task, the child listened to the experimenter reading the individual stories and looked at the accompanying illustrations. The experimenter used consistently the same stressed intonation for the ironic utterances across all participating children and made no facial expressions. This resulted in all children receiving the same prosodic cues and no visual cues. Importantly, this personalized way of administration of tasks to children, common in the experimental tradition of theory-of-mind research, not only lessens the information processing load imposed on a child to abstract the facts out of a recorded story but also offers a direct and personal way of approaching each child. Furthermore, whenever a parent's consent for video-recording the session was given, the consistency of prosody and visual cues was later checked from the videotape: The researchers and the transcriber checked for any deviations from the standard prescribed prosody patterns and for no eye contact or mimics while the ironic statements were read. No inconsistencies were found.

Passing both comprehension questions was a critical prerequisite for inclusion in the data analysis; if a child failed to respond correctly to either of the control questions, the story was reread and the two comprehension questions were asked once more to ensure that children understood the key story facts and remembered the ironic comment. None of the participants failed any control questions twice and so all participants and all trials are included in the data analysis. Subsequently, a set of four social-cognitive questions (i.e., detection of meaning, belief, communicative intention, and motivation of the speaker) was asked, followed by a set of three social-communicative questions (i.e., how nice, mean, and funny the statement was). Children were allowed to take as many breaks throughout the session as they needed, having also an opportunity to select their prizes (i.e., stickers) as their reward and motivation for further testing. Only the youngest participants required a short break or two.

The same eight irony stories were used across the adult volunteers, each of whom was asked to fill out eight questionnaires according to the short stories that preceded them. The stress in the ironic statements was marked and the protocols were identical to those used with the child participants (see the Appendix). In the instructions preceding the eight questionnaires, the adults were asked to read the statements out loud with a stress placed on the CAPITALIZED WORDS and to take breaks if they happened to get tired or bored by the format of the questions. As with the children, the order of the statements and stories was completely counterbalanced. Although the adult group is not, strictly speaking, a control group, it provides a sufficient approximation of the trend of adult answers to the questions of the study and a reasonable comparison between child and adult data.

Scoring and Coding

Individual scores for the social-cognitive aspects of irony understanding were obtained from each participant's answers to the meaning, belief, intention, and motivation questions in each tested scenario. The dichotomous yes–no questions investigating the meaning, belief, and intention of the ironist were scored as either *correct* (1) or *incorrect* (0). Based on our previous research (Filippova & Astington, 2008), participants' answers to the motivation question of each story were coded on a 5-point scale, reflecting levels of interpersonal understanding based on increasing cognitive complexity of the answers, identified from the patterns of adults' responses: a score of 0 was assigned for answers irrelevant to the identification of the speaker motivation (e.g., *he said it by accident*), for wrong answers, or two consecutive *I don't know* answers; a score of 1 was assigned for simple surface-level justifications, such as reference to relevant story facts (e.g., *because he spilled the water; because she watered her flowers*), to feelings of the speaker (e.g., *because she was mad at him; because she was happy about what he has done*), or for learned conventional answers (e.g., *that's not what you do at a store, that was a nice thing to do*); a score of 2 was assigned for a reference made to information that had an implication for another person's behavior (e.g., *she didn't want him to do it again*); a score of 3 was assigned for identification of the speaker's intention to affect another person's mental state rather than behavior (e.g., *she wanted to make him feel better about what he did*); and a score of 4 was assigned for a reference made to a speaker's attitude toward a person or a situation (e.g., *he was joking; she was mocking him*) or to the pragmatic function of irony that goes beyond the identification of the speaker's intention (e.g., *he was lightening the situation; he was adding humor; he was being sarcastic*). (This generalized coding is derived from 32 coding subschemes developed for each version of each story, based on the patterns of adult responses to the motivation question;

therefore, an answer "he was mad" would be coded as 1 if given in the critical scenarios but would be coded as 0 if given in the praise scenarios.) Based on the scoring procedures used in theory-of-mind literature, whenever a participant gave an answer reflecting more than a single level of the scale, he or she was credited for their best answer to this question by being given the highest possible score on the motivation question.

Finally, individual scores for the social-communicative aspects of irony understanding were obtained from each participant's rating of the ironic statements on the niceness, meanness, and funniness scales. A rated score (0–3) was recorded from each participant, on each of the stories, and on each of the three scales.

The responses of every child participant on each story were scored and coded by two independent scorers: one of the investigators and an assistant, naïve to the hypotheses being tested and blind to the ages of the participants. Twenty percent of the responses of adult participants were checked by an independent coder against the scores and coding of the full set of adult data coded by one of the investigators. Interrater reliability of the coded answers ranged from 92% to 100% agreement for the individual scenarios (Cohen's kappas ranged from .82 to 1). All discrepancies were resolved to a final resolution accepted by both coders.

Results

Analysis of variance (ANOVA), examining the effects of different factors on participants' judgment of social-cognitive and social-communicative variables showed that neither sex (2) nor order (12) yielded a significant main effect or an interaction. Thus, data from boys and girls in all orders were combined in the following analyses.

There was some concern that the information-processing load of the task was high, particularly for 5-year-olds. In order to allay this concern, an analysis was conducted to compare 5-year-olds' performance on the set of questions across the first two stories and the second two stories that each child received in each session. Repeated measures analyses on the individual variables were computed with valence (criticism/praise) and type of statement (counterfactual/hyperbolic) as within-subject factors and sequence (first two stories received in the sessions/second two stories received in the sessions) as between-subject factors. There were no significant main effects of sequence (first or second two stories of the given sessions) and no significant interactions of sequence and valence (criticism vs. praise) or type of statement (counterfactual vs. hyperbolic). Thus, the 5-year-olds' performance is comparable across the sequence of stories they heard first and later in the session. These findings demonstrate that an information-processing challenge was not occurring as the duration of the session increased and more information was presented. Thus, data from 5-year-olds are included in all analyses reported.

Repeated measures analyses determined the effect of valence (criticism vs. praise) and type of statement (counterfactual vs. hyperbole) as the within-subject factors and the effect of age (5-, 7-, 9-year-olds, and adults) as the between-subject factor.

Social-Cognitive Variables

As scores on three of four social-cognitive variables (i.e., meaning, belief, and intention) were dichotomous, an aggregate score was required for subsequent repeated-measures analyses. Reliability of individual measures was considered over the four different conditions (see Table 1): Valence (criticism vs. praise) × Type (counterfactual vs. hyperbole) with the resulting alphas: meaning, $\alpha = .80$; belief, $\alpha = .79$; intention, $\alpha = .79$. Because of an acceptable reliability on all measures, aggregate scores were generated from the dichotomous scores on the meaning, belief, and intention questions by summing the performance scores of each child across the two versions of the same condition. Although scores on the motivation variable ranged from 0 to 4, for the sake of consistency, it was treated in the same way. Reliability of the motivation measure over the four different conditions was $\alpha = .83$.

To examine the hypothesized age-related improvement on the irony task as well as the effect of valence of ironic statements—criticism versus praise—and type of statements—counterfactual versus hyperbole—a three-way repeated measures ANOVA was conducted on the meaning, belief, intention, and motivation variables across four conditions resulting from the factors of valence and type being crossed: CC, CP, HC, and HP.

In the repeated measures analysis, valence and type were crossed within-subject factors. The valence factor had two levels (criticism and praise), as did the type factor (counterfactual and hyperbole). Age (5-, 7-, 9-year-olds, and adults) was a between-subject factor. The Valence × Age and Type × Age interaction effects were tested using

[a] Out of 2. [b] Out of 8.

the multivariate criterion of Wilks's lambda (Λ). The valence main effect, the type main effect, and the Valence × Type interaction effect were tested using univariate tests. Table 2 summarizes the mean scores and standard deviations for the individual variables.

Meaning. The ANOVA on the meaning variable revealed a significant effect of age, $F(3, 92) = 21.51$, $p < .001$, partial $\eta^2 = .41$. Dunnett *C* post hoc test indicated significant differences between 5-year-olds and each other group and between 7-year-olds and adults. The univariate tests associated with valence main effect, type main effect, and the Valence × Type interaction were nonsignificant. Multivariate tests revealed marginally significant interactions between valence and age, Wilks's $\Lambda = .92$, $F(3, 92) = 2.61$, $p = .056$, multivariate $\eta^2 = .08$, and between type and age, Wilks's $\Lambda = .92$, $F(3, 92) = 2.43$, $p = .07$, multivariate $\eta^2 = .07$. Pairwise simple-effect analyses revealed that 5-year-olds were significantly poorer than the other groups on valence and type ($p \leq .001$) and that the 7-year-olds were poorer than adults on hyperbole ($p < .05$) when judging the literalness of the meaning (see Figure 1a and b), a finding consistent with the literature. Thus, age was the only significant factor in deciphering the nonliteral nature of the ironic speaker's meaning.

Belief. The ANOVA on the variable belief indicated a significant effect of age, $F(3, 92) = 18.13$, $p < .001$, partial $\eta^2 = .37$. Dunnett *C* post hoc test revealed significant differences between 5-year-olds and all other groups and between adults and all child groups. Univariate tests indicated a significant main effect of type, favoring counterfactual statements, Wilks's $\Lambda = .73$, $F(1, 92) = 34.74$, $p < .001$, partial $\eta^2 = .27$, and nonsignificant main effects of valence and the Valence × Type interaction. Multivariate tests revealed a nonsignificant Valence × Age interaction but indicated a significant Type × Age interaction, Wilks's $\Lambda = .88$, $F(3, 92) = 40.75$, $p < .01$, multivariate $\eta^2 = .12$. Pairwise simple-effect comparisons of the Type × Age interaction showed significant differences between 5-year-olds and all other age groups on counterfactual statements (all at $p < .001$). In the case of hyperbole, adults differed from all other groups (all at $p \leq .001$) and 5-year-olds differed from both 7-year-olds and 9-year-olds ($p < .01$; see Figure 1c and d).

Thus, participants detected the ironic speaker's belief in counterfactual statements more readily than in hyperbole. Again, performance of 5-year-

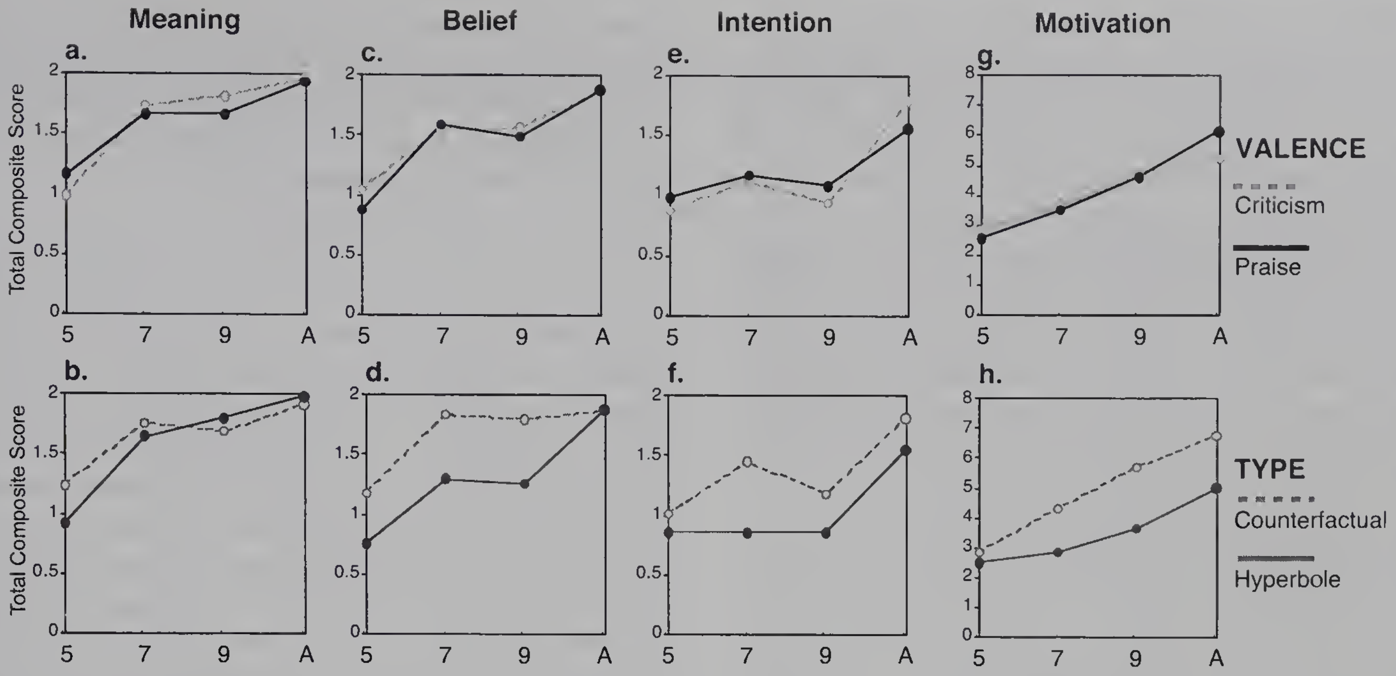

Figure 1. Performance on the social-cognitive variables for valence and type factors for the four age groups.
Note. Key for the x-axis: 5 = 5-year-olds; 7 = 7-year-olds; 9 = 9-year-olds; A = adults.

olds lagged behind that of the older groups. Although detection of the speaker's belief by 7- and 9-year-olds approached that of adults on counterfactual statements, their skills were poorer than those of adults on hyperbole.

Intention. The ANOVA on the intention variable revealed a significant effect of age, $F(3, 92) = 9.77$, $p < .001$, partial $\eta^2 = .24$. Dunnett *C* post hoc test showed significant differences between adults and all other age groups. Univariate tests indicated a nonsignificant main effect of valence. However, they revealed a significant type main effect, again favoring counterfactual statements, Wilks's $\Lambda = .77$, $F(1, 92) = 26.81$, $p < .001$, partial $\eta^2 = .23$, and a significant interaction between valence and type, Wilks's $\Lambda = .61$, $F(1, 92) = 59.21$, $p < .001$, partial $\eta^2 = .39$. Specifically, HP was the easiest condition for deciphering the intention of the speaker, followed by CC, and then HC, with CP being the most difficult condition of the four. Multivariate tests associated with the Valence × Age interaction and Type × Age interaction were nonsignificant, yet there was a significant three-way interaction between valence, type, and age, Wilks's $\Lambda = .90$, $F(3, 92) = 3.42$, $p < .05$. More precisely, adults were superior to all child groups in the cases of CC ($p \leq .001$), HC ($p < .01$), and HP ($p < .01$). In addition, 7-year-olds were significantly better than 5-year-olds in their understanding of the intention of a speaker using CC ($p < .01$). No significant differences among the groups were found in participants' recognition of the speaker's intention in HC, the condition in which the intent to criticize is the most salient of all the conditions used (see Figure 1e and f).

The detection of the speaker's intention occurred more readily, again, in counterfactual statements. Although 7-year-olds' performance exceeded that of 5-year-olds on counterfactual statements, even 9-year-olds performed no better than younger children on hyperbole. Adults' ability to discern the speaker's intention in both types of statements was superior to that of all age groups of children.

Motivation. The ANOVA on the motivation variable revealed a significant effect of age, $F(3, 92) = 20.78$, $p < .001$, partial $\eta^2 = .40$. Dunnett *C* post hoc test showed significant differences between adults and 5- and 7-year-olds and between 5- and 9-year-olds. Again, univariate tests showed a significant main effect of type, favoring counterfactual statements, Wilks's $\Lambda = .57$, $F(1, 92) = 68.17$, $p < .001$, partial $\eta^2 = .43$, but no significant main effect of valence. Furthermore, there was a significant interaction between valence and type, Wilks's $\Lambda = .91$, $F(1, 92) = 8.70$, $p < .01$, partial $\eta^2 = .09$, with the following order of increasing difficulty: CC, CP, HP, and HC. Multivariate tests indicated a significant Valence × Age interaction, Wilks's $\Lambda = .92$, $F(3, 92) = 2.86$, $p < .05$, multivariate $\eta^2 = .09$, and a significant interaction between type and age, Wilks's $\Lambda = .86$, $F(3, 92) = 5.09$, $p < .01$, multivariate $\eta^2 = .14$. In the case of counterfactual statements, pairwise simple-effect comparisons revealed significant differences between each group and every other group: 5- versus 7-year-olds ($p < .01$), 5- versus 9-year-olds and adults

($p < .001$), 7- versus 9-year-olds ($p < .01$), 7-year-olds versus adults ($p < .001$), and 9-year-olds versus adults ($p < .05$). In the case of hyperbole, pairwise simple-effect comparisons indicated significant differences between adults and all other groups ($p < .001$) and between 5- and 9-year-olds ($p < .01$).

Moreover, multivariate tests revealed a significant three-way interaction among valence, type, and age, Wilks's $\Lambda = .87$, $F(3, 92) = 4.55$, $p < .01$, multivariate $\eta^2 = .13$. The pairwise simple-effect comparisons revealed significant differences among age groups across the conditions: Adults differed from 5- and 7-year-olds on HP ($p < .001$), CP ($p < .001$), and HC ($p < .001$). The adults also differed from the 9-year-olds on HP ($p < .05$), CP ($p < .01$), and HC ($p < .01$). As well, 5-year-olds differed from 7-year-olds on CC ($p < .05$) and CP ($p < .05$), and from 9-year-olds on CC ($p < .001$), HC ($p < .05$), CP ($p < .001$), and HP ($p < .05$). Additionally, the 7- and 9-year-olds differed on CC ($p < .01$) and HP ($p < .05$; see Figure 1g and h).

Thus, participants were more sophisticated in judging an ironist's motivation in counterfactual statements than in hyperbole. More precisely, judging the motivation behind CCs by alluding to the speaker's mental states turned out to be easier than doing so for CP, which in turn, was easier than HP. HC represents the most difficult context for interpretation of the speaker's motivation for the use of irony. Nevertheless, there were pronounced differences across age in the ability to allude to the mental states of the speaker and his or her attitude toward the addressee or situation when asked to judge the ironist's motivation. There were clear indications of age-related changes in giving more elaborate references to speaker's higher order mental states with respect to an ironist's motivation between 5 years of age and adulthood.

To summarize, age was the most significant factor in the participants' judgment of the ironist's mind; whereas the 5-year-olds lagged behind the other groups overall, the adults were consistently superior to children of all ages, especially on the intention and motivation questions. This finding is consistent with a body of literature in that understanding the speaker's communicative intention and/or attitude continues to develop during the early school years. The adult scores are considerably higher than the 9-year-olds', suggesting that progress in understanding the social-cognitive aspects of irony is one that continues well into adulthood. Although counterfactual statements tended to offer an easier context for interpreting the mind of an ironist, hyperbole did so to a lesser extent. The valence of irony (i.e., criticism or praise) made significantly less difference in providing a context more readily interpretable for participants of all ages than the type of ironic statement. The age factor was persistently significant.

Social-Communicative (Pragmatic-Function) Variables

To examine the effects of the valence of irony (praise vs. criticism) and the type of ironic statement (counterfactual vs. hyperbole) on the participants' judgment of the pragmatic functions of the statements, a three-way repeated measures ANOVA was conducted on the niceness, meanness, and funniness variables across the four crossed conditions—CC, CP, HC, and HP. Aggregate scores, summed for each child across the two versions of the same condition ranging from 0 to 6, were used in the analysis.

In the following repeated measures analyses, valence and type were within-subject factors and age was a between-subject factor. Valence and type factors had two levels each (i.e., praise/criticism and counterfactual/hyperbole, respectively) and age had four levels (5-, 7-, 9-year-olds, and adults). The Valence × Age and Type × Age interaction effects were tested using the multivariate criterion of Wilks's lambda (Λ). The valence and type main effects, and the Valence × Type interaction were tested using univariate tests. Table 3 summarizes the mean scores and standard deviations for the three social-communicative variables.

Niceness. In the participants' judgment of the niceness of the ironic statements, the overall effect of age was not significant, $F(3, 92) = .46$, $p = .72$, partial $\eta^2 = .02$. Univariate tests indicated a significant main effect of valence, Wilks's $\Lambda = .31$, $F(1, 92) = 208.60$, $p < .001$, partial $\eta^2 = .69$, and a significant main effect of type, Wilks's $\Lambda = .66$, $F(1, 92) = 46.78$, $p < .001$, partial $\eta^2 = .34$. Praise was judged as significantly nicer than criticism and hyperbole as significantly nicer than counterfactual statements. There was also a significant interaction between valence and type, Wilks's $\Lambda = .34$, $F(1, 92) = 181.80$, $p < .001$, partial $\eta^2 = .64$: HP was judged as significantly nicer than both kinds of counterfactual statements and HC as the least nice statement of all.

In addition, multivariate tests revealed a significant interaction between valence and age, Wilks's $\Lambda = .70$, $F(3, 92) = 13.12$, $p < .001$, multivariate $\eta^2 = .30$. The pairwise simple-effect comparisons revealed the only difference between 5-year-olds and adults ($p < .001$) in the critical scenarios; in the praise

Note. All scores out of 6.

scenarios, the 5-year-olds differed from 7- and 9-year-olds ($p < .01$) and from adults ($p < .001$) and the adults differed also from 7- and 9-year-olds ($p < .05$). although the interaction between type and age was not significant, the tests showed a significant three-way interaction among valence, type, and age, Wilks's $\Lambda = .74$, $F(3, 92) = 10.55$, $p < .001$, multivariate $\eta^2 = .26$. The pairwise simple-effect comparisons showed no significant differences between the groups in their judgment of the niceness in HC or HP conditions. In the CC condition, however, 5-year-olds differed from 7- and 9-year-olds ($p < .05$) and from adults ($p < .001$) and the adults also differed from 7- and 9-year-olds ($p < .05$). Similarly, in the CP condition, 5-year-olds differed from both the 7- and 9-year-olds ($p < .01$) and the adults differed from all the child groups ($p \leq .001$; see Figure 2a and b).

Confirming our prediction, the participants judged HC as the least nice of all statements and HP as the nicest, with both counterfactual statements being judged in between. Although even the youngest group recognized the lack of niceness in the exaggerated criticism expressed through hyperbole, they judged CCs as significantly nicer than did the other groups. The 5-year-olds also found HP less nice than the rest of the groups. The niceness of CP differed most significantly across the ages: Although adults judged such statements significantly nicer than the rest of the groups, the youngest group found such statements significantly less nice.

The lack of an overall pronounced difference among the age groups indicates that children, with the exception of the youngest age group in certain conditions, are fairly good at detecting how nice the ironic statements are, relative to adults. With the exception of HP, however, none of the age groups including the adults judged irony to be very nice. This suggests that irony in the forms used does not communicate overly positive attitudes to our group of respondents.

Meanness. The analysis of the meanness variable revealed a significant age effect, $F(3, 92) = 9.56$, $p < .001$, partial $\eta^2 = .24$. Dunnett *C* post hoc test revealed significant differences between adults and each child group. Univariate tests showed a significant main effect of valence, Wilks's $\Lambda = .36$, $F(1, 92) = 162.00$, $p < .001$, partial $\eta^2 = .64$, and a significant main effect of type, Wilks's $\Lambda = .71$, $F(1, 92) = 38.29$, $p < .001$, partial $\eta^2 = .29$. Criticism was judged as significantly meaner than praise and counterfactual statements as significantly meaner than hyperbole. There was also a significant interaction between valence and type, Wilks's $\Lambda = .40$, $F(1, 92) = 137.60$, $p < .001$, partial $\eta^2 = .60$. HC was judged as the meanest of all, followed by both kinds of counterfactual statements. HP was judged as the least mean of all statements.

Multivariate tests revealed a significant interaction between valence and age, Wilks's $\Lambda = .79$, $F(3, 92) = 9.26$, $p < .001$, multivariate $\eta^2 = .23$. The

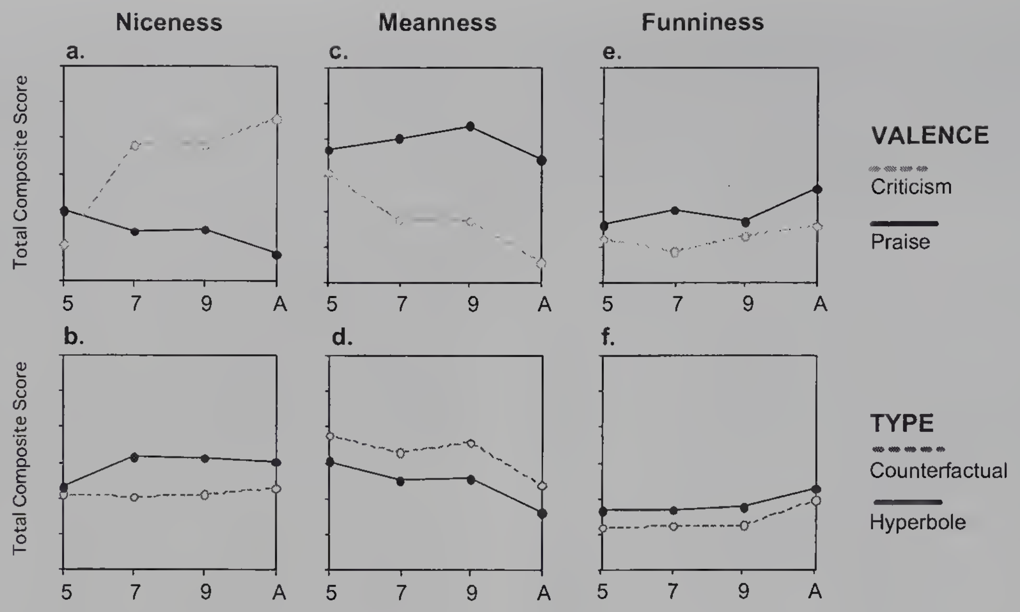

Figure 2. Performance on the social-communicative variables for valence and type factors for the four age groups.
Note. Key for the *x*-axis: 5 = 5-year-olds; 7 = 7-year-olds; 9 = 9-year-olds; A = adults.

pairwise simple-effect comparisons revealed that only the difference between the adults and 9-year-olds was significant in the critical scenarios ($p < .05$). There were more pronounced age differences in the praise scenarios, in which both 5-year-olds and adults differed from all the other groups ($p < .001$). The multivariate test for the Type × Age interaction was nonsignificant. In addition, there was a significant three-way interaction among valence, type, and age, Wilks's $\Lambda = .70$, $F(3, 92) = 13.18$, $p < .001$, multivariate $\eta^2 = .30$. The pairwise simple-effect comparisons revealed the following differences between the groups: Although the adults judged HC and CP as significantly less mean than all child groups did ($p < .001$), the 5-year-olds judged CP as significantly more mean than both 7- and 9-year-olds ($p < .01$) and HP as significantly less mean than all the other groups ($p < .01$; see Figure 2c and d).

Consistent with the findings on the niceness scale, the participants judged HCs as the meanest statements of all and HP as the least mean of all statements, counterfactual statements being judged in between. Again, the youngest group tended to judge the statement as significantly more mean than the other groups did and the adults judged them as significantly less mean than the children did. Thus, although the youngest group lagged behind the rest of the groups in their judgment of the meanness of irony, the adults were on the other extreme of the scale. Overall, there seems to be a pattern of the decreasing judgment of the meanness of irony with increasing age.

Funniness. Similar to the judgment of niceness, the age effect on the judgment of the funniness of the statements was not significant, $F(3, 92) = 1.82$, $p = .15$, partial $\eta^2 = .06$. However, univariate tests revealed a significant main effect of valence, Wilks's $\Lambda = .71$, $F(1, 92) = 37.99$, $p < .001$, partial $\eta^2 = .29$, and a significant main effect of type, Wilks's $\Lambda = .86$, $F(1, 92) = 15.64$, $p < .001$, partial $\eta^2 = .15$. Praise was judged as significantly funnier than criticism and hyperbole as significantly funnier than counterfactual statements. The interaction between valence and type was also significant, Wilks's $\Lambda = .95$, $F(1, 92) = 4.46$, $p < .05$, multivariate $\eta^2 = .05$: HP was judged funnier than both kinds of counterfactual statements and HC as the least funny type of statement.

Multivariate tests revealed a nonsignificant interaction between type and age but showed a significant interaction between valence and age, Wilks's $\Lambda = .91$, $F(3, 92) = 2.87$, $p < .05$, multivariate $\eta^2 = .07$. The pairwise simple-effect comparisons yielded significant differences in the praise scenarios only, namely, between adults and 5-year-olds ($p < .01$) and 9-year-olds ($p < .05$). The three-way interaction among valence, type, and age was nonsignificant, as were the remaining interactions. There was general consistency among all the child groups and adults in how funny they judged the statements to be. Overall, and contrary to our expectation, not even adults judged the ironic statements as very funny (see Figure 2e and f).

In sum, the age differences in the participants' judgment of the niceness, meanness, and funniness of irony were far less pronounced than was the case for their judgment of the social-cognitive aspects of an ironist's mind. In general, the judgment of irony was not too positive. Yet the adults judged CP as significantly nicer than did the other groups. There was also a trend to regard irony as less mean with increasing age. In support of our hypothesis, ironic criticism was judged as significantly less nice and meaner than ironic praise. By the same token, counterfactual statements were judged less nice and meaner than hyperbole. However, and contrary to the prediction, hyperbole was judged as funnier than counterfactual statements. Overall though, irony was not perceived to be funny by the participants of the study. Thus, both valence and type of statements were significant factors predicting the performance of our groups on their judgment of the pragmatic function of irony.

Discussion

Findings of this study indicate an age-related improvement in children's understanding of the social-cognitive aspects of irony interpretation. Overall, 5-year-olds lagged behind older children in reasoning about the social-cognitive aspects of irony (i.e., speaker's meaning, belief, intention, and motivation), and children of all ages performed more poorly than adults. In contrast, the judgment of the social-communicative functions of irony fell short of displaying a similar developmental trend; the 7- and 9-year-olds judged the niceness and funniness of irony comparably with adults. (Reasons for this discrepancy in trend are discussed later.)

Further, the results offer partial confirmation and partial disconfirmation of the hypothesized asymmetry in understanding different kinds of discourse irony. Understanding counterfactual statements was easier than hyperbole on the belief, intention, and motivation questions. However, the effect of valence (criticism vs. praise) was not significant overall. Although the asymmetry between criticism and praise was revealed within counterfactual statements, confirming Hancock et al.'s (2000) findings, the bias toward criticism or praise was not confirmed in the case of hyperbole (discussed in the following section). In general, ironic messages were not evaluated positively, but adults judged CP more favorably than children did. There was suggestive evidence that ironic messages seemed less mean, although not necessarily nicer, with increasing age. Ironic criticism was considered less nice and meaner than ironic praise, and counterfactual statements were considered less nice and meaner than hyperbolic statements.

Overall, the ironic messages used in the study were not evaluated as humorous. The degree of the judged ''funniness'' of ironic statements varies across different studies. We speculate that the statements used in our study may have been judged as less funny than in some other studies because the judgment of funniness came at the very end of the questionnaire by which time the spontaneity of a potential appreciation of humor might have dissipated in the process of reflecting on the ironist's mind. In addition, the type of irony used will determine the level of funniness; that is, a sarcastic remark would not be expected to be overly funny, nor would an exaggerated criticism. Both of these would likely be judged as more mean and consequently, not too entertaining.

The Role of Valence (Criticism vs. Praise)

The findings revealed no overall effect of valence on the participants' understanding of the social-cognitive aspects of irony. Although the present findings confirm the bias toward an easier understanding of criticism in counterfactual statements (Hancock et al., 2000), the bias was not found in hyperbolic statements. Thus, the present study revealed no general asymmetry between ironic forms of criticism versus praise that would also be expected on the basis of allusional-pretense theory (Kumon-Nakamura et al., 1995). According to the allusional-pretense model, the positive antecedent in the criticism condition is implicitly assumed, as ironic criticism echoes or alludes to presupposed positive norms or expectations. In contrast, ironic praise does not allude to such positive assumptions. For instance, commenting on someone's accomplishment by using a critical statement does not presuppose general negative expectations. As a result, the ironist's explicit echoing of an earlier comment improves the rate of irony detection in the praise condition only (Hancock et al., 2000). The present results are inconsistent with the general assumption that social and cultural norms favor indirect criticism or indirect praise.

In contrast to Hancock et al.'s (2000) design, the present study did not use echoic markers on ironic statements because the types of statements used do not require echoic markers (Gibbs, 2000) and because the participants in the study were older than those in Hancock et al.'s study. Nevertheless, the implicit allusion to positive norms did not help the children in our study to identify the speaker's mental state more readily in critical hyperbolic forms, as allusional-pretense theory would suggest.

Note, however that all forms of irony used (i.e., jocularity as an instance of CP, sarcasm as an instance of CC, and hyperbole) are common in everyday adult conversation (Gibbs, 2000). If children are exposed to these utterances in social interactions, they may accept them as socially appropriate and as alluding to cultural norms in their community. Moreover, the mean age of children in the present study was higher than that in Hancock et al.'s study, making it likely that the school-aged children in our study were better primed to hear both ironic criticism and ironic praise. Thus, the high frequency of these utterance types in everyday discourse and the older age of participants might have reduced potential asymmetries in children's understanding of non-counterfactual criticism versus praise.

Although the valence did not affect children's overall identification of different aspects of the speaker's mind, it affected their evaluation of the pragmatic function of irony. Specifically, older children as well as adults judged ironic praise more positively than ironic criticism; ironic criticism was judged to be considerably meaner than ironic praise, and ironic praise funnier than ironic criticism. Thus, although valence had no overall effect on children's judgment of the speaker's mind, it had a predictably strong effect on the evaluation of the pragmatic function of ironic praise versus criticism.

The Role of Type (Counterfactual vs. Hyperbolic)

The type of irony affected identification of the speaker's beliefs, intentions, and motivations. Specifically, performance on counterfactual statements was superior to that on hyperbolic statements ($p < .001$ on the belief, intention, and motivation variables). This result is consistent with children's recognition of context–utterance discrepancy when the discrepancy is large (e.g., sarcasm) rather than small (e.g., hyperbole; Demorest et al., 1983). The findings are consistent with the claim of Demorest et al. (1983) that recognition of the nonliteral nature of a discrepant utterance (i.e., counterfactual statement) influences the effort to resolve the discrepancy. Because discrepancy and dissonance are greater in counterfactual statements than in hyperbole, the motivation to resolve the discrepancy would be greater (Demorest et al., 1983).

Nevertheless, the present findings contrast with those of Creusere (2000), who found that the form of statements—counterfactual assertions, true assertions, questions, offerings, or thanking—did not affect 8-year-olds' ability to identify the speaker's belief and intention. In other words, in her study children's performance on the counterfactual statements did not differ from that on noncounterfactual statements. Perhaps Creusere's 8-year-olds' failure to identify an ironist's first-order belief and second-order intention more readily in counterfactual statements than in other utterance types stems from ceiling effects. The understanding of first-order beliefs occurs at around 4 years of age, and the understanding of second-order intentions shortly thereafter (Leekam, 1991). Thus, Creusere's findings do not undermine those of the present study, which are consistent with those of Demorest et al. (1983).

Furthermore, the type of utterance had comparably strong effects on children's and adults' judgment of niceness, meanness, and funniness. Specifically, hyperbolic statements were judged as significantly nicer than counterfactual statements, which, in turn, were judged as meaner and less funny than hyperbolic statements.

The findings of this study revealed that understanding counterfactual statements is easier than understanding hyperbole. There are two plausible explanations for this asymmetry: First, children may have greater familiarity with counterfactual statements because jocularity and sarcasm occur more frequently in casual conversations than hyperbole does (Gibbs, 2000). Second, because counterfactual statements signal the discrepancy between context and utterance more strongly than hyperbole, attempts to resolve the dissonance may be more prominent for counterfactual statements than for hyperbole (Demorest et al., 1983). Thus, irony type makes a greater contribution to school-aged children's overall interpretation of irony than the valence of an ironic statement (criticism vs. praise).

Understanding of Social-Cognitive and Social-Communicative Aspects

Consistent with previously published data, our findings demonstrate that although 5-year-olds fail to interpret both the ironist's mind and the communicative effect of irony, 7- and 9-year-olds approach the adult level of interpretation of the social-communicative aspects of some forms of irony. Yet, the novelty of this study is the finding that although school-aged children are able to judge the pragmatic function or the communicative effect of counterfactual and hyperbolic statements in a similar way to adults, they are still unable to properly assess the ironic speaker's mind. Social-cognitive skills at representing beliefs, communicative intentions, and motivations of an indirect speaker continue to develop in and beyond the middle-school years.

Thus, the findings demonstrate continued development during the school-age years in understanding different aspects of mind beyond the well-documented understanding of second-order beliefs (Astington, Pelletier, & Homer, 2002; Perner & Wimmer, 1985; Sullivan et al., 1995). Representing communicative intentions and identifying a speaker's motivations and attitudes are critical aspects of sophisticated communication (Gibbs, 2000; Happé, 1993; Leggitt & Gibbs, 2000; Sperber & Wilson, 1995), particularly in communicative exchanges involving the speaker's allusion to prior attributed thoughts or beliefs (Kumon-Nakamura et al., 1995). The present findings confirm that reflective interpretation of everyday speech is difficult, even for 9-year-olds, who did not reach adult skill levels. In particular, the ability to represent communicative intentions and to identify the motivations and attitudes underlying the speaker's choice of particular utterances develops after the early school years.

In this study, adults in the comparison group were superior to children in constructing an appropriate interpretation of the speaker's intention, motivation, and attitude (attitude coded as the highest score on the motivation coding scheme). Children's interpretation of these aspects of the speaker's mind is imperfect (Pexman & Glenwright, 2007); they have a long way to go before they can construct interpretations of the speaker's complex mental states in the way that adults do (Filippova & Astington, 2008). Importantly, however, we did not find the same striking age differences in understanding of the social-communicative aspects of irony, specifically, in the interpretation of the function of the utterances in discourse (i.e., how nice, mean, and funny the statements are). It is intriguing to speculate about why children find it so easy to interpret the function of some ironic utterances, yet so difficult to infer complex mental states. What distinguishes children's ability to interpret the function of statements from their representation of the speaker's intentions, motivations, and attitudes? How is the process of interpreting the pragmatic function of statements different from that of recognizing a speaker's communicative intent, motivations, and attitudes?

One way to answer these questions is to view the judgment of the speaker's intentions, motivations, and attitudes as requiring interpretation in contrast to the more evaluative character of judging the pragmatic function of ironic statements. That is to say, the assessment of pragmatic function involves one's own evaluation of the communicative effect of irony in the discourse, which is not contingent on one's constructing a mental representation of another's state of mind. In contrast, understanding the social-cognitive aspect of irony depends on making complex interpretative judgments of a speaker's mental states.

This interpretative judgment is a reflective process. For Wilson (2000), the basic metacommunicative capacity is intuitive rather than reflective. Thus, children's ability to assess the pragmatic (i.e., communicative) function of ironic utterances may be more intuitive in the sense that very young children judge things or situations as nice, mean, or funny. Because of exposure to social standards and norms very early in life, children's evaluation of the appropriateness of certain behaviors, including speech, can be construed as intuitive rather than reflective. In contrast, the interpretation of complex intentions, motivations, and attitudes is not a matter of simple intuition. Instead, it involves an active construction of a representation of the speaker's mind (i.e., interpretative judgment). Thus, children's difficulty in interpreting complex mental states may stem from the complex metarepresentational and metacommunicative nature of higher order intentions, motivations, and attitudes. The judgment of the niceness, meanness, and funniness of statements does not require such interpretative skills. Rather, assessing such statements in discourse is less reflective in the sense that this evaluation does not necessitate the representation of cognitive states whereas, in contrast, metarepresentational reasoning is involved in inferences about the speaker's state of mind.

It is also plausible to speculate that the reflective/interpretative and intuitive/evaluative processes take place in different parts of human brain and reveal ontogenetic constraints associated with the development of respective brain regions. In her review of neuroimaging research conducted on theory of mind and empathy, Singer (2006) argues that although our ability to share feelings, emotions, or sensations of others relies on sensorimotor cortices and limbic and paralimbic structures developed early in ontogeny, theory of mind relies on structures of the temporal lobe and prefrontal cortex, maturing considerably later. Singer proposes that the human ability to understand other people's minds and to share affects display different ontogenetic trajectories reflecting the different routes of their underlying neural structures. If the assessment of niceness, meanness, and funniness of irony is a proxy for an empathizing ability (i.e., our participants evaluated the pragmatic impact of the utterances on the addressee from their own perspective), this may help to explain our child participants' ease at evaluating the social-communicative aspects of irony in contrast to their persisting difficulties in judging social-cognitive aspects of irony when compared with the skills documented in adults. As the brain structures associated with understanding others' minds are ones among the last to fully mature (Singer, 2006), it is perhaps not surprising to see the development in understanding complex aspects of a speaker's mind lagging behind the skills at assessing the pragmatic function (i.e., emotional impact) documented to be well under way.

Appendix

Sample of Irony Task

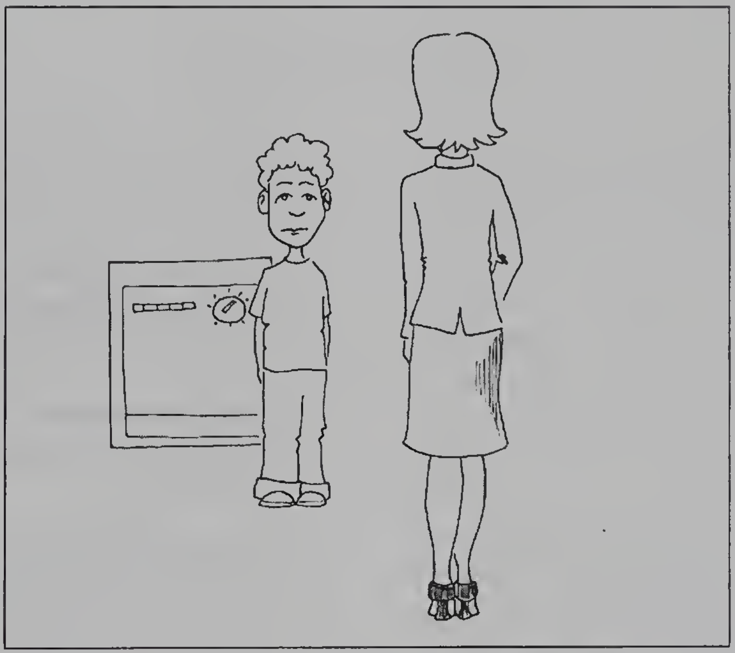
Dinner
Mom asks Billy to help her empty the dishwasher before dinner.
Billy starts to empty the dishwasher while mom is making dinner.

Criticism:
Billy drops a plate and it breaks.
Mom turns around and says to Billy:

Counterfactual: "You sure ARE a GREAT helper!"
Hyperbolic: "You sure KNOW how to WRECK the house!"

Praise:
Billy neatly puts all the dishes from the dishwasher in the cupboards.
He even sets the table for dinner.
Mom turns around and says to Billy:

Counterfactual: "You sure ARE a CRUMMY helper!"
Hyperbolic: "You MUST be a kitchen SUPERMAN!"



Sample of Questionnaire

Counterfactual Criticism Condition

Comprehension Questions:				
1. Did Billy end up helping his mom?	[correct answer: no]			
2. What did mom say to Billy?	[exact retell, a paraphrase, or the correct gist]			
[exact statement reiterated: "*You sure ARE a GREAT helper!*"]				
Meaning:				
3.1 Does mom mean that?	[correct answer: no]			
3.2 What does she mean?	[acknowledged meaning opposite to the literal statement]			
Belief:				
4. Does mom think Billy is a great helper?	[correct answer: no]			
Intention:				
Mom said to Billy: "*You sure ARE a GREAT helper!*"				
5. Does mom want Billy to believe that she thinks that?	[correct answer: no]			
Motivation/Attitude:				
Mom said to Billy: "*You sure ARE a GREAT helper!*"				
6. Why did she say that?	[coded on a 5-point scale]			
Pragmatic Function:				
7. Mom said to Billy: "*You sure ARE a GREAT helper!*"				
Pick one of these four glasses to show				
(a) How nice was what mom said?	0	1	2	3
(b) How mean was what mom said?	0	1	2	3
(c) How funny was what mom said?	0	1	2	3

Sample of Questionnaire

Hyperbolic Criticism Condition

Comprehension Questions:				
1. Did Billy end up helping his mom?	[correct answer: no]			
2. What did mom say to Billy?	[exact retell, a paraphrase, or the correct gist]			
[exact statement reiterated: "*You sure KNOW how to WRECK the house!*"]				
Meaning:				
3.1 Does mom mean that?	[correct answer: no]			
3.2 What does she mean?	[acknowledgement of meaning reduced from the exaggeration]			
Belief:				
4. Does mom think Billy knows how to wreck the house?	[correct answer: no]			
Intention:				
Mom said to Billy: "*You sure KNOW how to WRECK the house!*"				
5. Does mom want Billy to believe that she thinks that?	[correct answer: no]			
Motivation/Attitude:				
Mom said to Billy: "*You sure KNOW how to WRECK the house!*"				
6. Why did she say that?	[coded on a 5-point scale]

Inconsistency With Prior Knowledge Triggers Children's Causal Explanatory Reasoning

Cristine H. Legare
University of Texas at Austin

Susan A. Gelman and
Henry M. Wellman
University of Michigan

What events trigger causal explanatory reasoning in young children? Children's explanations could be triggered by either consistent events (suggesting that explanations serve a confirmatory function) or inconsistent events (suggesting that they promote discovery of new information). In 2 studies with preschool children ($N = 80$), events that were consistent with children's prior knowledge were simultaneously contrasted with events that were inconsistent with prior knowledge, and children were invited to explain either outcome (or both). Results demonstrate that inconsistent outcomes are an especially powerful trigger for children's explanations and that the explanations children provide for inconsistent outcomes refer to internal causal properties, overriding perceptual appearances. In sum, the data provide empirical evidence that inconsistent events motivate children to construct explanations, thereby suggesting that children's explanations function in the service of discovery.

> *Observation is always selection. It needs a chosen object, a definite task, an interest, a point of view, a problem.*
>
> —Popper, 1963

A fundamental task for all humans is explaining why things happen. By 3 years of age, children can use causal knowledge to make predictions (Shultz, 1982), engage in effective interventions (Kushnir & Gopnik, 2005; Schulz & Gopnik, 2004), and provide explanations for things that happen (Wellman, Hickling, & Schult, 1997). Not only do young children frequently seek explanations by asking questions, they also construct their own explanations (Callanan & Oakes, 1992; Hickling & Wellman, 2001).

At the same time, young children are surprisingly poor at assessing their own explanatory understanding. This ability develops dramatically across development, but adults and especially children overestimate the detail and depth of their explanatory knowledge (Mills & Keil, 2004; Wilson & Keil, 1998). Thus, on the one hand, children are active explanation seekers and readily request and provide causal explanations. Yet on the other hand, they seem to be poor at assessing their own causal knowledge and often think they understand things when they do not. What then motivates children to ask questions and generate explanations? More specifically, what kinds of events provoke causal explanatory reasoning in children? Children could make use of causal-explanatory understanding when reasoning about either *consistent events* (when events unfold as anticipated based on prior knowledge) or *inconsistent events* (when something unusual or contrary to prior knowledge happens).

Accordingly, children's explanations may serve at least two distinct functions. First, explanation might be systematically confirmatory. Research on the development of scientific reasoning provides evidence for a confirmation bias in both children and adults (Nickerson, 1998) whereby reasoners tend to seek information that supports a favored hypothesis and to interpret events in ways that are partial to that hypothesis. Both children and adults also tend to avoid, ignore, or distort information that is inconsistent with their beliefs (Kuhn, 1989).

This research was supported by a foundation grant from the McDonnell foundation to Wellman and Gelman, NICHD Grant HD22149 to Wellman, and NICHD Grant HD36043 to Gelman. We are grateful to the teachers, staff, and children of the University of Michigan Children's Centers, Pooh Corner Preschool, and Bemis Farms Preschool for participating in this research. We would also like to thank Tamar Kushnir for her insightful input on study design, Paul Theron for his assistance with stimuli design, and Andrea Kiss for her assistance with data collection.

Confirmatory information can be favored and privileged even when people have no vested interest in a hypothesis (Bruner, Goodnow, & Austin, 1956).

There is much evidence for a confirmation bias in older children and adults. But young children may be especially prone to such a bias, because they are early in the process of developing explanatory knowledge and so can benefit from consolidating, confirming, and deepening their current explanations. Thus, not only do young children anticipate that future outcomes will proceed in accord with prior expectations (Gopnik, Sobel, Schulz, & Glymour, 2001; Kushnir & Gopnik, 2007; Schulz & Gopnik, 2004), they may also find such outcomes easy to explain and worthy of explanation.

Alternatively, however, young children's explanation might be especially triggered by *inconsistent* information, that is information inconsistent with expectations. If so, providing explanations might be as much a childhood process of discovery as a process of confirmation. Children may systematically attend to and attempt to explain information that is inconsistent with expectations. Notably, the motivation to construct causal explanation may be driven by the puzzle of inconsistent outcomes, and not merely by unpredicted, low probability, or novel outcomes. Forming explanations for inconsistent outcomes may provide children with the opportunity to generate new hypotheses, and to accommodate inconsistent information in the context of prior beliefs.

Several arguments and findings make this alternative possibility plausible as well. The idea that inconsistent, problematic, or surprising outcomes play an important role in causal reasoning for adults and school-age children appears across multiple literatures—including philosophy of science (Hempel, 1965), social psychology (Hilton, 1995; Weiner, 1985), and educational research (Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Wong & Weiner, 1981). Moreover, it is well documented that infants often attend to inconsistent or unexpected outcomes (Baillargeon, 2002).

Against these theoretical possibilities, there is a dearth of empirical research on what actually motivates young children to construct explanations. Thus, it is unclear which model better predicts children's causal explanations. We take an empirical approach by assessing what motivates young children to provide the explanations that they do.

The present studies focus on children's explanations for confirmatory versus disconfirmatory events. We provided children with the following basic scenario. Children viewed two equivalent events simultaneously: one in accord with prior knowledge and the other not. If, for young children, explanation is largely confirmatory, then they should simply explain what they already have an explanation for. If explanation is instead especially employed for discordant or anomalous information, children should explain the event that falls outside their prior expectations. We measured not only *what* children explain but also *how* they do so, by examining whether they appealed to surface features or instead to less obvious causal properties and category membership. We assume that explanations reflect the nature of children's conceptual understanding (Keil, 2006; Legare, Wellman, & Gelman, 2009; Lombrozo, 2006; Medin, Coley, & Storms, 2003; Sloman, 1994). For example, consider category membership. Even children as young as 3 years of age can categorize objects in terms of novel, nonobvious properties (Gelman & Coley, 1990; Gelman & Markman, 1986, 1987; Graham, Kilbreath, & Welder, 2004; Jaswal & Markman, 2007), apply names to objects with the same functional properties (Kemler-Nelson, 1995), and categorize and name objects based on novel causal properties (Gopnik & Sobel, 2000), overriding perceptual appearances. Whether and how preschool children might make use of such information in their causal explanations (as opposed to their predictions or judgments) is, however, an open question.

Study 1

To address these issues, we designed a set of novel "light boxes"—devices that glowed brightly when activated. The activation of the boxes was experimenter controlled, but appeared to be caused by placing an object on top (modeled after Gopnik & Sobel, 2000; Gopnik et al., 2001). These materials were first used to teach children briefly about different categories of objects that turned a box on, turned it off, or did nothing. In Study 1, these training objects were labeled according to their causal properties: "starters" (which lit the light box when placed on top), "stoppers" (which turned off a lit box), and "do-nothings" (which neither lit nor unlit the light box). Items within each object category (e.g., do-nothings) were perceptually identical. After training, children were presented with scenarios in which a new object that looked like one type (e.g., it looked like a starter) actually behaved like another type (e.g., it behaved like a do-nothing). This was simultaneously paired within test trials where a contrasting object looked and behaved like those previously seen (e.g., it looked like a do-nothing and behaved like a do-nothing). Upon viewing such paired outcomes, children were asked a nonspecific explanatory question ambiguously referring to either (visible) outcome: "Why did that happen?"

Comparing outcomes consistent or inconsistent with prior knowledge was our primary interest, but state changes and negative outcomes may also function as explanatory triggers. Therefore, two focal conditions were designed that controlled for these factors by holding them constant. In the *generative condition*, both light boxes began off, both turned on in one of the test trials, and both remained off in the other test trial. So, in the test trial in which both boxes turned on, both outcomes involved state change and neither outcome involved a negative outcome (defined here as failing to turn the boxes on). In the parallel test trial in which both boxes stayed off, neither outcome involved a state change and both outcomes involved a negative outcome (failing to turn the boxes on). In the contrasting *inhibitory condition*, both light boxes began on and this pattern of outcomes was reversed.

Prior to these test trials but after initial training, children participated in a confirmation trial. The confirmation trial not only served to remind children of how various objects functioned, but also had the advantage of isolating change-of-state outcomes from outcomes inconsistent with prior knowledge. For example, in the confirmation trials, because both outcomes work as expected based on prior experience, starters and stoppers changed the state of the box, and do-nothings did not change the state of the box.

Our interest was in which events yielded not just greater attention, but most importantly, increased explanation. If state change plays a role, on the *confirmation trials* children should differentially explain outcomes when a box turned off (after being on) or turned on (after being off). If negative outcomes provoke explanation, on the *confirmation trials* children should differentially explain outcomes when a box failed to turn on, or when a box turned off. Most importantly, if the role of explanations for children is confirmatory, children should be interested in and provide explanations for the consistent event in each *test trial* pair, whereas if the role of explanations is discovery, children should be specifically interested in and provide hypotheses and explanations for the inconsistent event in each *test trial* pair.

Method

Participants

Sixteen 3-year-olds (*M* age = 3.6; range = 3.2–3.11), sixteen 4-year-olds (*M* = 4.6; range = 4.0–4.11), and sixteen 5-year-olds (*M* = 5.3; range = 5.0–5.6) were recruited from a Midwestern U.S. university town. Participants were primarily White and from middle-class families. Approximately equal numbers of boys and girls participated in the study.

Materials

Four light boxes (5 in. × 5 in. × 5 in.) were made of wood with thin translucent laminate tops. The boxes were identical except one pair was red and the other pair was yellow. Each pair of boxes (red or yellow) was attached to a switch box operated surreptitiously by a confederate. If the switch was turned on, the box would light up and stay on until it was switched off. Alternately, if the switch was turned off, the box would turn off and stay off until it was switched on. For objects with a causal effect, each box was turned off or on as soon as an object made contact with it, and would stay off or on until the object was removed. This yielded the strong impression that some objects turned the boxes on, some turned them off, and some had no effect on the boxes. The switchbox was hidden from the children's view, and none of the participants mentioned the confederate or indicated any suspicion that the confederate influenced the functioning of the boxes.

There were four perceptually distinct sets of objects, shown in Figure 1, each consisting of five identical wooden blocks (20 blocks total). Objects were always presented in paired sets. The perceptual features of different kinds of objects were not indicative of the observed causal properties of the objects (lighting or not lighting the boxes). Additionally, the placement of the objects on the boxes was counterbalanced across trials.

Design

Trials were designed both to isolate state change and negative outcomes as potential explanatory triggers (confirmation trial) and to control for these factors by holding them constant (test trials). To help assess these factors, there were two different conditions. In the *generative condition*, the boxes (either yellow or red, counterbalanced across children) started with the light off, and in the training trial, the two distinctive sorts of objects were

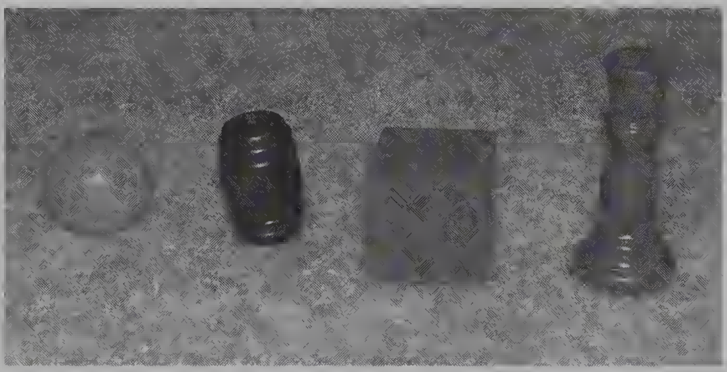

Figure 1. Studies 1 and 2: Pictures of object stimuli.

labeled as either starters or do-nothings. In the *inhibitory condition*, this pattern was reversed; the boxes started with the light on, and, in the training trial, the objects were labeled as either stoppers or do-nothings. One test trial displayed both light boxes turned on and the other test trial displayed both light boxes turned off. Therefore, in each test trial, inconsistency with prior knowledge was isolated; one outcome was inconsistent with prior knowledge and one outcome was consistent with prior knowledge, but both changed (or don't change) state, and both boxes were on (positive) or off (negative).

Generative condition. Table 1 provides an outline of the factors and design for the entire study. In each condition, after training, there was one confirmation trial followed by two test trials. For the generative condition, in the confirmation trial, both outcomes were consistent; there was no inconsistent outcome. As listed in Table 1, the object that looked like a starter turned the box on and therefore produced a state change and a positive outcome (light box was on). The object that looked like a do-nothing did not change the state of the box and produced a negative outcome (light box was off; see Figure 2). Therefore, if the child was motivated to explain a state change, he or she would have explained the outcome involving the object that looked like a starter first, and if the child was motivated to explain the negative outcome, he or she would have explained the object that looked like a do-nothing first.

In the generative test trial in which both boxes turned on, both outcomes involved state change and neither involved a negative outcome (defined here as failing to turn the boxes on). However, the object that looked like a starter produced an outcome consistent with prior knowledge and the object that looked like a do-nothing produced an outcome inconsistent with prior knowledge (see Table 1). Therefore, if the child was motivated to explain inconsistency with prior knowledge, he or she should explain the object that looked like a do-nothing first. In the parallel generative test trial in which both boxes stayed off, neither outcome involved a state-change and both outcomes involved a negative outcome (both failed to turn the boxes on). In this trial, instead of the object that looked like a do-nothing producing an inconsistent outcome, it was the object that looked like a starter that produced an inconsistent outcome.

Inhibitory condition. In the inhibitory confirmation trial, again both outcomes were consistent;

Table 1
Studies 1 and 2: Study Design

Condition	Generative (off → X)						Inhibitory (on → X)					
Trial	Confirmation trial		Test trial		Test trial		Confirmation trial		Test trial		Test trial	
Initial state of light box	Off	Off	Off	Off	Off	Off	On	On	On	On	On	On
Type of object	Starter	Do-nothing	Starter	Do-nothing	Starter	Do-nothing	Stopper	Do-nothing	Stopper	Do-nothing	Stopper	Do-nothing
Final state of light box	On	Off	Off	Off	On	On	Off	On	Off	Off	On	On
Inconsistent outcome = 1	0	0	1	0	0	1	0	0	0	1	1	0
State change = 1	1	0	0	0	1	1	1	0	1	1	0	0
Negative outcome = 1 (off)	0	1	1	1	0	0	1	0	1	1	0	0

Generative Condition
■ = Starter/Toma
▲ = Do-Nothing/Not-a-Toma
Confirmation Trial
Test Trial: Light Boxes Both Turn On
Test Trial: Light Boxes Both Stay Off

Figure 2. Studies 1 and 2: Generative condition.

there was no inconsistent outcome. As seen in Table 1, the object that looked like a stopper turned the box off and therefore produced a state change *and* a negative outcome (the light box was off). This correspondence of a state change and negative outcome was unlike the generative condition, in which state change and negative outcome competed in the confirmation trial. The object that looked like a do-nothing did not change the state of the box and produced a positive outcome (the light box was on; see Figure 3). So if the child was motivated to explain a state change or a negative outcome, he or she would have explained the outcome involving the object that looked like a stopper first. If neither state change nor negative outcomes were explanatory triggers, the child would have explained the object that looked like a do-nothing first.

In the inhibitory test trial in which both boxes turned on, neither outcome involved state change nor a negative outcome. However, the object that looked like a do-nothing produced an outcome consistent with prior knowledge, and the object that looked like a stopper produced an outcome inconsistent with prior knowledge (see Table 1). Therefore, if the child was motivated to explain inconsistency with prior knowledge, he or she should explain the object that looked like a stopper first (the opposite pattern of the generative condition in the test trial, in which both boxes lit up). In the parallel inhibitory test trial in which both boxes turned off, both outcomes involved a state-change and both outcomes involved a negative outcome (both turned the boxes off). In this trial, instead of the object that looked like a stopper producing an inconsistent outcome, it was the object that looked like a do-nothing that produced an inconsistent outcome.

Procedure

Children were tested individually in a 15-min session seated across from the experimenter and confederate at a table on which a pair of the wooden boxes was placed. Each child participated in both conditions: generative and inhibitory. After the objects' functions and labels were presented individually in the training trials, both objects were presented simultaneously on three trials: one confirmation trial followed by two test trials. Although the objects in the confirmation and test trials were perceptually identical to the objects in the training trial, they were never labeled for the child. For example, in the generative condition, after demonstrating how a starter and a do-nothing work for one set of objects in the training trial, the experimenter placed another object perceptually identical to a starter and another object perceptually identical to a do-nothing simultaneously on two unlit boxes. In this confirmation trial, both objects worked in a manner consistent with prior knowledge (upon contact with one box, the object that looked like a starter turned the light on, and the object that looked like a do-nothing had no effect). Children were asked to explain this initial paired event, to provide a baseline comparison for their subsequent test trial explanations. Specifically, with both objects on their boxes, one box on and one off, children were asked, "Why did that happen?"

For each test trial, two objects were again simultaneously placed on the boxes. One object worked in a manner consistent with prior knowledge and the other object worked in a manner that was inconsistent. Unlike the confirmation trial, in the test trials the outcomes in both cases were causally identical (both boxes lit up in one test trial and neither box lit up in the other test trial). After viewing the paired outcomes of each trial, children were again asked, "Why did that happen?" Children were prompted several times in a nondirected manner after that initial causal question to provide additional explanatory information (e.g., "Can you tell me more?" or "Do you have any other ideas?"). For each trial, the child was encouraged to provide as many explanations as possible, and the trial was terminated after the child indicated that he or she had no other information to share.

Each child had one generative block of trials with one pair of light boxes (one confirmation trial and two test trials) and one inhibitory block of trials with the other pair of light boxes (one confirmation trial and two test trials). Which condition came first (generative or inhibitory) was counterbalanced.

Transcription and Coding

Interviews were videotaped and transcribed verbatim yielding the following measures for each trial: what the child looked at first, what he or she explained first, his or her overall explanatory response, and the kind of explanations he or she provided. During the confirmation trial, the outcome the child looked at first was coded (starter or stopper = 1, do-nothing = 0), followed by the outcome the child mentioned first (starter or stopper = 1, do-nothing = 0, both = 0.5, if a child referred to both outcomes in their first explanation).

For each test trial per condition, as in the confirmation trial, the outcome the child looked at first was coded (inconsistent = 1, consistent = 0). The outcome the child explained first was coded (inconsistent = 1, consistent = 0, both = 0.5), followed by a similar coding (inconsistent, consistent) for any additional explanations the child provided. Children's explanations for inconsistent and consistent outcomes were coded separately. For example, if the child provided an explanation for the inconsistent outcome, "'Cause this starter is broken, the parts inside don't work," and then provided an explanation for the consistent outcome, "'Cause this do-nothing is working, it doesn't make anything happen to the box," the child was coded as explaining the inconsistent outcome first, and then their overall explanations were coded individually as providing at least one explanation for the inconsistent outcome and providing at least one explanation for the consistent outcome.

Explanatory Categories

Children's explanations were also coded for content, separately for consistent and inconsistent outcomes. Causal explanations for inconsistent outcomes were coded into three primary categories: category switch, causal function, and causal action. In category switch explanations, children referred to a switch in category membership based on function (e.g., "It is a do-nothing now" or "It's really a starter; it only looks like a do-nothing"; see Table 2 for more examples). Notably, such explanations go beyond the past history of perceptually identical objects.

Explanations that discussed a problem with the functioning of the object were coded as causal function explanations. These explanations included reference to the object being broken ("The stopper is not working anymore. It is broken"), the box being broken ("The box does not light anymore. It is broken"), or differences among the objects ("This one is heavier than the others"). Explanations that referred to insides were also included ("There aren't stoppers inside" or "All out of batteries"). Explanations that referred to problems using the objects or problems with the placement of the objects were coded as causal action explanations ("You set the stopper/do nothing on the wrong sides" or "It's on the wrong box"; see Table 2).

Noncausal explanations were coded into four other categories: expectation violation, descriptive statements, psychological references, and don't know. Explanations that described what could be expected to happen on the basis of appearance or past events without providing a cause were coded as expectation violation (e.g., "it wasn't supposed to turn on"). Explanations that referred to the criteria children used as a basis for their conclusion without further explanation were coded as *descriptive statements* (e.g., "It's not on because it's not glowing up"). Explanations that referred to psychological constructs such as preference or desire (e.g., "maybe it wanted to") were also recorded, although these were quite rare. If children were unable to provide an explanation, their responses were coded as *don't know.*

Causal explanations for consistent outcomes were coded into three primary parallel categories: category label, causal function, and causal action. Explanations that referred to category membership using a label were coded as *category label* explanations (e.g., "Because this one is a stopper" or "this one is a do-nothing"). Unlike the category switch explanations for inconsistent outcomes, category label explanations involved providing a label that was consistent with the past history of perceptually identical objects. Causal function, causal action, and noncausal explanations for consistent outcomes

Table 2
Sample Causal Explanations for Inconsistent Outcomes

Category switch (Study 1): "It looks like there was one do-nothing, and it seems like it wasn't going to start but it did start. It's really a starter." "It looks like that one was a do-nothing, but it wasn't a do-nothing it was a stopper. It makes the box stop." "Because that is a starter, too. Because some are starters, too. Some of these are starters too."

Causal function (Study 1): "The stopper isn't working anymore; it's broken inside." "Because this went out of power. Because it doesn't have stoppers in it." "Because it's broken. I think because it doesn't have batteries in it."

Causal action (Study 1): "You set the starter on the wrong side." "The stopper should be on the other box, that's why it isn't working right." "They are on the wrong boxes."

Causal category (Study 2): "It's a toma, it just looks like it isn't one." "It turned on because it is a blick." "Because that one can make it turn off. It is the same kind of thing as the toma."

Causal function (Study 2): "The toma isn't working anymore; it's broken inside." "Maybe because this one has more air and energy." "The toma didn't stop. It didn't stop because it doesn't have any magnets in it."

Causal action (Study 2): "You set the blicket on the wrong side." "The toma should be on the other box; maybe try putting it on there." "Because that one (blicket) is supposed to be on the other side and the one that isn't a blicket is supposed to be on the other box."

were coded using the same criteria as explanations for inconsistent outcomes.

Interrater reliability was established using a randomly selected sample of 25% of the data. Two persons independently coded the reliability sample with 95% agreement. Reliability was also calculated for explanatory coding categories for both consistent and inconsistent outcomes, with kappas ranging from .86 to .94 (near perfect levels; Landis & Koch, 1977).

Results

We examined separately the events that resulted in greater attention and the events that resulted in increased explanation.

Which Outcomes Do Children Look at and Explain First?

Confirmation trials. In the confirmation trials, children were asked to explain a paired event in which both objects functioned in a manner consistent with prior knowledge. Among two possible trials, children were more likely both to look first at the object (starter or stopper) that changed the state of the box (63% of the time), $t(47) = 2.84$, $p < .01$, and to first explain the object that changed the state of the box (71% of the time), $t(47) = 4.57$, $p < .001$, when compared with the object that had no effect on the box (do-nothing). Beyond initial attention, children were significantly more likely to first explain the object that changed the state of the box in both the generative ($M = 69\%$) and the inhibitory ($M = 74\%$) conditions, with both of these greater than chance, $ps < .001$. Thus, in the absence of an inconsistent event or outcome, state change systematically trigged children's explanations. Negative outcomes, however, did not; even in the generative condition, where the confirmation trial pitted a state change event against a negative outcome event, children were significantly more likely to first explain the state change outcome than the negative outcome.

Test trials. In the test trials, events inconsistent with children's prior knowledge first attracted children's attention and provoked their explanations. Thus, across age groups and test trials (of four possible trials), children were much more likely to look first at the inconsistent outcomes than the consistent outcomes ($M = 3.73$, or 93% of the test trials), $t(47) = 18.61$, $p < .001$. More importantly, children were much more likely to explain the inconsistent outcome first ($M = 3.18$ out of 4, or 80%), $t(47) = 11.72$, $p < .001$.

In order to investigate potential age and condition-related effects, we conducted two separate repeated measures analyses of variance (ANOVAs) involving Age Group (3-, 4-, and 5-year-olds) × Condition (inhibitory vs. generative) × Final Outcome (both boxes on vs. both boxes off). Condition and final outcome were within-subjects factors, and age group was a between-subjects factor. One ANOVA involved first-look responses; the other involved first-explanation responses. In all age groups and conditions, children were very likely to look first at (3-year-olds on 90% of their test trials, 4-year-olds 95%, and 5-year-olds 95%) and explain first (3-year-olds 85%, 4-year-olds 78%, and 5-year-olds 78%) the inconsistent outcome. There was no main effect of age (for either the first-look or first-explanation analysis). Similarly, there were no significant main effects of condition (inhibitory vs. generative) or final outcome (both on vs. both off).

However, for the first-explanation analysis, the Condition × Final Outcome interaction was significant, $F(1, 45) = 4.62$, $p < .05$. Post hoc tests indicated that for the inhibitory condition, children were more likely to explain the inconsistent outcome when both boxes remained on (no state change) (84% of the time) than when both boxes turned off (state change; $M = 70\%$), $p < .05$. Importantly however, in both cases children were significantly more likely to look first at the inconsistent outcome than chance alone would predict, $ps < .001$.

As noted earlier, children participated in a confirmation trial prior to the test trials. One possibility is that participating in a confirmation trial may have influenced the pragmatics of the explanation task. For example, because children provided an explanation for an outcome in the confirmation trial, they may have been motivated to explain a different outcome in the trial that came next (i.e., the first test trial). Thus, if children provided an explanation for a state-change outcome in the confirmation trial (object that looks like a starter turned the box from off to on), and if their first test trial included a perceptually identical outcome (object that looks like a starter turned the box from off to on) compared with a different outcome (object that looks like a do-nothing turned the box from off to on), they may have been motivated to explain the latter because they had just explained the former on the prior (confirmation) trial. To investigate whether this sequencing influenced the results, we compared what the children explained first in their first test trial (following the confirmation trial) with what they explained first in their second test trial. There were no significant differences for test trial order, $t(47) = 0.97$, *ns*.

We also analyzed children's spontaneous explanations (provided prior to an explicit explanatory question) in order to address pragmatic concerns with the procedure. Namely, this analysis allows us to rule out the possibility that children were simply generating the explanation they believed the experimenter was requesting. For first explanations, spontaneous explanations revealed the same pattern of responses as elicited explanations. Sixteen of 48 children (33%) provided a spontaneous explanation at least once in the test trials. For 81% of the spontaneous explanations, children explained the inconsistent outcome first, $F(1, 47) = 132.89$, $p < .001$. Children's spontaneous explanation of inconsistent outcomes provides clear evidence that they were not merely explaining what they thought the experimenter was interested in.

Which Outcomes Do Children Provide an Explanation for Overall?

Children often provided multiple explanations for any test trial: 19%, 25%, and 50% of trials at ages 3, 4, and 5 years, respectively. For this analysis, the total number of explanations provided was the dependent variable. We conducted a 3 (age group: 3-, 4-, and 5-year-olds) × 2 (condition: inhibitory vs. generative) × 2 (final outcome; both boxes on vs. both boxes off) × 2 (consistent vs. inconsistent outcome) repeated measures ANOVA on the entirety of children's explanations. Condition, final outcome, and consistent versus inconsistent outcome were within-subjects factors. As can be seen in Figure 4, there were significant main effects for age group, $F(2, 45) = 14.18$, $p < .001$; condition, $F(1, 45) = 12.71$, $p < .001$; and, most importantly, consistent versus inconsistent outcome, $F(1, 45) = 63.12$, $p < .001$. Post hoc tests indicated that 5- and 4-year-olds gave explanations more consistently than 3-year-olds (Ms = 94%, 89%, and 69% of total responses, respectively), which is not surprising, given developmental changes in children's language skills over this age period. Most importantly, however, the significant main effect for consistent versus inconsistent outcome demonstrates that inconsistent outcomes were more likely to be explained than consistent outcomes (Ms = 3.98 and 2.73 of 4, or 99% and 68%, respectively). Not shown in Figure 4 is that overall explanations were more prevalent in the inhibitory ($M = 88\%$) than the generative condition ($M = 80\%$), as shown by the effect of condition. We can offer no firm account for this effect, but perhaps children found the initial state of the light boxes being on (inhibitory condition) more novel or unexpected than the initial state of the light boxes being off (generative condition).

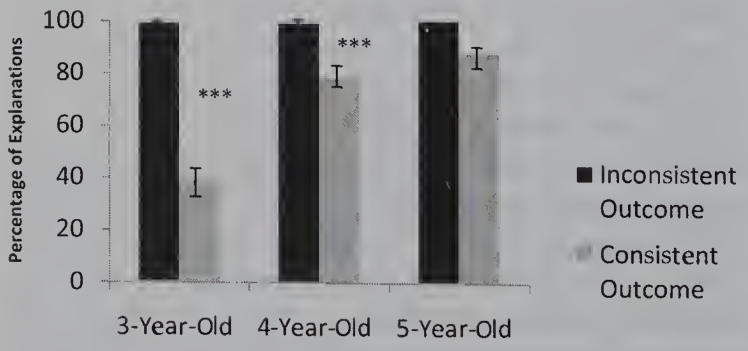

Figure 4. Study 1: Percentage of explanations children provided for inconsistent versus consistent outcomes by age group.
Note. Comparisons between explanations for consistent versus inconsistent outcomes.
$^{***}p < .001$.

The ANOVA also yielded a significant Consistent Versus Inconsistent Outcome × Age Group interaction, $F(2, 45) = 13.90$, $p < .001$, indicating developmental differences in the outcome children were most likely to explain overall. Post hoc tests reveal that although 3- and 4-year-olds were more likely to explain inconsistent than consistent outcomes, $ps < .001$, 5-year-olds were equally likely to explain both. The lack of effect for 5-year-olds reflects a ceiling effect (see Figure 4). There were as well a significant Condition × Consistent Versus Inconsistent Outcome interaction, $F(1, 45) = 12.62$, $p < .001$; a Condition × Final-Outcome interaction, $F(1, 45) = 6.88$, $p < .05$; and a three-way Condition × Final Outcome × Consistent Versus Inconsistent Outcome interaction, $F(1, 45) = 8.25$, $p < .001$. Nonetheless, for all four test trials (in each condition and each final outcome), children were more likely to provide an explanation for an inconsistent than a consistent outcome.

The Kinds of Causal Explanations Children Provided

Recall that children's explanations were coded into three primary causal categories: category switch (or category label in the case of consistent events), causal function, and causal action explanations. The majority of children's explanations at all age groups were causal (rather than the noncausal categories of expectation violation, descriptive statements, psychological references, and don't know). This was true for both inconsistent outcomes (55%, 81%, and 95% of the explanations provided at ages 3, 4, and 5, respectively) and consistent outcomes (76%, 74%, and 88% of the explanations provided at ages 3, 4, and 5). Explanations that made use of psychological explanations were very rare; only one 3-year-old and two 4-year-olds used psychological language in their explanations ("This one thinks it's a starter").

An Age Group (3-, 4-, and 5-year-olds) × Condition (inhibitory, generative) × Consistent Versus Inconsistent Outcome × Causal Explanation Type (causal function, causal action, category label/category switch) repeated measures ANOVA was conducted in order to investigate age and condition-related changes in the kinds of causal explanations children provided. Condition, consistent versus inconsistent outcome, and causal explanation type were within-subject factors. The number of total explanations provided (of each type) was the dependent variable. This analysis yielded the same main effects for age group, $F(2, 45) = 10.83$, $p < .001$, and consistent versus inconsistent outcome, $F(1, 45) = 24.19$, $p < .001$, described earlier; therefore, only results involving the different types of causal explanations given will be discussed here. Here, there was a significant main effect for causal explanation type, $F(2, 90) = 11.64$, $p < .001$. Causal function and category switch explanations (or category label explanations for consistent outcomes) were most common (and not significantly different from one another), and each was more frequent than causal action explanations, $ps < .01$.

Additionally, the Age Group × Consistent Versus Inconsistent Outcome × Causal Explanation Type interaction was significant, $F(4, 84) = 2.74$, $p < .05$. In post hoc simple effects analyses of children's explanations for inconsistent outcomes only, as shown in Figure 5, causal function ($M = 1.44$ out of 4 trials or 36%) and causal action ($M = 0.23$ out of 4 trials or 6%) explanations remained constant across age groups. Category switch explanations, however, increased significantly with age (16%, 38%, and 53% of total explanations at ages 3, 4, and 5, respectively), $F(2, 47) = 3.95$, $p < .05$. The percentage of participants that gave category switch, causal function, and causal action explanations at least once was calculated. These data are displayed in Table 3a. This analysis is a useful supplement to the data on proportion of total explanations of each explanatory type, because it demonstrates that a substantial portion of 3- and 4-year-olds make use of this kind of explanation. This finding is especially noteworthy given that category switch explanations require overriding perceptual appearances and prior knowledge about an object and spontaneously redefining category boundaries around function.

For consistent outcomes (not shown in Figure 5), whereas causal function explanations ($M = 1.19$ out

Study 2: Percentage of Children Giving Each Kind of Causal Explanation for Inconsistent Outcomes at Least Once by Age Group

	Category switch	Causal function	Causal action
3-year-olds	25%	94%	13%
4-year-olds	69%	50%	19%

of 4 trials or 30%) and causal action explanations ($M = 0.21$ or 5%) remained constant across age groups, $F(2, 47) = 1.47$, *ns*; $F(2, 47) = 1.78$, *ns*, category label explanations increased with age (6%, 24%, and 31% of total explanations at ages 3, 4, and 5), $F(2, 47) = 3.56$, $p < .05$. The increase in category label explanations with age for consistent outcomes parallels the increase in category switch explanations with age for inconsistent outcomes.

Discussion

The test trial data from Study 1 demonstrate that inconsistent outcomes are an especially powerful trigger for children's explanations. Given that children had readily available explanations for the consistent outcome, they could have easily ignored the inconsistent outcome and just explained the consistent outcome. Instead, children found outcomes inconsistent with prior knowledge especially noteworthy and were much more likely to explain an inconsistent outcome first, as well as more likely to provide multiple explanations for an inconsistent outcome overall. This pattern held across the generative and inhibitory conditions. Further, if children had just been paying attention to the perceptual outcome (such as state change or negative outcome), the event they explained should have been at chance, given that in the test trials the outcomes were identical (both boxes were on or off). Indeed, data from the confirmation trials showed that in the absence of an inconsistent event or outcome, state change did serve as a trigger for children's explanations. But on test trials children explained inconsistent outcomes whether they involved state change or not. Finally, one could argue that children were primed to provide an explanation for the *consistent* outcomes prior to the test trials, because the confirmation trial (which appeared first) asked children to explain outcomes that were consistent with their prior knowledge about how the objects function. Nonetheless on test trials children systematically explained inconsistent events.

At the same time, it was not the case that children never explained consistent outcomes and therefore that children's explanations were never confirmatory. In their overall explanations, children did competently and easily provide explanations for consistent events as well. Constructing explanations for events that are consistent with children's prior knowledge and experience must at times also be important, providing children with opportunities to deepen their understanding of expected phenomena. (Indeed, in our data children often did generate "deeper" explanations of consistent events by generating causal function explanations that cited possible mechanisms, such as underlying causal properties and internal components.) In short, we propose that outcomes inconsistent with prior knowledge are especially powerful triggers for causal explanatory cognition, not that children do not or cannot generate explanations for outcomes consistent with their prior knowledge.

Exactly how children explain events provides further insight into their understanding of the causal basis for the outcome. Children provided three distinct kinds of causal explanations: causal function, category switch (or category label in the case of consistent outcomes), and causal action explanations. Across age groups, causal function explanations were given quite frequently overall, with more than half of the children at each age providing at least one such explanation. Causal function explanations referred to alternative or problematic functioning for inconsistent outcomes and referred to the object functioning correctly for consistent outcomes. Causal function explanations often included information about unobserved inside parts (power, batteries) or underlying causal properties (energy, electricity). For example, a 3-year-old explained, "Because this ran out of lights. Because it doesn't have light stoppers in it," and according to a 4-year-old, "The starter isn't working right, its inside parts must be all broken."

Category switch explanations for inconsistent outcomes were also frequent (e.g., "It's really a starter; it only looks like a do-nothing" or "Hey! This one is a starter too! I thought it wasn't but it is!"). These explanations are noteworthy because they entail spontaneously redefining category boundaries and privileging functional information over appearance. When explaining consistent outcomes, children also evoked the category label (e.g., "Because it's a starter. Starters make the light in the boxes turn on"), but without these additional features. Category switch explanations increased with age, and by 5 years of age, more than two thirds of participants provided at least one such explanation for inconsistent outcomes.

Prior research shows that even 3-year-olds can categorize objects in terms of novel, nonobvious properties (Gelman & Coley, 1990; Gelman & Markman, 1986, 1987), can apply names to objects with the same functional properties (Kemler-Nelson, 1995), and can categorize and name objects based on novel causal properties (Gopnik & Sobel, 2000). What is unique about the present task is that children spontaneously generated nonobvious, invisible properties for items and recruited this sort of reasoning to explain why items functioned in both expected and unexpected ways.

Several open questions remain, in particular about our use of functional labels in Study 1. Children's responses might have been scaffolded by the object labels (starters, stoppers, and do-nothings), which were straightforward descriptions of their functions. For example, during inconsistent events, rather than truly noting the inconsistent outcomes, children instead may have noted the inconsistency of the observed function compared to the (inferred) label. Additionally, among the most interesting kinds of explanations provided by children in Study 1 were category switch explanations. However, given the nature of the functional label, it is unclear whether children were actually relabeling on the basis of causal effects or whether instead they were simply giving a more literal description of function (i.e., "it's not really a starter" may be equivalent to "it didn't start it"). Study 2 was designed specifically to address these possibilities.

Study 2

Study 2 addressed whether explanations for events not in accord with prior knowledge were scaffolded by the use of functional labels (*starters*, *stoppers*, and *do-nothings*) in Study 1, because the objects violated labeled functions. To investigate this, in Study 2 we used novel, nonfunctional labels for the objects (*toma*, *blicket*). Given that even 2-year-olds can extend novel labels based on function (Kemler-Nelson, 1995), we expected that children in Study 2 would also make use of information about function and underlying causal properties, much as in Study 1, even when the labels are novel and do not, in themselves, provide additional causal information. Additionally, based on Study 1, we predicted that children would again focus more on explaining events inconsistent with prior knowledge, even when the labels themselves do not carry any functional information.

Method

Participants

Given the near ceiling performance by 5-year-olds on several measures in Study 1, here we focused on younger children. Sixteen 3-year-olds (*M* age = 3.5; range = 3.0–3.10) and sixteen 4-year-olds (*M* age = 4.4; range = 4.0–4.11) who had not participated in Study 1 were recruited from a Midwestern U.S. university town. Participants were primarily White and from middle-class families. Approximately equal numbers of boys and girls participated in the study.

Materials

The materials used in Study 2 were identical to those from Study 1.

Procedure

The procedure for Study 2 was modeled on Study 1, with a single critical modification: The objects were given nonfunctional, novel labels (*a toma/not a toma* and *a blicket/not a blicket*), and were never referred to as *a starter*, *a stopper*, or *a do-nothing*. The confirmation and test trials were identical to those of Study 1.

Transcribing and Coding

The same procedure for coding Study 1 was amended slightly for Study 2 (to encompass reference to tomas and blickets instead of starters and stoppers). Table 2 provides examples of category switch, causal function, and causal action explanations from Study 2. Interrater reliability was established using a randomly selected sample of 25% of the data. Two persons independently coded the reliability sample with 98% agreement. Reliability was calculated for explanatory coding categories for both consistent and inconsistent outcomes, with kappas ranging from .92 to .94, all within near perfect levels (Landis & Koch, 1977).

Results

As in Study 1, we assessed whether events inconsistent with prior knowledge led to greater interest and attention, and most importantly, were first and most often explained.

Which Outcomes Do Children Look at and Explain First?

Confirmation trials. In the confirmation trials, children were more likely to look first at the object that changed the state of the box (started or stopped it) (64% of the time), $t(31) = 2.06$, $p < .05$, and to first explain the object that changed the state of the box (62% of the time), $t(31) = 1.97$, $p < .05$, when compared with the object that had no effect on the box. Although children were more likely to first explain the object that changed the state of the box in both conditions, in the generative condition ($M = 70\%$) they did so above chance, $t(31) = 2.63$, $p < .01$, but in the inhibitory condition ($M = 53\%$) they were at chance, $t(31) = 0.32$, *ns*. One possible explanation is that children are more compelled by an object that fails to turn the light box off than an object that fails to turn the light box on. More importantly, and as in Study 1, in the generative condition, where the confirmation trial pitted a state change event against a negative outcome, children were significantly more likely to first explain the state change outcome than the negative outcome.

Test trials. Again, inconsistent outcomes both attracted children's attention first and provoked children's explanations. Across age groups, children were much more likely to look first at the inconsistent outcomes than the consistent outcomes ($M = 3.25$ out of 4 or 81%), $t(31) = 7.44$, $p < .001$. Likewise, children were much more likely to explain the inconsistent outcome first ($M = 3.05$ or 76%), $t(31) = 9.86$, $p < .001$.

In order to investigate potential age- and condition-related effects, an Age Group (3- and 4-year-olds) × Condition (inhibitory, generative) × Final Outcome (both boxes on, both boxes off) repeated measures ANOVA was conducted. Condition and final outcome were within-subjects factors and age group was a between-subjects factor. As in Study 1, at all age groups and conditions, children were very likely to look at (3-year-olds 83%, 4-year-olds 80%) and explain (3-year-olds 75%, 4-year-olds 78%) the inconsistent outcome first. Thus, there was no significant main effect of age (for either the first look or first explanation analysis). There were also no significant main effects of condition (inhibitory vs. generative) or final outcome (both on vs. both off). Moreover, unlike Study 1, none of the interactions were significant.

As in Study 1, to investigate the possibility that the sequential structure of the task may have influenced the outcome children were motivated to explain first, across conditions, the outcome children explained in the test trials they were presented with first (following the confirmation trial) were compared to the outcome they explained in the test trials they were presented with second. There were no significant differences for test trial order, $t(31) = .71$, *ns*.

Spontaneous explanations children provided prior to an explicit explanatory question were also analyzed as a supplementary analysis. As in Study 1, spontaneous explanations revealed the same pattern of responses as elicited explanations for first explanation. Ten of the 32 children participating provided a spontaneous explanation at least once in the test trials (31%). For 90% of the spontaneous explanations children explained the inconsistent outcome first, $F(1, 31) = 185.61$, $p < .001$. Children's interest in explaining inconsistent outcomes even without an explicit explanatory question provides clear evidence that children were not merely explaining what they thought the experimenter was interested in.

Which Outcomes Do Children Provide an Explanation for Overall?

As in Study 1, children often provided multiple explanations. When focused on the total number of explanations provided, children were again much more likely to explain events inconsistent with their prior knowledge than events consistent with their prior knowledge. In order to investigate potential age and condition-related effects, we conducted a 2 (age group: 3- and 4-year-olds) × 2 (condition: inhibitory, generative) × 2 (final outcome: both boxes on, both boxes off) × 2 (consistent vs. inconsistent outcome) repeated measures ANOVA on the entirety of children's explanations. Condition, final outcome, and consistent versus inconsistent outcome were within-subjects factors. The only significant effect was for consistent versus inconsistent outcome, $F(1, 30) = 22.64$, $p < .001$, reflecting that inconsistent outcomes were more likely to be explained than consistent outcomes ($M = 3.94$ or 99% for inconsistent outcomes and $M = 2.78$ or 70% for consistent outcomes). As shown in Figure 6, both 3-year-olds, $t(15) = 3.47$, $p < .01$, and 4-year-olds, $t(15) = 2.7$, $p < .05$, showed this effect. The

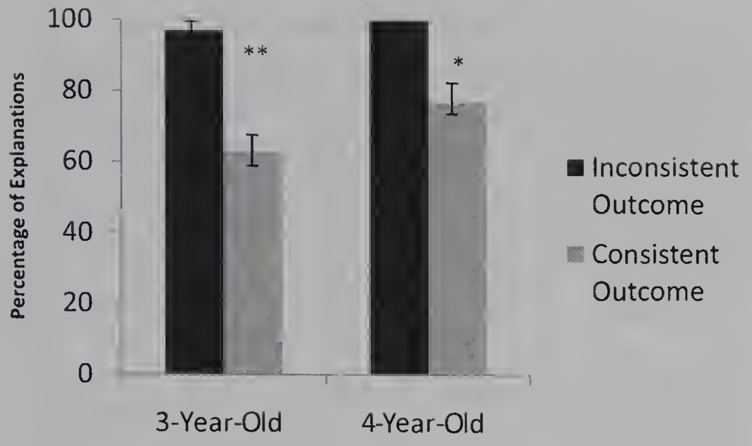

Figure 6. Study 2: Percentage of explanations children provided for inconsistent versus consistent outcomes by age group.
Note. Comparisons between explanations for consistent versus inconsistent outcomes.
$^{*}p < .05$. $^{**}p < .01$.

lack of any significant effects for age group and condition may reflect the more narrow age range in Study 2 (only 3- and 4-year-olds) in comparison with Study 1 (3-, 4-, and 5-year-olds).

The Kinds of Causal Explanations Children Provided

As in Study 1, the majority of children's explanations at all age groups were causal, for both inconsistent outcomes (81% and 84% at ages 3 and 4, respectively) and consistent outcomes (63% and 74% at ages 3 and 4). An Age Group (3- and 4-year-olds) × Condition (inhibitory, generative) × Consistent Versus Inconsistent Outcome × Causal Explanation Type (causal function, causal action, category label/category switch) repeated measures ANOVA was conducted in order to investigate age-related changes in the kinds of causal explanations children provided. Condition, consistent versus inconsistent outcome, and causal explanation type were within-subject factors. The number of total explanations provided (of each type) was the dependent variable.

As predicted, and as noted earlier, there was a significant main effect for consistent versus inconsistent outcome, $F(1, 30) = 25.94$, $p < .001$. The main effect for causal explanation type was also significant, $F(2, 60) = 9.77$, $p < .001$. Post hoc tests indicate that children were more likely to provide causal function explanations than causal action explanations, *ps* < .01. This can be seen in Figure 7.

The three-way Age Group × Consistent Versus Inconsistent Outcome × Causal Explanation Type interaction was also significant, $F(2, 60) = 5.64$, $p < .01$. This interaction indicates, as in Study 1, that there were changes with age in the kinds of causal explanations that children provided for inconsistent outcomes. Whereas causal action explanations remained constant (and infrequent) across age groups, causal function explanations decreased with age, $p < .001$, and category switch explanations increased with age, $p < .01$ (see Figure 7). We also examined the number of participants that gave category switch, causal function, and causal action explanations for inconsistent outcomes at least once. These results are informative because, as in Study 1, they indicate that a substantial portion of 3-year-olds and most 4-year-olds provided at least one category switch explanation, but also that 3-year-olds were very likely to provide explanations based on the causal functioning of the objects, even though the objects were given novel, *nonfunctional* labels (Table 3b).

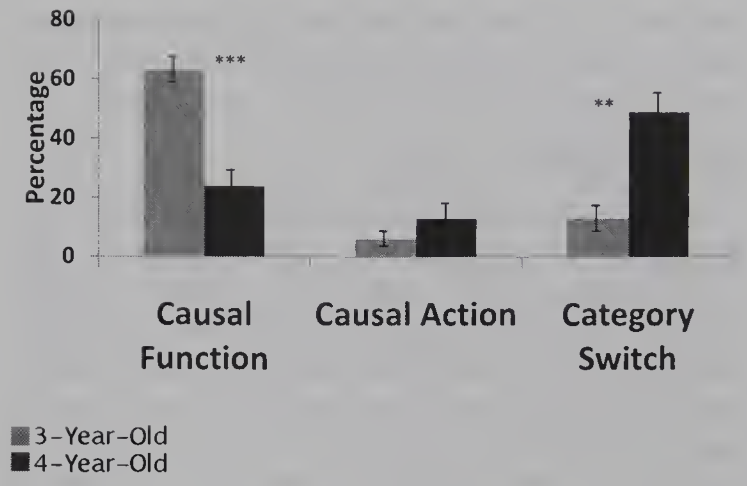

Figure 7. Study 2: Percentage of explanations types for inconsistent outcome by age group.
Note. Comparisons between age groups.
$^{**}p < .01$. $^{***}p < .001$.

For consistent outcomes (not shown in Figure 5), whereas causal function explanations and causal action explanations remained constant across age groups, category label explanations increased with age, $p < .05$. As in Study 1, this parallels the increase in category switch explanations with age for inconsistent outcomes.

Additional post hoc tests revealed that 3-year-olds were more likely to give causal function explanations for inconsistent ($M = 2.5$ out of 4 or 63%) than consistent outcomes ($M = 1.4$ or 35%), $p < .01$. Four-year-olds were more likely to give causal action explanations for inconsistent (13%) than consistent outcomes (3%), $p < .05$, and more likely to give category switch explanations for inconsistent outcomes (48%) than category label explanations for the consistent outcomes (24%), $p < .01$. Explanations that made use of psychological causes/descriptions were very rare; only two 3-year-olds and one 4-year-old used psychological language in their explanations (''This one doesn't know how to act; it isn't working right'').

Comparing Studies 1 and 2

Overall, the results from Studies 1 and 2 were highly similar. Across both studies, children's explanations on the confirmation trials focused on state changes. For test trials for both studies, inconsistent outcomes were especially likely to provoke children's explanations. Moreover in both studies, the content of children's explanations, specifically category and causal function explanations, consistently referred to underlying, internal causal mechanisms, overriding perceptual appearances. This is especially noteworthy for Study 2, where the labels were novel and provided no explicit functional information. Thus, the results of Study 1 cannot be attributed merely to the use of functional labels. One difference did occur: Children were more likely to look at the inconsistent outcome first in Study 1 (93%) than in Study 2 (81%), $F(1, 79) = 7.24$, $p < .01$, indicating that the functional labels seem to have increased children's attention to the inconsistent outcome. However, in both studies, children were equally likely to explain the inconsistent outcome first (80% in Study 1 and 76% in Study 2). Thus, children's explanations of inconsistent outcomes depend on noticing those outcomes, but language can influence children's attention and explanation.

Discussion

Study 2 further demonstrates that children focus more on explaining events inconsistent with prior knowledge than events consistent with prior knowledge, even when the labels themselves do not provide functional information. Moreover, children's causal explanations make reference to function and underlying causal properties. As in Study 1, children privileged function information over perceptual features; evoked causal mechanisms and unobservable, internal causal properties; and spontaneously used (novel) labels to redefine category boundaries around shared function. Thus, several key results of Study 1 were not merely redescription based on the functional labels provided there. Finally, Study 2 provides evidence that use of functional labels was not what drew children to explain inconsistent events (because of the inconsistency of the outcome with a functional label), but instead children are more generally motivated to provide explanations for outcomes that were inconsistent with their prior knowledge.

General Discussion

Causal explanation is a goal-directed cognitive activity that depends on what is relevant or important to the explainer. Given the potentially unlimited number of outcomes one could explain, especially for young children early in the process of developing causal knowledge, identifying the specific kinds of events, outcomes, and goals that trigger explanation provides insight into what motivates and guides causal cognition. Although a substantial amount of developmental literature has demonstrated that young children frequently seek (Callanan & Oakes, 1992) and provide explanations (Wellman et al., 1997), little is known about what triggers this childhood explanatory activity.

If children have a cognitive model of the world based on a framework of anticipatory regularities, they would be well equipped to rapidly form expectations contingent on prior beliefs or knowledge. Indeed, even infants differentially attend to and explore events or objects inconsistent with such anticipatory regularities (Baldwin, Markman, & Melartin, 1993). In our data so do preschoolers; they first attend to inconsistent over consistent outcomes. Attention is not explanation, however. Research on confirmation bias in scientific reasoning provides evidence that patterns of attention do not guarantee sufficient motivation to generate explanations or promote causal learning (Dunbar & Klahr, 1988; Kuhn, 1989). Children could easily note inconsistent outcomes but be motivated primarily to explain consistent outcomes. Because such events conform to known expectations, they provide a foundation for constructing more generalizable causal explanations—particularly for young learners. In contrast, our data demonstrate that inconsistent outcomes were an especially powerful trigger for young children's explanations. Across both generative and inhibitory conditions, with meaningful functional labels and with arbitrary novel labels, children were much more likely not only to attend to but also to explain the inconsistent outcome.

In the course of this research we considered additional factors possibly relevant to children's explanations (such as state change or negative outcomes). An important feature of the test trials in Studies 1 and 2 was that they controlled for these additional potential explanatory triggers by holding them constant. Confirmation trials, however, allowed examination of state change or negative outcome as a potential explanatory trigger in the absence of an inconsistent outcome. Although inconsistency with prior knowledge is a compelling trigger for children's causal explanations, in the absence of this information, state change was an additional explanatory trigger. We suggest that attention to state change may hold generally, beyond the particulars of this experiment. For example, children may expect individuals to stay healthy or objects to remain in motion—in which case state changes, such as contracting illness, may trigger children's explanations.

Another interesting possibility is that there may be differences in what one attends to, depending on where one is in the theory construction process. It is quite striking that children attend to and explain inconsistent outcomes after only minimal exposure to the contingencies. It may be the case that earlier in the theory construction process children are more receptive to inconsistent information and less so later on. Schema research supports this possibility. The memory advantage of schema-inconsistent items became weaker as the proportion of anomalous or schema-inconsistent items becomes larger (Rojahn & Pettigrew, 1992). Attending to frequency information would also help reconcile the motivation to seek causal regularities while responding to inconsistent information. Research on clustering accounts of causal learning predicts that inconsistent items are better remembered because they are differentiated from clusters that capture regularities (Sakamoto & Love, 2004). Frequency information may then drive the decision to integrate inconsistent information into an existing cluster or schema or create an additional schema to accommodate the new information. Further exploration of the conditions in which children focus on consistent information versus inconsistent information would be an interesting direction for future research.

More generally, an important open question is the role that explanatory processes play in children's development. There is mounting evidence that children's causal explanations may in fact constitute a mechanism for causal learning (Chi et al., 1989). When children are asked to explain events, they learn better than when given simple feedback about whether their predictions are correct (e.g., Amsterlaw & Wellman, 2006; Chi, DeLeeuw, Chiu, & LaVancher, 1994; Siegler, 1995). But how does this work? If explanation is a mechanism for learning, children should provide explanations for events that have the potential to teach them something new. Events that are inconsistent with prior knowledge provide just such an opportunity. Such an explanatory tendency could aid in learning by focusing children on events that challenge current causal knowledge and provoke additional, amended causal reasoning. Given that mere attention to inconsistent information is insufficient to ensure causal learning or theory revision (Kuhn, 1989), explanation may serve as a critical mechanism for integrating and reconciling inconsistent information with existing theories or knowledge structures.

The nature of children's explanations, in appealing to unobserved explanatory processes and functional properties, could similarly aid learning. Explanations that appeal to underlying causes and mechanisms engage children in the important interplay between data and theory that leads to theory change (Wellman & Gelman, 1998). Children's explanations for inconsistent outcomes, in particular, systematically referred to such features. For example, as shown in Table 2, children explained inconsistent outcomes by stating that "All the energy is gone" or "Maybe that toma doesn't have batteries in it." Additionally, category switch explanations (e.g., "It looks like a toma, but it's not. It's not really a toma at all") indicate that even 3-year-olds privilege functional information over appearances.

Our data offer insight into the function of children's explanations by providing empirical evidence for the kinds of events that guide causal cognition by motivating children to construct explanations. Although the present experiments do not directly test the hypothesis that children's explanations play an active role in the learning process, they are consistent with this proposal and provide a promising empirical basis for investigating the interplay of explanation and learning in ongoing and future research.

Tattling, defined as the reporting to a second party of norm violations committed by a third party, is a frequent but little-studied activity among young children. Participant observation and quantitative sampling are used to provide a detailed characterization of tattling in 2 preschools (initial mean age = 4.08 years, $N = 40$). In these populations, tattling represents the majority of talk about peers' behavior to third parties. It is usually truthful, it rarely refers to transgressions committed against other individuals, it is not often ignored by adults, it is performed more frequently by dominant children, and it correlates with teacher reports of relational aggression. These exploratory results suggest several new avenues of research into children's developing understanding of social norms.

Moral understanding does not develop in isolation from other competences, but is used by children to navigate everyday social interactions (for overviews, see Dunn, 2006; Turiel, 2006). An example is the use of normative appeals (e.g., "That's not fair!") in attempts to resolve social conflicts. Naturalistic observation has proved useful in analyzing such behavior, dating back to Piaget (1932), who studied appeals to social norms in the context of children's street games. In family contexts, Dunn (1988) carried out extensive naturalistic studies of young children's spontaneous justification and condemnation of everyday social behavior (see especially Dunn & Munn, 1987). Despite Piaget's lead, such activities have received less attention in peer contexts, although Nucci and Turiel (1978) did observe the responses of preschool children to moral and conventional transgressions by peers in naturalistic settings. One of the categories of responses that they considered was that of verbal reports to the teacher. This kind of response is interesting because it represents the use of evaluative language to recruit third-party involvement in social problems, suggesting an early awareness of the moral force of language.

In the present article, we link preschool children's everyday language use to their social and moral development through a naturalistic study of *tattling*. We define tattling as *the reporting to a second party of a third party's counternormative behavior*, where "counternormative" may refer to explicitly proscribed behavior, or to behavior that is unwelcome to the individual who reports it and that they implicitly believe will also be unwelcome to their audience. The structure of tattling therefore offers a window on how individual children start to relate to social norms and to incorporate them in everyday discourse.

Social norms can operate effectively only if they are taught to new generations of children. Nichols (2004) has argued that norms are more likely to be selected for—through cultural selection—if they can effectively pass through the "cognitive filter" of children's learning processes, which are more likely to happen if they produce a strong affective response. Independent of this affective component, Nichols also postulated that children are primed to acquire a "normative theory" early in development, suggesting that even very young children are sensitive to normative statements by adults. He cited the experiments of Harris and Núñez (1996), who showed that 3- to 4-year-old children were especially sensitive to actions that breached a

permission rule, compared to actions that breached a description rule. Their participants were better at identifying a picture where a child was "doing something naughty" than a picture where a child was "doing something different" (1996, Experiment 4; cf. Cosmides, 1989). Results similar to this have been found in cross-cultural studies with children (Harris, Núñez, & Brett, 2001) and adults (Sugiyama, Tooby, & Cosmides, 2002), suggesting that there may be an innate cognitive bias toward identifying breaches of social norms. Harris (2000) has pointed out that young children seem to generalize very readily about normative obligations: "Any novel obligation is understood in the light of a well-organized, pre-existing concept of constraint" (p. 158). The same point was made by Rakoczy, Warneken, and Tomasello (2008), who conducted experiments in which an experimenter demonstrated novel games (e.g., "daxing"), played by unfamiliar rules, to 2- and 3-year-old children. When a puppet started playing and broke these rules, the 3-year-olds spontaneously made both "normative protests" (e.g., "That's not how you do it!") and "imperative protests" (e.g., "Don't do that"). The 2-year-olds were apparently too young to make a significant number of normative protests, but even at this early age they were given to making imperative protests about the puppet's behavior.

If young children are especially sensitive to norm violations in an experimental context, the same cognitive bias might influence their natural verbal behavior. We suspected that the general sensitivity toward norm violations revealed by these experiments would make young children more likely to report everyday norm violations by peers. This led us to predict that tattling (as broadly defined above) would make up a large part of children's everyday communication about third-party behavior, and that a study of the general characteristics of tattling would reveal interesting features of children's attitudes to social norms.

Although analogous activities—such as snitching (Rosenfeld, Jacobs, & Wright, 2003), whistleblowing (Brewer & Selden, 1998), or eyewitness testimony (Loftus, 1979)—are practiced by adults when they report criminal behavior to an authority figure, the word *tattling* is usually associated with young children's behavior. For much of the 20th century it was disapproved of by educators, and seen as a practice that children needed to be educated away from (Williams, 1989). While not infrequently mentioned in studies of child development, tattling has rarely been analyzed in depth, but more often simply listed as an example of undesirable behavior (e.g., Hurlock & McDonald, 1934; McConnell, 1963). A more detailed early treatment was by Smith (1932), who noted that negative "criticism" of a third party by children was much more common than positive comments, and that unlike adults, children often made their criticisms within earshot of the target. This suggests that children did not see anything counternormative about the act of tattling, even in an era when tattling was likely to be frowned upon by adults.

Apart from Smith's (1932) early and rather unsystematic study of children's criticisms, no previous observational study seems to have focused on tattling in an educational setting. The only modern observational study devoted to tattling was by Ross and den Bak-Lammers, who carried out a longitudinal study of sibling dyads aged 2 and 4 (Den Bak & Ross, 1996), and 4 and 6 (Ross & den Bak-Lammers, 1998). Siblings were observed in their family homes, and all their utterances recorded for later analysis. For all the age groups studied, tattling made up a large proportion of talk about the sibling's behavior. This proportion decreased with age (although tattling did increase in absolute frequency), ranging from 87.1% among the 2-year-olds, through 74.8% among the 4-year-olds, to 56.4% among the 6-year-olds. One of the main aims of the present study was to find out whether the preponderance of tattling in young children's communication about siblings would generalize to their communication about unrelated peers.

Tattling on peers is quite prevalent among children in elementary school settings, as Skinner, Cashwell, and Skinner (2000) anecdotally attested for the 9- to 10-year-old children with whom they studied. Skinner and his colleagues had some success with their program to encourage "tootling" (a term they coined for the reporting of prosocial behavior) by providing a collective reward for the class when they reached a target number of "tootles" (see also Morrison & Jones, 2007). Implicit in their account was the point that tattling, unlike tootling, does not have to be extrinsically rewarded in order to take place but presumably has some sort of intrinsic motivation. In some situations tattling may be motivated by processes of emotion regulation (Thompson, 1994). Cooney, Hutchison, and Costigan (1996) postulated that toddlers' tattling is an intermediate stage in emotion regulation, which supersedes direct physical aggression and precedes more sophisticated forms of negotiation with peers that do not rely on adult intervention.

By adolescence, the overt reporting of peers' transgressions to adult authority figures seems to become much less common. In a questionnaire-based study of tattling among teenagers in a residential care program, Friman et al. (2004) found that perceived rates of tattling correlated negatively with likeability and positively with social rejection. On the other hand, evaluative talk about peers to other peers becomes more important during preadolescence and adolescence (e.g., Cameron, 1997; Fine, 1986; Goodwin, 1990). Several groups of researchers have considered evaluative talk among these age groups in terms of the theoretical constructs of *relational*, *indirect* and *social aggression* (reviewed by Archer & Coyne, 2005). Central to the first two of these constructs, and often implicit in the third, is the idea that such verbal aggression is often covert, so that perpetrators are able to conceal their identities from their victims.

However, few observers have recorded covert talk about others' behavior among children younger than 9 years. In a discussion of children's gossip, Fine (1977) pointed out that early forms of talk about peers are rarely covert: "One salient difference between the social structure of adult gossip and that of children is that adult gossip is virtually always about non-present others, whereas children often gossip in front of the target" (p. 183). Mettetal (1983) conducted quantitative, naturalistic research into children's everyday talk about peers, and found that the frequency of gossip-like discussions between dyads of girls increased dramatically between the ages of 6–7 and 11–12, rising to about one third of all conversations. A similar pattern was found by Engel and Li (2004), who asked three groups of children—aged 4, 7, and 10—to tell stories about their friends in semistructured interviews. The length, descriptiveness, and evaluative content of the stories all increased significantly with age, implying that the younger children's stories were far less informative than the older children's. This supported Engel and Li's naturalistic observation, from tape recordings of conversations in a day-care center, that 4-year-old children very rarely told stories about absent peers: "It was surprisingly difficult to catch the children gossiping" (p. 160). Coupled with the observation of Ross and den Bak-Lammers (1998) that tattling occupies a decreasing proportion of overall communication about sibling behavior, these results suggest that overt tattling may decrease in importance through middle childhood at about the same time that covert gossip increases.

From this brief survey of the existing literature on tattling and other forms of evaluative social discourse in children, the following points informed our research design. First, tattling is a widespread activity among young children, but one that has been little studied in any context—and that has never been systematically studied in the context of the preschool classroom. Second, as children grow older, tattling to adults becomes both less frequent and less overt: It tends to have negative reputational consequences, whereas the covert reporting of peers' activities to other peers becomes more common. Third, tattling may involve the socialization of aggressive impulses, representing an intermediate stage between physical violence and negotiation when a child is confronted with unwelcome behavior from a peer. With these points in mind, we carried out an exploratory observational study of tattling in the preschool classroom. As tattling had never been systematically studied in the preschool context, our study sought principally to establish a baseline of data about the general characteristics of young children's tattling within peer groups. The aim was to compare the results with existing data on tattling in the home, and ultimately to generate hypotheses for more focused observational and experimental work.

Method

We used a mixture of quantitative and qualitative empirical approaches (Tashakkori & Teddlie, 2003) to characterize as many different properties of tattling as possible. The first author engaged in participant observation of the children while working as a volunteer classroom assistant in two preschools. For about half of the observation time, he took on the more detached role of an independent observer and conducted behavioral sampling. The qualitative and quantitative methodologies were complementary in that the former helped us understand the meanings and motivations of acts of tattling for both children and adults, whereas the latter allowed us to quantify various descriptive properties of tattling.

Participants

Research was conducted in two inner-city preschools in Belfast, the principal city of Northern Ireland. The first preschool studied (Preschool A) was situated in a low-income residential area of Belfast, inhabited overwhelmingly by working-class Catholics. All the children came from (Northern) Irish families, with the exception of one child who was of mixed Irish/Portuguese parentage. When research began in November 2006, there were 15 children in the preschool (8 boys and 7 girls). Their age at the start of the research, which lasted for three calendar months, ranged from 3.52 to 4.32 years ($M = 3.97$). In January 2007 they were joined by a younger girl aged 3.09 years, who was present for about half of the study time. Preschool B was situated in a semiresidential area of inner Belfast with a large immigrant population and was attended by a mixture of children who lived locally and those whose parents worked nearby. Hence, the children's cultural backgrounds were more diverse than in Preschool A: The majority came from (Northern) Irish families, but 4 of the children studied were Chinese, 1 was Malaysian, 1 Nigerian, and 1 Zimbabwean. In addition, 2 children were of mixed ethnicity (Irish/German and Irish/Spanish). The study group comprised 24 children (13 boys and 11 girls). Their age at the start of the study, which lasted for 2 months from April 2007, ranged from 3.23 to 4.65 years ($M = 4.11$).

Participant Observation

Participant observation allows a researcher to map out the social and cultural context of human activities, rather than taking an isolated reading of behavior as with more structured observational techniques (Hammersley & Atkinson, 2007; see Corsaro, 2003, on participant observation in preschool settings). This method was used to contextualize the quantitative research, partly by investigating the meaning and motivation of children's acts of tattling, and partly by getting a sense of how it felt, as an adult in a position of authority, to receive behavioral reports from children about their peers. The first author spent 2 months engaged in participant observation at Preschool A, working 3–4 days per week, for a total of 98 hr over 33 study days. He later spent 2 months at Preschool B, working 2–3 days per week, for a total of 96 hr over 23 study days. Both figures include time spent in quantitative sampling: After the first week, which was devoted solely to participant observation, most observation sessions started and finished with a period of participant observation. Field notes were typed up each afternoon after school had finished. In between the visits to the two preschools, and during the analysis phase after all observation was over, we analyzed the qualitative field notes and categorized emergent themes in the research (e.g., the various motivations for tattling).

Event Sampling

The quantitative method used most extensively in this study was the event sampling of children's reports of peers' behavior. Event sampling was chosen because it is a useful method for systematically recording a wide range of properties of everyday experience, and for generating novel hypotheses (Reis & Gable, 2000). At Preschool A, the first author spent 31 hr on event sampling, spread over 15 study days in continuous sessions of between 1 and 3 hr in duration. At Preschool B, he spent 35 hr on event sampling, over 15 study days. An event in this study was defined as a verbal report of a peer's behavior (whether counternormative or not), made by a child to someone else. Every event that was overheard by the observer was recorded on paper, as soon as possible after it occurred (usually within 1 min, and nearly always within 5 min). A small number of events in the sessions (< 20 in total) were omitted, either because of partial inaudibility or because the observer was too busy to record them when they occurred.

For each event, the following information was coded on preformatted coding sheets in the observer's notebook: the *time* at which the event occurred; the child(ren) who made the report (the *tattler*); the child(ren) who performed the reported action (the *miscreant*); the adult(s) or (occasionally) child to whom the report was made (the *audience*); the person most affected by the reported behavior (the *victim*), which was defined as either the tattler themselves, the audience, a third party, or nobody in particular; the *truth value* of the tattler's account (true, false, or indeterminate); the free-text *content* of the tattler's report (often verbatim); and a free-text description of the audience's *response* to the event. After data collection, content analysis of the content and response free-text fields was used to code data using the coding schemes in the two paragraphs below. For these additional categories, half of the events were rated independently by a second person who was blind to the observational predictions and was given the definitions below, along with examples similar to those in the appendices. Interrater reliability for content type was 90%, and for response type it was 89% (Cohen's kappas were .87 and .84, respectively).

Content type. Reports of peers' behavior were assigned to one of 10 categories, following Ross and den Bak-Lammers (1998). See Appendix A for examples. Eight of these categories were considered to represent various kinds of norm violation. Reports of *physical aggression* referred to any kind of unwanted physical contact, for example, hitting or pushing. *Property damage* reports described any kind of damage to property, for example, breaking a toy, or knocking over some blocks. *Property entitlement* covered reports of someone taking something that belonged to another child, or that another child had been using, as well as children refusing to share objects that they themselves owned or were using. A report of *social convention* referred to a violation of some conventional rule of the classroom, such as standing on a chair, or poor table manners. *Joint play violations* included reports of a child obstructing another child's play, or refusing to play alongside them. Reports of *taunting* referred to one child shouting at another or calling them names. *Deception* reports described another child lying to or otherwise misleading someone. Reports of *disagreement* referred to one child denying something that another child had said or believed in. There were also two categories of reports that did not meet the definition of tattling, as they did not describe counternormative behavior. In *nonjudgmental* reports the behavior described was innocent and the child who reported it did not seem to be seeking any punishment. Finally, *positive* reports consisted of an approving description of another child's prosocial behavior.

Response type. The actions of the audience in response to a behavioral report were assigned to one of eight categories, again following Ross and den Bak-Lammers (1998). See Appendix B for examples. *Supporting* a tattler involved intervening on his or her behalf, such as by verbally admonishing the miscreant, or compelling her to hand over a toy to another child. *Acknowledging* a report consisted of agreeing or sympathizing with the tattler but not saying anything to the miscreant about the reported behavior. *Excusing* an action involved asserting to the tattler that the behavior reported is innocent or justified. *Ignoring* was coded if the audience did not seem to respond to the tattler in any meaningful way. When *reprimanding* a tattler, the audience reproached the tattler for tattling or for the tattler's own reported behavior. In some cases, *both* tattler and miscreant were reprimanded—the implication being that they had both been involved in the reported activity—and this received its own code. Finally, a *questioning* response took place when the audience tried to find out exactly what had happened by questioning the tattler, the miscreant, or both, but was unable to reach any firm conclusions (i.e., the response did not resolve into any other category).

Point Sampling of Social Networks

Tattling is not just an individual activity but a relational activity between children and the peers whose behavior they report. It might therefore vary according to the social relations between individuals. We built up a picture of the social networks in the two classrooms and the sociability of individual children, by using point sampling to record the composition of children's play groups during free play sessions. In Preschool A, group membership was surveyed at a set time every morning. Several study days were also devoted to point sampling, taking a sample every 15 min for the duration of the morning. In all, 106 point samples were taken, each of which recorded the group membership of every child present. In the busier environment of Preschool B, point sampling was conducted on a more infrequent and ad hoc basis (18 samples, spread over nine study days).

Focal Follows and Dominance Analysis

In Preschool A, each child was observed individually for 1 hr. This hour was made up of one 30-min and two 15-min sessions per child, carried out on three separate days. Everything that the focal child did during these sessions was noted. The motivation for the focal follows was twofold: first, to check that the event sampling of the children's verbal reports was not biased toward the most audible or attention-grabbing children, and second, to investigate the dominance hierarchy within the classroom. A common method for analyzing the dominance hierarchies of toddlers is to code for incidences of direct aggression (e.g., Strayer & Strayer, 1976). However, examples of direct aggression become much less frequent by age 4 (Hawley, 1999) and were rarely observed in Preschool A; therefore, instead we analyzed several types of social interaction that included a clear element of direction of one child's behavior by another (cf. Barner-Barry, 1988; La Freniere & Charlesworth, 1983).

Child X was considered to have taken part in a dominant interaction with Child Y if any one of the following behavioral patterns occurred: (a) X initiated physical contact with Y, and Y did not resist; (b) X told Y to do something, and Y complied; (c) Y imitated X's behavior; (d) Y followed X to another part of the room. In each case, the behavior of both children was important, emphasizing the point that dominance is a function of dyadic relations rather than of individual behavior alone (Strayer & Strayer, 1976). However, for many dyads there were no examples of such interactions, and so it was impossible to construct a single transitive hierarchy that included all the children. Therefore, the ratio of total dominant to submissive interactions for each child was used as an index of relative dominance. The dominance hierarchy constructed using this measure was in accordance with the transitive subhierarchies that were constructed based on interactions between specific dyads, and with qualitative observations and informal teacher reports of children's relative dominance.

Teacher Ratings of Relational Aggression

Due to time constraints and the larger class size, and because we had some confidence from the first preschool that the event sampling procedure would not underestimate the level of tattling, no focal follows were carried out in Preschool B. Instead, we administered the Relational Aggression factor of the Preschool Social Behavior Scale–Teacher form (PSBS-T; see Crick, Casas, & Mosher, 1997) to the teacher and classroom assistant in Preschool B, to find out if there was a link between tattling and relational aggression. As mentioned in our Introduction, some forms of evaluative discourse in children have been analyzed as instances of relational aggression, defined as ''harming others through purposeful manipulation and damage of their peer relationships'' (Crick & Grotpeter, 1995, p. 711). The relational aggression factor of the PSBS–T consists of six descriptions of children's characteristic behavior (e.g., ''Tells others not to play with or be a peer's friend''), on which each child was rated using a 5-point Likert scale. Crick et al. (1997) demonstrated that this factor was internally consistent and independent of the overt aggression, prosocial behavior, and depressed affect factors. McEvoy, Estrem, Rodriguez, and Olson (2003) found strong intermethod agreement between teacher ratings on the PSBS–T, peer nominations, and direct observation of relational aggression.

Results

Content of Children's Behavioral Reports

Children's tattling, operationalized as the reporting of the various categories of norm violations described in the Method section, was far more frequent than the reporting of positive or neutral behavior. Event sampling recorded 354 examples (93.1%) of tattling ($M = 1.26$ reports per child per day attended, $SD = 1.12$), 25 examples (6.6%) of nonjudgmental talk ($M = 0.09$, $SD = 0.14$), and just 1 example (.3%) of positive talk about a peer's activities. There were no significant differences between the preschools either in the mean frequency of all behavioral reports per child, or in the mean proportion of negative reports, both $ts < 1$, both $ps > .5$. The range of behavioral reporting was 0–6.31 events per child per day attended.

Tattling might be expected to be more noticeable, and thus more readily observable, than other forms of talk about peers. However, a similar effect was observed in the data from the focal follows, where it would have been difficult to miss any kind of behavioral report about a third party made by the focal child. Of 32 instances in the focal follow data where a focal child was involved in a behavioral report, only two reports (6.3%) were nonjudgmental, and none were positive. Examples of actual tattling content are listed in Appendix A. No examples were found of one of the predefined categories of tattling content (deception). For the other seven categories, mean frequencies of children's tattling are shown in Table 1. A series of t tests revealed no significant differences in tattling content between preschools, though there were trends for children in Preschool A more frequently to report both social conventional issues, $t(16.2) = 1.86$, $p = .081$, and disputes over property entitlement, $t(38) = 1.74$, $p = .090$.

Truthfulness

For event samples where it was possible to determine unambiguously the truth of a behavioral

Table 1
Frequency of Reported Categories of Counter-normative Behavior

	Preschool A M^a (*SD*)	Preschool B M^a (*SD*)	Overall M^a (*SD*)
Property entitlement	0.53 (0.49)	0.32 (0.29)	0.41 (0.39)
Physical aggression	0.25 (0.27)	0.38 (0.40)	0.33 (0.36)
Social convention	0.31 (0.47)	0.09 (0.11)	0.18 (0.32)
Joint play	0.08 (0.21)	0.17 (0.20)	0.14 (0.21)
Property damage	0.16 (0.23)	0.06 (0.16)	0.10 (0.20)
Taunting	0.07 (0.10)	0.12 (0.15)	0.10 (0.14)
Disagreement	0.02 (0.05)	0.01 (0.03)	0.01 (0.04)

[a] Mean frequency of events reported by each child, per standardized school day attended.

report, a mean of 90.0% of reports were found to be true. As many children in each preschool were never observed to make a false report, there was no difference whatsoever between the two schools on this measure, $t(32) = 0.020$, $p = .99$. However in 43.1% of event samples, on average, the truth value of the report was undetermined. This was partly because the busy nature of the classroom environment sometimes made it difficult to record all the relevant antecedents of the children's disputes, and partly because some reports (e.g., "He's not listening to me!") were difficult to assign objective truth values to without intensive questioning of the children involved. In the focal follow data, where it was much easier to determine the truth of children's claims, only 9 of 32 (28.1%) reports were of undetermined truth value, and no false reports were recorded. In most of the undetermined cases, it is unlikely that the reports were false, as the alleged miscreants rarely denied their offenses, and the teachers rarely accused tattlers of lying. Moreover, the proportions of *deceptive* reports in our study were well below the 10% of *false* reports that were recorded. For example, Child *B* might crash into Child *A* on a tricycle, and Child *A* might falsely report to the teacher that Child *C* had crashed into him. This might be an error in face recognition, or a slip of the tongue: There were very few events in which the observer suspected that deliberate fabrication of a report was occurring. Mistaken ascriptions of intention (e.g., "She pushed me!" when one child accidentally knocked into another) were more common.

Audience Responses to Tattling

Children were far more likely to report the behavior of their peers to adults than to other children: In the event samples, only 4 of 380 events (1.1%) were reports made to other children. Table 2 shows the mean shares of the various types of audience response to tattling, ordered by overall frequency. Examples of actual responses are supplied in Appendix B. The most common response was supporting the tattler, which accounted for around 50% of responses. If acknowledging is included as a favorable response for the tattler, as it constitutes positive attention from an authority figure, almost 70% of responses were favorable for the tattler, and only 6% were clearly unfavorable (a reprimand for the tattler alone or for both tattler and miscreant). There were no significant differences between the preschools in the proportions of these responses, all ts < 1.5, all ps > .1.

Table 2
Proportions of Audience Responses to Tattling

	Preschool A M^a (*SD*)	Preschool B M^a (*SD*)	Overall M^a (*SD*)
Supporting	0.52 (0.27)	0.44 (0.19)	0.47 (0.23)
Acknowledging	0.17 (0.27)	0.25 (0.24)	0.22 (0.25)
Excusing	0.08 (0.09)	0.12 (0.13)	0.11 (0.11)
Ignoring	0.14 (0.17)	0.07 (0.09)	0.10 (0.13)
Reprimanding	0.03 (0.05)	0.03 (0.09)	0.03 (0.08)
Both reprimanded	0.04 (0.13)	0.02 (0.04)	0.03 (0.09)
Questioning	0.12 (0.26)	0.13 (0.13)	0.12 (0.19)

[a] Mean share of responses for each child who was tattling.

Egocentric and Sociocentric Reports

Tattling was highly egocentric, in that it tended to focus on achieving help or punishment for another child's negative behavior toward the tattler (mean share = 0.77, $SD = 0.24$). Tattling on behalf of third parties was quite rare ($M = 0.06$, $SD = 0.11$), and reporting a transgression that directly affected the audience was more unusual still ($M = 0.01$, $SD = 0.02$). Tattling where there was no clear victim—as with most breaches of social convention—was more common ($M = 0.16$, $SD = 0.17$). Children in Preschool A were more likely than in Preschool B to report incidents where there was no clear victim, $t(34) = 2.17$, $p = .037$, which might be linked to their tendency to report more social conventional violations.

Dominance

In Preschool A there was a strong positive correlation between children's dominance, as measured by the ratio of their dominant to subordinate interactions, and the rate at which they tattled on other children, $r = .881$, $N = 16$, $p = .000007$. That is, dominant children reported others' transgressions significantly more than subordinate children. One possible explanation for this is that children who talked to the teacher more often were more likely to engage in tattling. However, there were no correlations between overall rates of addressing an adult in the classroom, as recorded in the focal follows, and either rates of tattling or ratio of dominant to subordinate interactions, both rs < .25, both ps > .3. Alternatively, sociability might be expected to increase tattling on the part of dominant children, as more social interactions might lead to more potential for conflicts and therefore more opportunities to report those conflicts. As the average number of play partners for a given child would be affected by total attendance on the days that he or she was present, we calculated an index of sociability for each child, based on the ratio between the actual number of interactions with every other child and the potential number of interactions that could have taken place (i.e., the number of point samples at which both children were present). There was no correlation between this sociability index and either the frequency of children's tattling or the ratio of dominant to subordinate interactions, both $r < .3$, both $p > .3$. Hence, there seemed to be a specific link between dominance and tattling in this preschool. (As explained in the Method section, dominance was not analyzed in Preschool B.)

Relational Aggression

In Preschool B there was a strong correlation between tattling frequency and a child's score on the relational aggression section of the PSBS–T teacher-rated questionnaire, $r = .590$, $N = 24$, $p = .002$. This demonstrates that tattling in this preschool covaried with verbal indices of relational aggression. (The PSBS–T questionnaire was not administered in Preschool A, as explained in the Method section.)

Gender Effects

No specific gender effects were predicted. Boys ($M = 3.21$, $SD = 0.88$, $n = 13$) were far more likely than girls ($M = 1.60$, $SD = 0.72$, $n = 11$), to be seen by the teacher as relationally aggressive, $t(22) = 4.84$, $p = .00008$. Girls' behavioral reports were slightly more truthful than boys' reports, but both were highly truthful ($M = 0.98$, $SD = 0.05$, $n = 19$ for girls; $M = 0.84$, $SD = 0.26$, $n = 21$ for boys), and this effect was not particularly significant, $t(19.8) = 2.36$, $p = .029$, given the number of potential gender effects that were tested (Bonferroni-corrected $\alpha = 0.0025$). As there was no difference in the overall tattling rates between genders, $t(38) = .882$, $p = .383$, it was possible to directly compare the frequencies of tattling by boys and girls on the various categories of norm violation (see Figure 1). The only significant difference was in tattling on physical aggression, which boys ($M = 0.49$ per day, $SD = 0.41$, $n = 21$) reported much more frequently than girls ($M = 0.15$ per day, $SD = 0.16$, $n = 19$), $t(26.7) = 3.46$, $p = .002$. There was no significant effect of tattler gender on the frequency of any of the various types of response to tattling, all $ts < 1.5$, all $ps \geq .15$. No effects of tattler gender were found on the frequency of behavioral reports, proportion of negative reports, or the likelihood of the tattler being the victim, all $ts < 1.0$, all $ps > .3$.

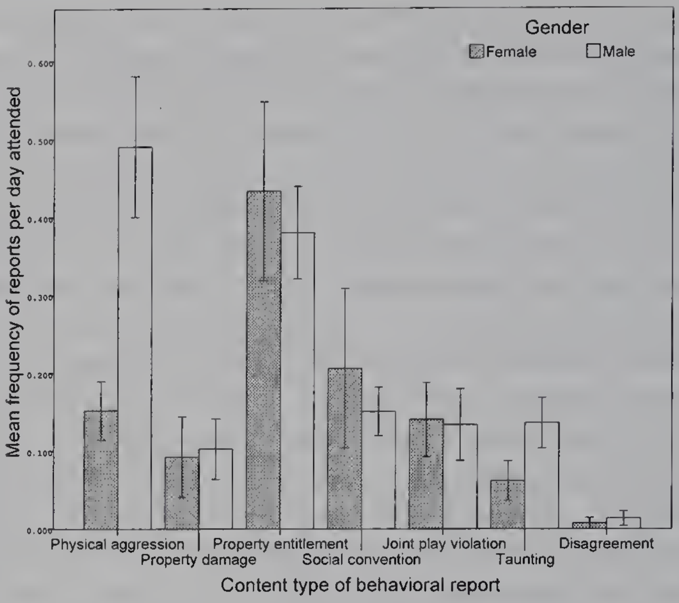

Figure 1. Mean frequencies of tattling (adjusted for attendance) by boys and girls in both preschools on the various categories of norm violation. Error bars represent ±1 *SE*.

Discussion

Our data suggest that tattling is an important form of social communication for many young children. The great majority of children's talk about their peers' behavior took the form of descriptions of norm violations. This was a robust finding that held across both sexes in both preschools, and also in the focal follow data (for which sampling bias was less of an issue). Moreover, our data reiterate the finding of a bias toward talk about counternormative behavior among all four groups of siblings studied by Ross and den Bak-Lammers (1998). Taken together, our preschool study and their sibling study demonstrate that a bias toward reporting norm violations by other children—while not necessarily universal—is present in children of various ages in differing social contexts. It seems that when children first start talking to adults about what another child has done, they use this faculty largely to report behavior of which they disapprove. More generally, Miller and Sperry (1988) found that 2-year-olds' stories about past events were highly evaluative, and that 64% of stories were concerned with negative experiences. This may reflect an early bias toward sharing negative experiences with caregivers, perhaps caused by an "ontogenetic adaptation" (Bjorklund & Pellegrini, 2000) for children to seek aid or sympathy from adults when suffering a negative affective response. However, the extent to which such a bias is recruited in everyday life and the precise kinds of events that are reported are likely to be affected by local cultural norms of discourse (Burger & Miller, 1999; Miller, Cho, & Bracey, 2005).

Children in the present study were much more likely to report disputes arising from issues of property entitlement or physical aggression than they were to report joint play disputes, taunting, property damage, simple disagreements, or deception. Again, this is consistent with the findings of Ross and den Bak-Lammers (1998). Nucci and Turiel (1978) likewise found that preschool children were more likely to protest about moral (harm-related) than conventional violations in a classroom setting. Events involving physical harm are also common in 2-year-olds' stories about the past (Miller & Sperry, 1988). It seems that young children may preferentially report breaches of "affect-backed" norms (see Nichols, 2004), involving physical harm or property loss. Even at the age of 3, nonetheless, they can generalize this form of communication to breaches of simple social norms (such as shouting, or going into inappropriate areas of the classroom) but very rarely report instances of deception or disagreement—perhaps because an understanding of such complex linguistic norms requires an advanced theory of mind (Astington, 2006).

Regardless of content, the great majority (90%) of children's reports about peers' behavior were true, at least for cases in which truth could be easily determined. This figure is similar to Ross and den Bak-Lammers's (1998) finding of a mean of 94.3% truthful reports across all four groups that they studied. Moreover, most false reports seemed to be mistaken rather than fabricated. This bias toward truthful communication is interesting because children of this age—and younger—are certainly capable of lying in both naturalistic and experimental settings (for a review, see Lee & Talwar, in press). Indeed, children in the present study were often observed to lie in response to tattling, usually by means of a simple denial such as "No I didn't!" As strategic deception requires a high level of executive control (Hala & Russell, 2001), it may be that by this stage of development children's executive competence enables them to make false denials of responsibility, but not yet to fabricate complex narratives that might successfully absolve them of responsibility. This finding argues against stereotypical views of tattling as "telling tales" (i.e., making up stories), suggesting as it does that young children's reports of peers' behavior are usually reliable.

Children were more inclined to report the behavior of those who had harmed or offended them directly. At a pragmatic level, this finding may reflect a general egocentric bias in children's discourse (Rubin, 1973). At a motivational level, it may also reflect a greater incentive to punish peers who have offended against the subject rather than those who have harmed a third party. Nevertheless, children as young as 2 are capable of sociocentric speech (Bruner, 1983), and indeed in about 25% of cases, in the present study, children reported social conventional violations for which there was no clear victim. It is interesting that children reported social conventional violations much more frequently than transgressions against a third party. This suggests a certain level of social cognitive awareness, in that they may have assumed that the victims in the latter type of case could speak up for themselves.

Tattling was rarely ignored by adults and often led to a teacher or classroom assistant intervening in support of a child—whether by punishing the reported miscreant or by resolving a dispute in favor of the tattler. There would seem to be little risk involved in tattling, in that few tattling events led to a negative response for the speaker (this is also true of the family context; Ross & den Bak-Lammers, 1998). Furthermore, qualitative observations during the participant observational part of the current study showed that while an explicit threat of tattling sometimes deterred peers from carrying out an undesired activity, tattling rarely led to aggressive retaliation on the part of peers (except in the form of reciprocal tattling). Compared to direct physical retaliation—which might lead either to an escalation in aggression or to punishment by staff—tattling might thus be a useful, and low-risk, social strategy for young children to follow in seeking punishment for a perceived wrong. Yet qualitative observations also indicated that children's motivations for tattling were highly variable across individuals and situations (see Ingram, 2009, for a detailed analysis). Punishment did not result in the majority of cases and was usually mild: Admonishment sometimes consisted simply of saying the transgressor's name in a disapproving tone. Often it seemed to be enough for children that an adult was paying attention to them and that their concerns about another's behavior were being acknowledged. Tattling is therefore more likely to be motivated by a general drive to externalize emotional problems, than by a conditionally learned strategy to achieve punishment.

There were notable individual differences in tattling. Analysis of social hierarchies in Preschool A showed that dominant individuals tattled significantly more frequently than other children. Tattling is sometimes a response to a (perceived) aggressive action by another individual, and this may mean that it is practiced more by dominant children, who more often retaliate against peers' aggression (Strayer & Strayer, 1976). In an environment where children's physical aggression is frequently punished by adults, dominant individuals' retaliatory impulses may be socialized and directed into indirect, verbal behavior (Cooney et al., 1996; Hawley, 1999). Tattling may be one of several interpersonal strategies—including relationally aggressive behavior such as saying "I'm not your friend," verbally aggressive behavior such as threats or taunts, and direct physical aggression such as pushing—which some preschool children use, to varying degrees, to achieve social dominance. Although dominant children were no more likely than other children to address the teachers in general terms, it could also be that dominant children were less shy about the specific activity of drawing an adult's attention to social problems. These possibilities are not mutually exclusive; that is, manipulating others' attention may contribute to dominance in young children.

The results of the PSBS–T questionnaire administered in Preschool B suggest that there are links between tattling and relational aggression. The same children who often engaged in relationally aggressive activities, such as telling peers that they would not be their friend, tended to tattle the most frequently. On the other hand, relational aggression has been defined as behavior that "harms others through damage to their peer relationships (e.g., using social exclusion or rumor spreading as a form of retaliation)" (Crick et al., 1997, p. 579). Relational aggression is often also characterized as covert (Archer & Coyne, 2005)—for example, whispering behind someone's back—whereas tattling in these two preschools was overt and unashamed, often taking place right in front of the tattling target. As it is often overt, tattling may be more closely related to social aggression, a construct defined to include both covert and overt forms of nonphysical aggression (Archer & Coyne, 2005; Galen & Underwood, 1997). Moreover, it is unlikely that children who tattled always intended to *harm* the tattling targets. Sometimes, they may well have been motivated by a desire to win praise from the teacher or to correct some inequity in the classroom (Ingram, 2009), in an early form of restorative justice. More research is needed on the affective dimensions of tattling, and on its relation with other forms of social communication.

One advantage of doing participant observation, in addition to quantitative sampling, was that it gave us a sense of the broad range of motivations for tattling. Tattling could sometimes be a strategic element of interchild conflict, as demonstrated by the fact that children occasionally threatened to do it ("I'm telling the teacher!") as a sanction against unwelcome behavior by a peer. Yet tattling was not always an aggressive reprisal for a perceived wrong against the tattler: It sometimes seemed to be more concerned with providing useful information about rule breaking to an authority figure. When children tattled about nonegocentric events, it often seemed to be the principle of justice that most concerned them—an assertion of the rights and wrongs of the matter, rather than any particular settlement. For example, a frequent topic of tattling occurred when one child was perceived to take more than his or her fair share of bread or milk at the snack table. Other children would report this even when they themselves had plenty of food and drink in front of them. They seemed to be concerned with the principle of one child having relatively more than the others, rather than with any absolute loss of resources on their own part (for related experimental results, see Damon, 1977; Fehr, Bernhard, & Rockenbach, 2008). Hence the motivating force behind tattling may sometimes be a drive to enforce the rules as the child perceives them, in pursuit of a sense of justice or social equity. What might produce such a drive? One cause might be a reluctance to see another go unpunished for an offense for which the tattler has been punished in the past, thus reducing the tattler's relative standing. Another cause, which would fit well with our dominance results, might be a tendency for leaders to gain prestige from enforcing social norms (O'Gorman, Henrich, & Van Vugt, 2009).

There were several limitations to the present study. It was based on hand-written observations of a large body of children's discourse: An analysis based on several hours of audio or video recording of focal children would contain fewer examples of tattling but might allow for finer-grained observation of the motivational and affective dimensions of tattling. Although two preschools were compared—and tattling took a generally similar form in each, with no robustly significant differences—both schools were in the same city, and so it would be interesting to contrast the results from these schools with results from culturally different populations. It would also be worth comparing preschoolers' reporting of peer behavior with similar activities by older children in educational settings, thus complementing and extending the longitudinal study of Ross and den Bak-Lammers (1998) in home settings. It would be especially useful to carry the study of tattling up to preadolescence, as this may be when the activity first becomes derogated by peers (cf. Friman et al., 2004).

In this article we have extended the study of tattling to preschool settings, showing that it took a similar form in this context as for preschool-age children in the home context. Our results in the areas of negative bias, truthfulness, and adult responses to tattling are broadly in agreement with the findings of Ross and den Bak-Lammers (1998) for tattling between siblings. Children's general bias toward reporting norm violations also recalls the sensitivity toward norm violations in experimental settings reported by Harris and Núñez (1996) and Rakoczy et al. (2008). Further experimental work needs to be done regarding the cognitive mechanisms responsible for this bias: Are norm violations simply more salient, and therefore more worthy of verbal attention, or are children's verbal accounts of behavior always influenced by strategic considerations? Individual variations in tattling, and in particular the relations that we found with dominance and relational aggression, require carefully designed follow-up research. We conclude that tattling is a robust but individually flexible pattern of behavior, which is likely to undergo interesting developmental changes as children grow older and acquire an advanced theory of mind (see Ingram, Piazza, & Bering, 2009). Tattling may be an active part of the process by which some children learn to live in a world of social norms and social conflicts. It is thus an early example of the human ability to use language to externalize strategic problems and draw them into the public sphere.

Appendix A

Example Content Types of Children's Behavioral Reports

Report category	Examples of report content
Physical aggression	"He tried to bited [sic] me" "Jack hurt me with the wheel"
Property damage	"She hit this thing" "Matthew, he's knocking down the tower"
Property entitlement	"He won't let me have the scissors" "Mudiwa took two breads"
Social convention	"Both of them 'uns have Power Rangers—I seen them under the table" "They're being very loud"
Joint play violation	"She's not finished yet [with the paintbrush]; she won't hurry up" "I wanted to be in there [the box] and Jack pushed it off me"
Taunting	"She's shouting at me" "James said I'm not Superman; James said I'm bad"
Disagreement	"She said she was in a different school" "I stood on Adam's foot—he said I did it on purpose but I didn't"
Nonjudgmental	"He didn't get any milk" "He was trying to get in the car and I jumped in first"
Positive	"Emma gave me a flag"

Appendix B

Examples of Responses to Tattling by Audience

Response category	Examples of response content
Supporting	Confiscated toys: "You know you're not allowed them" "Tell him I'm not happy about that"
Acknowledging	Said "Does she?" and looked at the dolls Told tattler that she would talk to miscreant about it (but never seemed to)
Excusing	"That's OK" "It was probably an accident"
Ignoring	Pretty much ignored (probably because the boys had been throwing things too) More or less ignored, because everyone was going down into the playground
Reprimanding tattler	Told tattler not to be fighting "You are all little tell-tales, aren't you—always telling tales on each other!"
Both tattler and miscreant reprimanded	Ascertained that it was an accident, and told both boys to say sorry to each other Called both boys over and told them sternly not to climb on things
Questioning	Asked if it was an accident Questioning interrupted by arrival of tattler's mother

Conversation, Development, and Gender: A Study of Changes in Children's Concepts of Punishment

Patrick J. Leman
Royal Holloway, University of London

Marina Björnberg
Linköping University

One hundred thirty-three children, average age 9.58 years, were read vignettes describing a moral transgression and then discussed what would constitute a fair punishment. Children's gender influenced conversation dynamics (use of interruption and other simultaneous speech) but not conversation content (justifications for judgments). All children who engaged in conversation showed development in judgments after 8 weeks compared with a control (no interaction) group. However, there was no relation between conversation dynamics or content and development, or any effects of gender, on the developmental process. The benefits of peer collaboration were general rather than specific to the stimulus story.

Despite abundant evidence that peer conversation promotes learning and development, much remains to be known about the features of interaction that are associated with changes in cognition. For instance, although the quality and type of arguments used in discussion have been linked with advances in reasoning in some studies (e.g., Felton & Kuhn, 2001; Psaltis & Duveen, 2007), other studies have found no links between argument content, quality, or frequency and learning (Fernandez-Berrocal & Santamaria, 2006; Howe, Tolmie, & Rodgers, 1992). It is important to build a clear understanding of the features of conversation that promote development because if we can identify what makes a conversation lead to development, we can begin to devise ways of making peer collaboration more productive.

Our central research questions concern the relations among gender, conversation, and development. These more general research questions fall, broadly, into three separate sets of hypotheses: first, predictions relating to the links between gender and conversation; second, predictions about the link between conversation (peer interaction) and development; and third, predictions about how features of conversation may link with development. By focusing on gender, we are exploring a key aspect of children's social identity that is known to influence conversational dynamics and has been proposed as a source of variation in moral judgment and reasoning. In terms of conversation, we explore how the content and dynamics of children's conversations may link with longer term change in judgments. The present study examines children's conversations and judgments about what constitutes a fair (or just) punishment.

The development of an idea of punishment was first studied by Piaget (1932), but aside from a few studies (e.g., Brinker, Goldstein, & Tisak, 2003; Saunders & Goddard, 2007; Tisak, 1993), the question of how children conceptualize different forms of punishment has subsequently received little attention from researchers. This neglect is surprising because what constitutes a fair punishment is something to which children pay a great deal of attention, and anecdotal evidence suggests that it is a frequent topic of discussion with parents and peers.

Piaget distinguished two forms of punishment: *expiatory punishment* and *punishment by reciprocity*. Expiatory punishments focus on retribution or the severity of punishment as the best means of addressing any wrongdoing. Younger children often judge expiatory punishment as the most fair. Older children, in contrast, often judge punishment by reciprocity as fairer. This form of

punishment focuses on restorative aspects of punishment and putting right what was done wrong. According to Piaget, most children shift from a preference for expiatory to reciprocal forms of punishment between around 8 and 10 years. In the present study, we used the distinction between different forms of punishment as a trigger for 9-year-old children's conversations, and to gauge whether there were changes in children's punishment orientation (expiatory or reciprocal) after conversation.

Gender and Conversation

Gender has a profound influence on the dynamics of children's conversations. Examining the role of gender in conversation and development is important because if gender affects the dynamics of interaction then this may impact on the ideas and information that are introduced to a discussion and may also affect how far ideas are discussed and debated once they have been introduced. If, for instance, one child continually interrupts another in a discussion an important piece of information may be missed or an explanation may not be adequately scrutinized.

Boys' conversations are more dominance oriented, and involve more features such as interruption, whereas girls' conversations are more collaborative (see Leaper & Smith, 2004). Gender differences in conversations are evident from at least 7 years of age in both spontaneous interactions (Leaper, Tenenbaum, & Shaffer, 1999), classroom exchanges (Nelson-Le Gall & DeCooke, 1987), and more formal, problem-solving discussions (Leman, Ahmed, & Ozarow, 2005). In most contexts boys are more assertive and girls more affiliative in terms of conversation dynamics. Additionally, boys use more simultaneous speech acts than girls. Simultaneous speech acts include attempts to take the conversational "floor" such as interruptions and overlapping speech (Coates, 1989). Leman et al. (2005) found that the gender differences in the use of simultaneous speech acts were particularly pronounced in cross-gender (boy–girl) interaction.

Our first two hypotheses were derived from this previous work charting the influence of gender on children's conversations. Specifically, our first hypothesis predicted that boys will use more simultaneous speech acts (interruptions) than girls. Our second hypothesis predicted greater differences between genders in mixed than in same-sex interactions (i.e., boys will interrupt more than girls generally, but this difference will be especially marked in boy–girl pairs).

Gender and Moral Judgment

There has been considerable debate about whether there are gender differences in moral reasoning. Notably, Gilligan (1982) has argued that women and girls reason using an ethic of care with a focus on relationships, whereas men and boys tend to make more abstract, justice-based moral judgments. In conversation and discussion one might anticipate that these different moral orientations would lead to differences of opinion or even to conflict when children seek to justify their judgments. Even children who agree on the same moral judgment might disagree over the reasons for it.

Although the suggestion of gender differences in moral reasoning and orientation has received considerable research interest, review studies find no consistent gender differences in moral orientation in adults (e.g., Jaffee & Hyde, 2000; Walker, 1984, 2006). So in the present study, we did not expect gender to be a significant variable in terms of the choice of punishment (reciprocal or expiatory) or in the types of argument that children used to justify their choices.

Social Interaction and Development

Doise, Mugny, and Perret-Clermont (1975) demonstrated that children working in groups showed advances in conservation ability compared with those not involved in interaction. Subsequently, Doise and Mugny (1984) suggested that sociocognitive conflict—that is, the social manifestation of differences in perspective and understanding between children—is a vital driver for development. Ames and Murray (1982) also pointed to the importance of some forms of conflict in development by exploring the outcomes of nonconserving children's interactions on string of different conservation tasks. Further work has demonstrated that the benefits of interaction extend to promoting development in a range of different domains including science learning (Howe et al., 1992), moral reasoning (Damon & Killen, 1982; Leman & Duveen, 1999), and inference tasks (Roazzi & Bryant, 1998; Tudge, 2000).

Our third hypothesis therefore predicted that conversation (interaction) between children on this (punishment) task will be associated with developmental changes in preference for different sorts of punishment. In other words, children who initially chose expiatory punishments and who engaged in conversation would be more likely to choose reciprocal punishments after interaction compared with those who did not engage in interaction. This prediction is consistent with the more general observation that social interaction between peers promotes development.

Additionally, for our fourth hypothesis, we predicted that these advances would not differ in terms of gender or in terms of the gender mix of the children involved in a discussion. This prediction was made on the basis of previous research that finds no link between gender and decision making or developmental change (Leman & Duveen, 1999; Leman et al., 2005). However, while we predicted no gender differences in development, there is some other research pointing to an influence of gender on development: On a conservation of liquids task, Psaltis and Duveen (2007) found that conversation "types" differ according to gender and that these, in turn, were associated with variations in development. The present study offers an opportunity to examine effects of gender on development in a context of moral judgments, which is a domain in which gender differences in moral reasoning and judgment have often been proposed.

Development and the Features of Conversation

Although the association between interaction and learning is well established, the matter of identifying precisely which conversational features promote learning and development has proved surprisingly elusive. In a series of systematic studies exploring children's discussions about a range of group-based, science tasks, Howe found no consistent links between the quality or quantity of arguments that children produced in interaction and subsequent development (e.g., Howe, McWilliam, & Cross, 2005; Howe, Tolmie, Duchak-Tanner, & Rattray, 2000; Howe et al., 1992). Consequently, Howe proposed an *incubation hypothesis* whereby interaction between peers promotes development by stimulating consideration of alternative explanations for a particular scientific phenomenon. In short, Howe's hypothesis is that interaction between peers primes a child to search, individually, for explanations for a phenomenon after the period of interaction has finished. Thus the developmental "work" takes place on an individual level and is not a feature of group discussion itself. The incubation hypothesis provides an explanation why researchers have had such difficulty linking specific features of interaction with development because the benefits of peer interaction are not, necessarily, related to the quality (or quantity) of argument and explanation in peer interaction. Howe et al. (2005) argue that peer discussion serves an important role because it primes the search for information, and points children to the possibility of alternative explanations.

One might anticipate that gender influences on conversation dynamics will influence development too. Much research demonstrates that boys' dominance of classroom resources can set up marked differences in the opportunities for learning for boys and girls (e.g., Littleton, Light, Joiner, Messer, & Barnes, 1998; Strough, Berg, & Meegan, 2001). Yet surprisingly few studies have sought to establish whether any such gender differences feed into longer term learning, and those that have provided somewhat contradictory results (Jones et al., 2000; Psaltis & Duveen, 2006).

Our fifth hypothesis, following Howe et al. (2005), was that there would be no relation between conversation content (the arguments or justifications that children produce in conversation) and developmental changes in judgments about punishments. In other words, no particular argument or set of arguments would be associated with developmental changes. Given ambiguous previous research findings, we did not propose a hypothesis regarding the links between conversation dynamics and development.

Method

Design

The study was in four phases. In the first phase, all participants independently judged which was the fairest of two punishments in each of a set of stories concerning a child's misbehavior (see the Materials section, below). In the second phase (which occurred on the same day as the first phase), those children who were not in the control group were placed in a pair with a peer who had given a different response to one of the stories, *The Broken Window*, and were asked to discuss this and to reach an agreement about what the fairest punishment was. Children in the control (no interaction) group were asked to give a response on their own. The time interval between first and second test phases was kept roughly the same for all children, between 1 and 2 hr.

Two further, postinteraction tests were conducted. The third phase was conducted 2 weeks after the initial session and all children were asked, again independently, their response to the broken window story. Finally, for the fourth phase 8 weeks after the interaction phase, all participants were asked to make judgments on all stories once again, independently.

Pairs comprised children from the same year group at school who were identified by the teacher as neutral in terms of friendship; that is, they were neither good friends nor enemies. Otherwise, pairs were selected at random although, because a key aim was to establish the effects of gender on conversation and judgments, gender was used as a blocking variable. Thus, there was one key independent variable, pair type, that varied by the gender mix of the pair and children's initial responses (see Table 1) with a control group of children who did not engage in discussion with a peer on the task.

There were several dependent variables. There were two categories of outcome variable (moral judgment decisions). First, there were the children's responses to the stimulus story about the broken window that were either reciprocal or expiatory. These responses were given at four time points; *t*1 (preinteraction), *t*2 (either immediately postinteraction or 1 to 2 hr later), *t*3 (2 weeks later), and *t*4 (8 weeks after the initial session, *t*1). Second, there was a measure of punishment orientation that was based on children's responses to three punishment stories presented at *t*1 and *t*4. (Initially, four stories were presented to children. However, on reflection, it was felt that one of the stories might appear to be unusual for children in terms of normal adult–child relations, and so this story was not included in the calculation of the global measure of judgment at *t*1 and *t*4.) As each story yielded either a reciprocal or expiatory response, scores were added to create a total score out of three which represented the maximum reciprocal score based on the three stories. Finally, there were two further sets of conversation measures for children involved in interaction: (a) children's use of simultaneous speech acts (overlaps, negative and positive interruptions) and (b) types of justifications given.

Participants

A total of 133 children participated in the study. Children came from two consecutive year (age) groups in the same school in Berkshire, Southern England. In one year group, there were 42 boys and 26 girls (8.5–9.5 years; *M* = 9.10, *SD* = 0.71). In the other year group were 35 boys and 30 girls (9.4–10.5 years; *M* = 9.92, *SD* = 0.66). The average age of the sample as a whole was 9.58 years.

The mix of ethnicities in the school was broadly homogenous (96% White British) and they were all from middle-class backgrounds. Children were recruited through letters home to their parents or guardians, who were required to give written consent for their child's participation before the initial data collection phase. The children were also required to consent verbally to their participation at all stages.

Materials

Stimulus stories were selected after pretesting materials with five children of the same age as the participants in the main study. These children were read five stories, based on those originally developed by Piaget (1932, pp. 200–209), in order to determine whether they would invoke sufficient numbers of differing responses to make discussions possible. Each story provided a choice between two options which corresponded to either an expiatory punishment or a reciprocal punishment.

Following the pilot study, stories were chosen to be presented to children in the main study. In each story, children were told a brief description of an event involving a child who committed a moral transgression. Then, in each case, the child had to make a choice between alternative punishments

Table 1
Definition of Pair Types

Independent response				
Reciprocal	Expiatory	Pair type	Description	*N*
Girl	Girl	Girl–girl	Reciprocal female with expiatory female	24
Girl	Boy	Girl–boy	Reciprocal female with expiatory male	24
Boy	Boy	Boy–boy	Reciprocal male with expiatory male	24
Boy	Girl	Boy–girl	Reciprocal male with expiatory female	24
Girl–boy	Boy–girl	Control	Did not engage in interaction	37

that corresponded to more mature (reciprocal) and less mature (expiatory) answers.

The broken window story was used as the stimulus story for the children to discuss together in a pair because it had the closest to a 50% response rate for each of the alternatives (reciprocal and expiatory). The text of the story is as follows:

> Late one afternoon there was a boy who was playing with a ball on his own in the garden. His dad saw him playing with it and asked him not to play with it so near to the house because it might break a window. The boy didn't really listen to his dad, and carried on playing near the house. Then suddenly, the ball bounced up high and broke the window in the boy's room. His dad heard the noise and came out to see what had happened. The father wonders what would be the fairest way to punish the boy. He thinks of two punishments. The first is to say: "Now, you didn't do as I asked. You will have to pay for the window to be mended, and I am going to take the money from your pocket money." The second is to say: "Now, you didn't do as I asked. As a punishment you have to go to your room and stay there for the rest of the evening." Which of these punishments do you think is the fairest?

The story text was read out to the children and they were all shown a picture of the act (i.e., Sam breaking the window), along with pictures depicting the two choices of punishment. The text of the other stories is given in the Appendix.

In the interaction phase of the study, children discussed their differing responses to the first story about the boy who broke the window in pairs in order to together arrive at an agreement on which was the preferable punishment. Children's conversations were videotaped using a camera and specialist microphone.

Procedure

In the independent response parts of the study (i.e., Phases 1, 3, and 4), the participating children were presented a booklet in a paper-and-pencil test of moral judgment, which was carried out in groups of 15–20 children. Each story was read out to the children and alongside this the child was shown a picture of the event or misdeed that lead to the punishment. The two punishments were then read out to the child who was also shown the corresponding pictures alongside one another. The child was asked to indicate, by ticking the relevant picture, which response he or she felt was the fairest. This procedure was then repeated with all four stories at *t*1 and *t*4. For children at *t*2 and *t*3 only material relating to the broken window story was presented.

For the second part of the study children were paired together with a partner who in the preinteraction phase had given a contrasting response to the broken window story. In addition, pairs comprised one child who was classified as reciprocal *overall* (three out of four responses to the stories had been reciprocal) and one child who was classified as expiatory overall (three out of four expiatory).

Children were allocated at random to control or interaction groups. Those children who were selected to participate in interaction were placed in pairs on the basis of their sex (with sex used as a blocking variable). The control group of children did not participate in the interaction phase. Pairs were seated in a quiet room and were read the story. They were reminded of their individual responses given in the first phase and were then asked to discuss the task together and to try to reach agreement. During the discussion, the interviewer left the room so the children could talk undisturbed. In cases when the interviewer returned before consensus was reached, the children were asked to continue their discussion. All pairs reached an agreement after 5 min.

Analysis of Conversations

Conversation dynamics. Three categories of *simultaneous speech act* were examined in the study: *overlaps*, *positive interruptions*, and *negative interruptions*. Simultaneous speech acts occur in conversations when the next speaker starts speaking at a point in the current speaker's turn that would not be defined as being at or close to a transition relevant place (Jefferson, 1973). In the present study, an overlap was defined as simultaneous speech that constituted no bid to take the floor. This included back channel utterances and simultaneously uttering the same word or phrase. It also covered cases when one speaker thought the other speaker had finished their turn, started speaking, but immediately stopped as they noticed that the partner was not yet done. Positive interruptions were defined as bids to take the floor that were not performed in a hostile or negative manner. These also included interruptions to make clarifications, reassertions of one's own position, or interruptions made to help the other finish a sentence. The latter would be a sign of active listenership that was performed in a somewhat collaborative manner, as the speakers could be perceived as constructing the utterance together. Negative interruptions were interruptions where the speaker attempted to take the floor in a hostile fashion. These included successful interruptions such as when the interrupter succeeds in taking the turn, and interruptions made in an aggressive or dominant manner. A count of each different type of interruption was made which, necessarily, occurred at turn boundaries.

Conversation content. We were also interested in examining the justifications used by the children to convince a conversation partner. To identify an appropriate list of such justifications, we employed an iterative qualitative process that commenced with listing *all* justifications used throughout the conversations. The next stage was to examine this list of justifications to identify common themes or categories of justification. Through this iterative process these justifications were refined into seven categories that covered all justifications observed throughout the corpus of conversational data and that were relevant to the study (see Table 2).

All justifications observed in the study were assigned to a category and the total number of justifications used within each category was counted. A child could use more than one justification and could include more than one type of justification in each turn. The total use of each justification category by each child was counted, as well as the proportionate use of each category. The proportionate use was calculated dividing all uses of one justification category with the total uses of justifications by one child.

Interrater reliability. Conversations were coded by the second author. For simultaneous speech acts and justification categories, 15 conversations (about 30% of the total number of conversations) were also coded by the first author. Interjudge agreement for simultaneous speech acts was excellent (kappa = .97). There was also excellent agreement between judges for the justification categories (kappa = .88).

Results

Statistical Note

As the focus of this study is dyadic interactions the issue of nonindependence needs to be accounted for. In conversation with their partner the participants are likely to adapt their behavior according to the behavior of the other. As has been pointed out (Carli, 1989a, 1989b) in a study where the gender mix of the pair varies, it is likely that the participants change their conversation and interaction according to both their own gender and the gender of their conversational partner. In the present study, this issue of nonindependence has been addressed using the same approach as Leman et al. (2005). Separate analyses of variance (ANOVAs) for the data for same- and mixed-gender pairs were performed. In the first analysis, gender differences were compared between boys in the all-boy pairs and girls in the all-girl pairs. In the second analysis, the comparison was between the boys

Table 2
Justification Categories With Corresponding Examples

Category	Definition	Example
Assertion	Assertions that only state the subject's belief, without any justifications	"I think staying in his bedroom"
Intention	Reference to the intention of the transgressor	"It might have been an accident" "He didn't mean to do it"
Reference to authority	Reference to what is right according to an authority figure	"My mum and dad did that to me"
Reciprocity	Putting right what is wrong	"He broke it and it's only fair that what he breaks he will replace I think"
Moral	Reference to a moral rule	"He didn't do as he was told"
Expiatory force	The punishment is preferred because it is severe	"If he just went to his room he might think that he can do it again because that's not a hard punishment"
Avoiding expiation	The punishment is preferred because it is mild, or the alternative is too severe.	"It should be stay in his room because then he can play"

Table 3

Mean Number of Overlaps, Positive Interruptions, and Negative Interruptions for Boys and Girls in Same- and Mixed-Gender Pairs and Associated Univariate Effects

	Same-sex pairs						Mixed-sex pairs					
	Boys $N = 24$		Girls $N = 24$				Boys $N = 23$		Girls $N = 23$			
Variable	*M*	*SD*	*M*	*SD*	*F*(1, 46)	Partial η^2	*M*	*SD*	*M*	*SD*	*F*(1, 44)	Partial η^2
Overlaps	0.83	1.01	0.67	0.96	0.343	.007	0.83	1.30	0.52	0.79	0.92	.020
Positive	0.50	1.18	0.25	0.44	0.945	.020	0.17	0.39	0.22	0.52	0.10	.002
Negative	0.63	1.06	0.21	0.41	3.24	.066	0.04	0.21	0.04	0.21	0.00	.000

and the girls in mixed-gender pairs. The means and mean error scores are then used in a set of formulae that yield separate *t* statistics concerning gender. The different comparisons all have the following denominator: $[(2\mathrm{MS}_e + 2\mathrm{MS}'_e)(1/n)]^{1/2}$, in which MS_e is the mean error score for gender effects in same-gender pairs, MS'_e is the mean error score for gender effects in mixed-gender pairs and n is the number of observations on which the means were calculated. The numerator for speaker gender effects is $(M_{gs} + M_{gm} - M_{bs} - M_{bm})$ and for partner gender effects $(M_{gs} - M_{gm} + M_{bm} - M_{bs})$, where M_{gs} is the mean for girls in same-gender pairs, M_{gm} is the mean for girls in mixed-gender pairs, M_{bs} is the mean for boys in same-gender pairs, and M_{bm} is the mean for boys in mixed-gender pairs. The interaction effect contrasts any gender differences found in same- and mixed-gender pairs to investigate in which pair type greater gender differences can be observed. The interaction effect has the numerator $(M_{gs} - M_{gm} - M_{bm} + M_{bs})$. For the speaker and partner gender effects a negative value of *t* indicates a higher score for boys than girls. Regarding the interaction effects, a negative value of *t* demonstrates that a greater difference can be observed in the mixed-gender compared to the same-gender pairs.

Analyses of Conversations

Conversation dynamics. Simultaneous speech acts were analyzed using the correction for nonindependence. Mean values for overlaps, positive interruptions, and negative interruptions, by gender and pair type, are given in Table 3, which also includes the results from the two ANOVAs: gender differences between boys and girls in mixed-gender pairs, and gender differences between boys and girls in same gender (i.e., all boy versus all girl) pairs. In Table 4, the *t* values and significance tests for children's use of simultaneous speech acts are presented.

Boys used more overlapping speech than girls. There were no significant differences regarding partner gender or interaction effects. There were no significant differences attributable to the gender of the speaker in terms of positive interruptions. However, all participants used more positive interruptions when talking with a boy than with a girl. An interaction effect was also observed, indicating that there was a greater gender difference in the same-gender pairs than in the mixed-gender pairs; both boys and girls use less positive interruptions when talking to someone of the opposite sex, with a greater decrease in the boys' use of positive interruptions when talking to a girl.

Boys used more negative interruptions than girls, and all children used more negative interruptions when paired with a boy. There were greater gender differences in the same-gender pairs than in the mixed-gender pairs. This difference was due to both boys and girls producing fewer negative interruptions in mixed-sex conversations, with a larger

Table 4

Speaker Gender, Partner Gender, and Interaction Effects Relating to Simultaneous Speech Acts

Variable	Speaker gender *t*(92)	Partner gender *t*(92)	Interaction *t*(92)
Overlaps	−2.25*	0.66	0.73
Positive interruptions	−1.22	−1.73*	2.12*
Negative interruptions	−2.84**	−2.84**	5.09***

Note. For speaker and partner effects, a negative value of *t* indicates a higher score for boys than girls. A negative value of *t* in the interaction effect indicates that there was a greater gender difference in mixed-gender compared to same-gender pairs.

Avoiding expiation	1.00	1.32	0.92	1.06	0.06	.001	0.82	0.98	0.96	1.33	0.14	.003

decrease in the boys' use of negative interruptions in mixed-gender pairs.

Conversation content. Justification categories were analyzed using the correction for nonindependence. The results from the mixed-gender and same-gender ANOVAs, and the mean values for the children's use of the different justification categories by gender and by pair type are shown in Table 5. The *t* scores and significance tests for the justifications used by the children are given in Table 6.

No significant differences between boys and girls were found in the use of justifications related to the categories reciprocity, intention, authority, moral, and avoiding expiation for either speaker gender, partner gender, or interaction effects.

However, boys used significantly more assertion justifications (merely restating one's own position without further elaboration) than girls, and all participants used more assertion justifications when talking with a boy than with a girl. In terms of expiatory force justifications, boys used these types of justifications significantly more frequently than girls. However, no differences for partner gender effects or interaction effects were observed.

The conversations varied in length, so the proportionate use of the justification categories was also calculated. To correct for non-normal distribution, a square root transformation was conducted and the transformed data were then analyzed using the correction for nonindependence. Significant gender differences in the proportionate use of assertion justifications were observed, $t(92) = -2.97$, $p < .01$, with boys using these more than girls. No partner or interaction effects were observed, and there were no other gender differences relating to the proportionate use of any of the other justification categories.

Table 6
Speaker Gender, Partner Gender, and Interaction Effects Relating to the Justification Categories

Variable	Speaker gender $t(92)$	Partner gender $t(92)$	Interaction $t(92)$
Assertions	−5.84***	−1.99*	1.37
Reciprocity	−1.55	−0.75	−0.85
Intention	0.04	−1.78	−0.72
Authority	−0.85	0.85	0.78
Moral	−0.35	−1.10	−1.92
Expiatory force	−2.15*	−1.59	0.97
Avoiding expiation	0.21	−0.95	0.60

Note. For speaker and partner effects, a negative value of *t* indicates a higher score for boys than girls. A negative value of *t* in the interaction effect indicates that there was difference in mixed-gender compared to same-gender pairs.
*$p < .05$. ***$p < .001$.

Moral Judgments: Changes in Concepts of Punishment

Preinteraction test (t1). There were no gender differences in terms of responses to any of the stories at any stage. However, there was a significant association between age group and response on the broken window story at *t*1, $\chi^2(1) = 3.86$, $p < .05$, contingency coefficient = .20. In the younger age group, 43% gave reciprocal response compared with 65% in the older age group. There was also a significant association between age group and response on the taking turns story at *t*1, $\chi^2(1) = 3.97$, $p < .05$, contingency coefficient = .20.

The more mature, reciprocal response was given by 75% of the younger age group and 90% of the older age group, respectively.

An overall punishment orientation score was calculated by adding together the total number of reciprocal responses to each story (where 3 was the maximum, indicating all reciprocal responses, and 0 the minimum, indicating all expiatory responses). A two-way Age Group × Gender ANOVA revealed a main effect of age group, $F(1, 132) = 7.34$, $p < .01$, partial $\eta^2 = .054$, with older children ($M = 2.28$, $SD = 0.74$) giving more reciprocal answers than younger children ($M = 1.94$, $SD = 0.71$).

There were no differences between those who were selected for interaction and those who were not in terms of overall score. As all pairs comprised one reciprocal and one expiatory child, there were no differences by pair type. There was no significant difference comparing the responses of children in the control group with the interaction groups. This analysis of age group differences is broadly consistent with Piaget's (1932) prediction that judgments in this domain undergo qualitative changes (from expiatory to reciprocal orientations) at around 8–11 years.

Immediate postinteraction or short delay test (t2). For children involved in interaction, *t*2 was the joint (agreed) response of the pair. For children in the control group (not involved in interaction) the *t*2 was delayed at around 1 or 2 hr after *t*1, which was a similar amount of time to the delay for the children in interaction. This second time point, *t*2, concerned only responses on the broken window story. There were no statistically significant differences attributable to pair type (and consequently, to gender) in this immediate posttest, although as can be seen from Figure 1, in all but one pair there was a slight drop in the proportion of reciprocal (more advanced) responses.

Two-week delayed posttest (t3). A 2-week delayed posttest (*t*3) asked children individually once again for their responses only to the broken window story. Again, analysis revealed no significant differences between those who had been in a pair and those who had not in terms of their responses to the stimulus story. There were, again, no differences in terms of the pair gender type, or gender, in terms of responses to the story.

Eight-Week Delayed Posttests (t4). In the 8-week delayed posttest (*t*4), responses were again collected individually for all stories. Examining each story in turn, there were no significant differences in responses to any of the individual stories between those who had, and those who had not, been involved in interaction, and no gender differences in responses to individual stories.

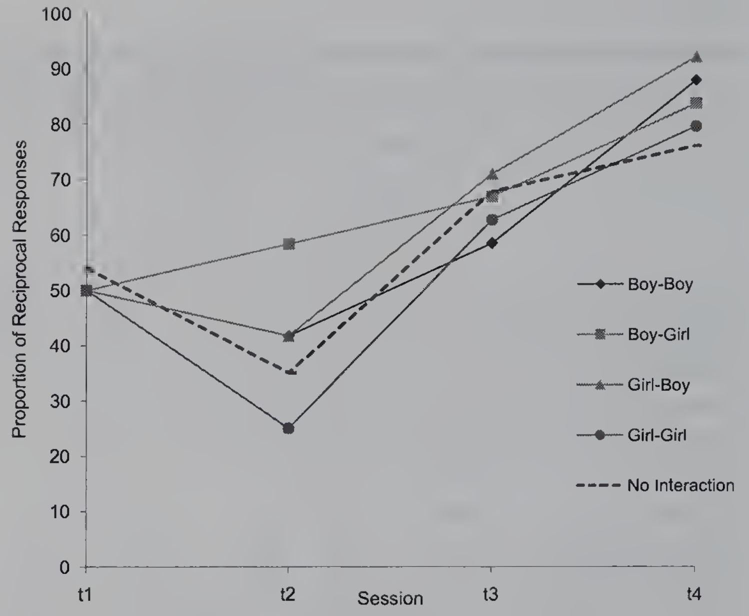

Figure 1. Proportion of reciprocal responses to the broken window story by pair type at *t*1, *t*2, *t*3, and *t*4.

However, overall (i.e., adding responses from three stories together) there was significant variation by pair type in punishment orientation scores, $F(4, 132) = 5.14$, $p < .001$, partial $\eta^2 = .138$ (see Figure 2). Post hoc Tukey honestly significant difference (HSD) tests ($p < .05$) revealed that the mean in the control group ($M = 2.27$, $SD = .73$) differed significantly from the mean in the boy–boy ($M = 2.79$, $SD = .42$), boy–girl ($M = 2.71$, $SD = .46$), and girl–boy ($M = 2.83$, $SD = .38$) pairs. The difference

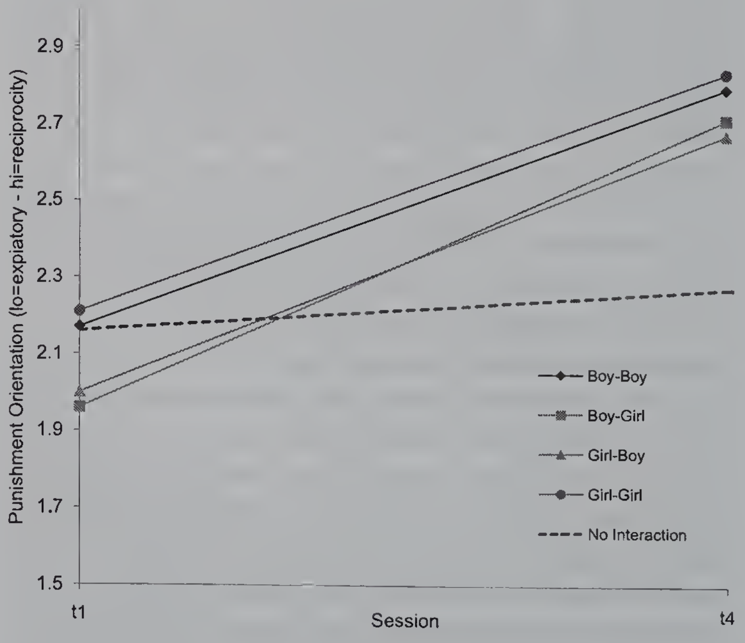

Figure 2. Mean punishment orientation score (0 = *all expiatory* to 3 = *all reciprocal*) by pair type at *t*1 and *t*4.

approached significance ($p = .061$) for the comparison between the control group and girl–girl ($M = 2.67$, $SD = .64$). Comparisons of boys and girls and of those only in the control group revealed no gender differences in orientation.

Changes in punishment orientation (t1–t4). To explore changes in punishment orientation, a repeated measures ANOVA compared responses by pair type at *t*1 and *t*4. This revealed a large and significant effect of the repeated measure, $F(1, 128) = 69.71$, $p < .001$, partial $\eta^2 = .353$. However, this was qualified by a significant effect of pair type, $F(4, 128) = 4.49$, $p < .01$, partial $\eta^2 = .123$. Post hoc follow-up *t* tests compared changes in punishment orientation for each pair type. These tests revealed higher scores (i.e., more reciprocal orientation) at 8 weeks (*t*4) than at initial testing (*t*1) for all pair types—boy–boy, $t(23) = 3.98$, $p < .001$; boy–girl, $t(23) = 4.10$, $p < .001$; girl–boy, $t(23) = 5.82$, $p < .001$; girl–girl, $t(23) = 3.82$, $p < .001$—with the exception of the control group, $t(36) = 0.85$, $p = .40$ (see Figure 2).

Conversation and moral development. In order to examine the impact of conversation features (content and dynamics) on outcomes, separate logistic regressions (forward stepwise, likelihood ratio method) were conducted for each of the test points (i.e., *t*2, *t*3, and *t*4). At *t*2 (i.e., leading up to the joint response of the pair) only the proportionate use of expiatory force justifications was found to relate to outcomes, $\chi^2(1) = 9.02$ $p < .001$, Wald = 6.40. The relation was positive, indicating that use of these justifications often led to a reciprocal joint reply. The analysis at time *t*3 revealed that the use of expiatory force justifications was once again positively related to outcomes, $\chi^2(1) = 6.02$, $p < .001$, Wald = 3.53. No features of conversation content or dynamics were associated with outcomes at the 8-week posttest (*t*4).

Discussion

The present study explored the relations among gender, conversation, and children's judgments about what constitutes a fair punishment. The results demonstrate that gender influences the dynamics of children's conversations. Moreover, conversation was associated with development: Children who discussed the task made more mature, reciprocal judgments than those who did not. Yet although gender affects conversation, and conversation leads to development, variations in the dynamics and content of conversations do not appear to carry over to influence learning and development.

Gender and Conversation

Our first hypothesis predicted that boys would use more simultaneous speech acts (overlaps and interruptions) than girls, and this was confirmed. Specifically, boys used more overlaps and negative interruptions than girls. In addition, all children used more interruptions with a boy. However, our second hypothesis was not confirmed. We predicted that gender differences would be accentuated in boy–girl pairs compared with the same-sex pairs. In fact, there was a greater difference when comparing boys and girls in same-gender (as opposed to mixed gender) pairs. Thus, in contrast to previous findings, in the present study boys and girls in mixed-sex interaction relied less on "male" and "female" conversational styles (at least in the use of simultaneous speech acts).

Results from the present study present us with partial confirmation of previous work on gender and conversation dynamics but also raise further questions about how children respond to mixed-sex interactions. The failure to confirm our second hypothesis might be attributable to several factors; for instance, compared with other studies there may have been differences in the way in which the coding scheme was applied or in sample characteristics. However, perhaps a key difference is that here we used a moral judgment story and although children in a pair had differing perspectives (expiatory and reciprocal responses) the tasks could be seen as relatively nonconflictual. In other studies (e.g., Leman et al., 2005) tasks may involve explicit conflict between children. Moreover, in important respects the present findings match work with preschoolers and older children (Killen & Naigles, 1995; Nelson-Le Gall & DeCooke, 1987), which found that gender differences were less marked in mixed-gender interaction compared with same-gender interaction, because in the former children used more collaboration whereas in the latter they used more commands. How and why different tasks might inspire different gender dynamics in interaction remains an open question. However, the results from the present study demonstrate the importance of context in eliciting different forms of interaction between children generally (Oliveira & Sadler, 2008), and in terms of gender dynamics specifically (Holmes-Lonergan, 2003). Future research is required to establish what features of context may interact with gender, and other social factors, to affect conversation dynamics.

There were gender differences in terms of the use of only two categories with regard to the content of children's conversations. Boys used more assertions than girls, and all children used more assertions when speaking with a boy. When children used an assertion they merely stated or restated a child's belief (e.g., ''He should stay in his room,'' ''Making him pay is fairer'') and did not offer any justification or explanation to support that belief. In conversational terms, assertions may not only communicate a factual statement of belief but also act as a kind of rhetorical gambit: Stating one's position or doing so repeatedly or in the face of another's contrary belief may also constitute an attempt to set or dominate the conversational agenda. Thus, the present finding that boys used more assertion in conversation than girls may reflect more general gender differences in conversation dynamics or style rather than any unwillingness or inability of the boys to elaborate on their positions.

Gender and Moral Judgment

There was also an effect of speaker gender on the use of justifications that appealed to *expiatory force*. These justifications point to the severity of punishment (i.e., a punishment is deemed fair because it is severe) and are closely associated with the expiatory position. In the present study, boys used more of these sorts of justifications than girls although equivalent numbers of boys and girls made expiratory judgments. It may be the case that the expiatory boys were more vociferous in arguing their position than expiatory girls in the present study.

Previous research suggests that there are few, if any, reliable gender differences in moral orientation (e.g., Walker, 2006). One might anticipate that differences in orientation would become evident in children's conversations, especially when children were given the task of justifying their own perspective that contrasted with that of a peer. But the results from the present study indicate that there were few gender differences in the ways in which children justified their judgments. This suggests that any underlying orientations to morality do not divide simply along gender lines at this age, although gender certainly is an important factor affecting the dynamics of children's interactions. Thus, it was not the case that the children were unaware of or insensitive to gender as a social category, or that boys and girls at this age do not reproduce typical ''male'' and ''female'' conversational styles. However, these effects of gender are not visible in terms of moral judgments and justifications.

Conversation and Development

Our third hypothesis predicted that interaction between children on this task would be associated with changes in punishment orientation (compared with a no-interaction, control group of children). Additionally, our fourth hypothesis predicted that there would be no relation between gender, or the gender mix of children involved in interaction, and developmental advances. Both of these hypotheses were confirmed.

On one hand, it should not come as a surprise that children who engaged in interaction with a peer changed their judgments to the more adaptive, reciprocal orientation. Previous research has demonstrated the benefits of interaction for the development of moral judgment (Damon & Killen, 1982; Leman & Duveen, 1999). Moreover, our finding that the gender of children engaged in conversation had no influence on developmental outcomes is also consistent with previous work on this topic (Leman et al., 2005). On the other hand, it is striking that such a brief period of conversation between children on a single vignette should have an influence on moral judgment after 8 weeks. The finding is striking, but it is consistent with other work (e.g., Psaltis & Duveen, 2006, 2007). Moreover, it is plausible to argue that once the ''penny drops'' in terms of an individual's understanding it is unlikely that the change in the basis of moral judgments will be quickly undone.

It is important, however, to include a note of caution in terms of limitations to the tasks that we used in the present study. In many of Piaget's (1932) vignettes the role of authority is often confounded with other significant aspects of a task that may obscure the nature of children's understanding (Costanzo, Coie, Grumet, & Farnhill, 1973). In this respect our punishment stories, like Piaget's, present children with situations where parents have the power to punish children and hence inevitably incorporate parental authority as an ingredient in the judgment that participants were asked to make. Although our observations during pretesting and data collection suggest that children did not have difficulty imagining that adults might choose between expiatory and reciprocal punishments, a limitation of the vignettes we used is that children may have responded in ways that sought to anticipate how an adult authority figure would behave rather than select the fairest punishment. Caution is therefore required in extending research findings to *all* children's interactions and, in particular, peer interactions which differ in important ways from adult–child interaction.

A further important qualification is that the confirmation of our third and fourth hypotheses was possible for our global (or overall) measure of punishment orientation, but not for judgments about the conversation stimulus story (the broken window). This suggests that any developmental benefits of conversation extend across a subdomain (conceptions of punishment) rather than being restricted to a particular story. In other words, this is development at a deep, structural level rather than merely a learned response to a particular story.

Development and the Features of Conversation

The final focus for the present study was on the links between features of conversations (content, dynamics, or interruptions) and developmental change. Ultimately, we found no relation between conversation content and development, although in the shorter term, justifications pointing to the use of expiatory force did relate to outcomes. From an educational and developmental perspective, the important finding was that features of conversations did not relate to judgments at 8 weeks after interaction, which was consistent with our fifth hypothesis.

The present findings are consistent with previous work (notably Howe et al., 2005) that has found no links between specific features of conversations and development. However, our findings hint that explicitly discussing justifications involving expiatory force may promote perspective taking in the short- to midterm. In this respect, it is important to note that justifications that focus on expiatory force are closely aligned to the *less* mature moral response. It may be that explicitly examining, and then rejecting, the justifications for a less mature response, helps children to appreciate the legitimacy of the more advanced position more quickly. Such an interpretation is certainly also consistent with Psaltis and Duveen's (2007) study, which indicated that explicit recognition of the reasons or grounds for an answer was closely associated with development after interaction.

We also found no links between conversation dynamics (gauged here by use of simultaneous speech acts) and (developmental) outcomes. The failure to find any connection between conversation dynamics and outcomes indicates that although gender (and the gender mix of children involved in interaction) affects conversation dynamics, this does not necessarily feed through to influence learning and development, or even shorter term decision making. At this age, children can ''work around'' the effects of gender on conversation in terms of decision making and learning (Leman & Lam, 2008; Leman et al., 2005); that is, although boys' and girls' conversations show distinctive characteristics, and although boys and girls react to the gender of their conversation partner in terms of their conversation styles, these do not ultimately affect learning. However, it should not be forgotten that gender effects on conversation may be insidious: For instance, boys' dominance may reinforce status hierarchies and differences between genders from an early age. Moreover, conversation and interaction (in the classroom and elsewhere) provide a key forum through which stereotypes may be communicated.

Conclusions. These findings demonstrate that conversation between peers leads to development. Moreover, there were no effects of conversation dynamics and conversation content on longer term development. Thus, conversation on a topic may stimulate a process of individual reflection that triggers developmental advances. However, it seems that the process may be accelerated by explicit recognition, in a conversation, of the reasons against a less advanced position or, to follow Psaltis and Duveen (2006, 2007), the reasons for a more advanced position. An implication of this finding is that educators do not necessarily need to guide the contents of a specific conversation between children too closely. Rather, following Howe et al. (2005), learning benefits are a consequence of postconversation reflection.

The present findings also suggest that educators, policy makers, and others need to be cautious in jumping to the conclusion that because gender can influence the dynamics of interaction in problem-solving tasks and the classroom it is inevitably detrimental to the learning of one or both gender groups. By 7 years, children are skilled social actors who recognize the influence of gender and other social categories such as race on social relations and interpersonal behavior (Leaper & Smith, 2004; Leman & Lam, 2008). In some contexts at least, children can work around these influences to make good judgments regardless of the dynamics or style of a conversation.

Appendix: Additional Punishment Stories

Taking Turns

A boy was playing on a slide in the garden with his little brother, and wouldn't let his brother have a turn. The little brother got very upset and started to cry. The boys' dad saw this and decided he needed to punish the older boy. He thinks of two punishments. The first is to say: ''You wouldn't let your little brother have a turn. Now, I'm going to let your little brother have two turns, and you will miss a turn.'' The second is to say: ''You wouldn't let your little brother have a turn. Now, I'm going to take away one of your favourite toys until you learn to play properly.'' Which of these punishments do you think is the fairest?

The Broken Doll

A girl was playing with her little sister's things and wasn't being careful. She broke her little sister's favourite doll. Her mum finds out what has happened and thinks of two ways to punish her. The first is to say to the girl: ''You broke your sister's doll, so now you must go and buy her another one from your own money.'' The second is to say: ''You broke your sister's doll, so now you are not allowed to go and play at your friend's house.'' Which of these punishments do you think is the fairest?

Note. In each story, the first choice of punishment corresponds to the reciprocal orientation, the second to the expiatory orientation.

The transition into school occurs at the intersection of multiple environmental settings. This study applied growth curve modeling to a sample of 1,364 American children, followed from birth through age 6, who had been categorized by their exposure to cognitive stimulation at home and in preschool child care and 1st-grade classrooms. Of special interest was the unique and combined contribution to early learning of these 3 settings. Net of socioeconomic selection into different settings, children had higher math achievement when they were consistently stimulated in all 3, and they had higher reading achievement when consistently stimulated at home and in child care. The observed benefits of consistent environmental stimulation tended to be more pronounced for low-income children.

Ecological perspectives, which emphasize connections among multiple settings of children's lives, are highly relevant to education (Bronfenbrenner, 1979; Elder, 1998). For example, efforts to elucidate the ways in which families and schools come together to create unique spaces for children's development of cognitive and academic skills have informed not only theory but also policy, including No Child Left Behind (Epstein, 2005). This appreciation of multiple settings of development should be expanded to recognize the ways in which experiences in child care come together with experiences at home and in school to influence children's transitions into elementary school. Yet, any associations of proximal experiences in these settings with early learning must be parsed in relation to the larger

system of socioeconomic stratification in the United States. The need to do so is driven by the possibility of spuriousness in observed environmental effects on children (Duncan, Magnuson, & Ludwig, 2004), the important role of the transition into school in the intergenerational transmission of socioeconomic inequality (Brooks-Gunn & Duncan, 1997), and the long tradition of viewing both family–school connections and preschool as policy levers to reduce socioeconomic (and related) disparities among children (Epstein et al., 2002; Winsler et al., 2008).

This study, therefore, traces the reading and math trajectories of children who have experienced consistency or inconsistency in cognitive stimulation across family, child care, and classrooms settings during their entry into formal education. This investigation will also address the potential for the number and type of early sources of stimulation to contribute to socioeconomic disparities in learning as well as assess the potential for the socioeconomic advantages of parents (e.g., income, education, marital status, neighborhood composition) to explain and/or condition any observed effects of various configurations of early stimulation. These aims will be pursued by applying growth curve techniques to multisetting data from the National Institute of Child Health and Human Development Study of Early Child Care and Youth Development (NICHD SECCYD). The general goal is to advance understanding of child development, education, and inequality by treating schools as one piece of a web of overlapping contexts contributing to the learning of children from different backgrounds and assessing the give and take between selection and socialization in this web.

The Transition Into Elementary School and Socioeconomic Inequality

The transition into elementary school is a vehicle for socioeconomic stratification in the United States (Winsler et al., 2008). At this point, the educational system magnifies existing disparities in cognitive and academic skills. Because perceived skills set class placements and performance expectations that then build on each other, even small early differences between child groups can expand into large end-of-school outcomes, such as dropout rates (Entwisle, Alexander, & Olson, 1997; Raver, Gershoff, & Aber, 2007). These findings are part of the rationale that early investments provide the greatest long-term payoff and support policy efforts targeting preschool and primary education (Fuller, 2007; Heckman, 2006; Takanishi & Bogard, 2007).

Ecological and life course perspectives elucidate the role of the transition into school in socioeconomic inequality by emphasizing how it is situated in the multifaceted ecology of early childhood (Alexander & Entwisle, 1988; Burchinal, Campbell, Bryant, Wasik, & Ramey, 1997; Crosnoe, 2006b; Raver et al., 2007). One example of this approach is contextual systems theory (Pianta & Kraft-Sayre, 2003), which contends that learning during the transition into elementary school is best understood as either supported or disrupted by transactions among environmental settings. Learning proceeds more smoothly when these settings provide positive resources in a parallel or linked manner, less so when they are disorganized and/or misaligned. Importantly, the theory also asserts that differences in such transactions help to explain why some children, such as those from families of low socioeconomic status (SES), are at risk for poor transitions.

For the most part, the ecological settings studied in relation to the transition into elementary school are families and schools (Christenson & Sheridan, 2001; Epstein et al., 2002; Patrikakou, Weisberg, Redding, & Walberg, 2005). Contextual systems theory emphasizes multiple forms of transaction between the two. One form is direct and interactional, with parents and school personnel engaging each other, for example, through a regular pattern of mutually respectful parent–teacher meetings or when parents volunteer at schools and schools offer services to parents. Another form is less coordinated, for example, parents and school personnel cultivating children's skills in similar, mutually reinforcing ways (e.g., both reading to child) whether they know that they are doing so or not. A child experiencing this type of transaction is growing up in a system of *consistently* enriching settings. Evidence from the Early Childhood Longitudinal Study indicates that both family–school transactions are associated with learning gains in early childhood but that the presence of environmental consistency (even when not coordinated) is more closely related to socioeconomic disparities in early learning (Crosnoe, 2006a). This study, therefore, focuses on consistency in learning environments around the transition into school and addresses two potential areas of expansion in this line of research: including child care and unpacking the role of family SES.

Expanding the Scope

More fully recognizing the insights of ecological perspectives requires the consideration of more than just family–school connections. Given the aforementioned value of early educational investments (Heckman, 2006), early child care is a logical setting to examine. Today, most children transition into elementary school after spending time in nonparental child care, including formal center care. The calibration and assets provided by families, schools, and child care, then, create a web of possible support for children as they enter the educational system (Committee on Family and Work Policies, 2003). Just as research on family–school connections has yielded insight into the value of consistent learning supports across home and school (Epstein et al., 2002), both naturalistic and intervention studies have demonstrated the value to learning of positive transactions between home and child care/preschool (NICHD ECCRN, 2005; Wasik, Ramey, Bryant, & Sparling, 1990). What is lacking is information about coordination and/or consistency among all three pieces of the triangle.

Following contextual systems theory, the *accumulation* of cognitively stimulating settings should boost children's prospects for learning in elementary school. In other words, children who are stimulated at home, in child care, and then in elementary school would be expected to do better than children who are stimulated in only two of these settings, who would be expected to do better than children who are stimulated in only one of these settings. Beyond the accumulation of cognitively stimulating environmental settings, the *configuration* of exposures to cognitive stimulation matters. For example, children may not benefit equally from stimulation in two of three settings if the two settings in question differ between them (e.g., home and school for Child 1, child care and school for Child 2).

Given that parents are typically the most consistent agents of young children's learning and given the many ways that parents prepare children for school (Hart & Risley, 1995; Lareau, 2004), the absence of cognitive stimulation at home during early childhood should be especially problematic. Stimulation in *either* child care *or* school only, therefore, would be less beneficial than stimulation at home only. Furthermore, stimulation in *both* child care *and* school only would be less beneficial than stimulation in both home and child care only or in both home and school only. If stimulation at home is paired with stimulation in only one other setting, a case could be made that either school or child care will be more important. Of course, the school classroom is where formal instruction takes place, and, again, the demands of such instruction are what many parents are tailoring their in-home stimulation to eventually support (Entwisle et al., 1997). Yet, given the increasingly strong link between early child care and school readiness (NICHD ECCRN, 2005), children may be less able to take advantage of stimulating school settings if they do not enter school with a strong foundation for learning developed during years of consistent stimulation at home and in child care (Walker, Greenwood, Hart, & Carta, 1994).

The first aim of this study, therefore, is to identify configurations of cognitive stimulation across home, early child care, and school settings around the initial school transition. The second is to determine the degree to which these configurations are associated with children's learning trajectories during elementary school.

Elucidating the Role of Family SES

Given what is known about family SES and education (Entwisle et al., 1997; Walker et al., 1994), any assessment of consistent environmental stimulation during this transition would be incomplete without assessing how family SES fits into the puzzle. Theoretical perspectives on socioeconomic disparities in all stages of education have a basic underlying argument (Alexander & Entwisle, 1988; Lareau, 2004). In short, because socioeconomic disparities in access to social resources for learning drive socioeconomic differences in learning, equal access to such resources across socioeconomic strata should narrow these differences. This argument connects to the aims of this study in two ways.

First, one arrangement of family SES, social resources for learning, and child learning is that social resources mediate the link between family SES and child learning. An alternate explanation, however, is that the association between resources and learning is spurious, with both produced by family SES. In this case, social resources for learning are merely proxies for families' socioeconomic circumstances. Of course, both arrangements could be at work. The degree to which both, either, or neither apply here, then, needs to be determined.

Second, the link between consistent environmental stimulation and learning may also be moderated by SES. Again, the working hypothesis has long been that reducing group differences in access to social resources will reduce disparities in child outcomes. Yet, universal interventions often reveal that equal access to resources can lead to greater disparities in outcomes when non-at-risk children are better able to capitalize on having that resource than at-risk children (Ceci & Papierno, 2005). Following this pattern of cumulative advantage, high-SES children might benefit more from having the same kind of environmental stimulation as low-SES children. If so, socioeconomic disparities in learning would increase even if the absolute levels of learning of low-SES children were raised. Another scenario is that access to any new resource will make more of a difference to the children for whom it is nonredundant. Thus, the impact of a resource has added value for at-risk children. Following this buffering pattern, making sure that high- and low-SES children have the same kind of environmental stimulation should reduce socioeconomic disparities (Winsler et al., 2008). In other words, two moderation patterns are plausible.

The final aim of this study, therefore, involves three related questions. Are relations between family SES and child learning mediated by consistent environmental stimulation? Does consistent stimulation proxy family SES? Does SES condition effects of consistent stimulation?

Method

Data Source

Data collection for the SECCYD (http://secc.rti.org) began in 1991 in 10 locations: Little Rock, AR; Irvine, CA; Lawrence, KS; Boston, MA; Philadelphia, PA; Pittsburgh, PA; Charlottesville, VA; Morganton, NC; Seattle, WA; Madison, WI. During selected sampling periods, study personnel visited new mothers in the hospital. To be eligible, the mother had to be 18 years of age or older, healthy, and conversant in English, and the infant had to be a singleton. A month later, 1,364 families were enrolled in the study. The collection of data from parents, children, and other adults in home, laboratory playroom, child care, and school visits proceeded in several stages from birth and is ongoing. Because of our focus on the transition into school, we drew on the SECCYD data through the children's fifth-grade year. Some families dropped out or were lost by this time point (*n* = 287), and others missed some data collections. Because deleting cases with item- or wave-specific missingness can bias the sample, full information estimation methods were employed to allow for the retention of all observed data.

Measures

Child learning. Two Woodcock–Johnson Psycho-Educational Battery–Revised subtests (WJ–R; Woodcock & Johnson, 1989) were assessed in the laboratory at 54 months and Grades 1, 3, and 5. Letter–Word Identification gauged reading skills, and Applied Problems gauged math skills. Raw scores on the subtests were converted to *W* scores, transformations of the Rasch ability scale that centered the raw score at 500 in order to ease comparisons across the multiple WJ–R administrations. Table 1 includes mean scores on these subtests at each time point (as well as descriptive statistics for the other study variables). Scores increased across grades.

Family SES. Three SES measures tapped characteristics of the families themselves, reported by parents when children were 1 month old. Parent education was a binary marker (1 = *at least one parent had a college degree*, 0 = *other*). Income-to-needs was a continuous variable representing total income divided by the federal poverty threshold for a family of that size (U.S. Census Bureau, 2008). Marital status was a binary marker (1 = *parents married*, 0 = *other*). A fourth SES measure tapped collective characteristics of families in children's

Table 1

Child, family, and setting characteristics	*M*	*SD*
Child test scores		
Reading score (54 months)	424.72	19.72
Reading score (Grade 1)	470.05	15.54
Reading score (Grade 3)	493.50	12.76
Reading score (Grade 5)	510.54	13.04
Math score (54 months)	369.36	21.41
Math score (Grade 1)	452.59	23.99
Math score (Grade 3)	494.60	15.75
Math score (Grade 5)	507.63	14.12
Family socioeconomic circumstances		
Parent education (college graduate)	0.44	0.50
Family income-to-needs	3.63	3.17
Parent marital status (married)	0.77	0.42
Neighborhood affluence	−0.04	0.89
Environmental stimulation		
HOME stimulation (54 months)	17.84	2.47
Child-care stimulation (54 months)	2.21	0.80
School classroom stimulation (Grade 1)	15.67	4.16
Other child/family factors		
Gender (male)	0.52	0.50
Race (non-White)	0.20	0.40
School readiness (36 months)	9.02	2.89
Maternal employment	0.67	0.47
Maternal employment (unemployed)	0.31	0.46
Maternal employment (on leave)	0.02	0.15

Note. For binary measures (parent education, marital status, gender, race, maternal employment), means represent the percentage of respondents in the one category. HOME = Home Observation of Measurement of the Environment.

neighborhoods. Neighborhood affluence was the mean of two standardized census block variables: (a) the percentage of professionally educated persons over the age of 25 in the block group and (b) the median household income in the block group ($\alpha = .89$). The descriptive statistics in Table 1 reveal that the sample exceeds national averages on many socioeconomic indicators. Ancillary analyses revealed a great degree of stability in these measures over time.

Environmental stimulation. Our typology was based on three *observational* indicators of environmental cognitive stimulation. First, cognitive stimulation in the family at 54 months was measured with the Home Observation of Measurement of the Environment (HOME; Bradley & Caldwell, 1979). The HOME enrichment scale summed the learning materials (sum of 11 binary items), academic stimulation (5 items), and variety (9 items) subscales ($\alpha = .88$). Second, cognitive stimulation in child care at 54 months was based on the Observational Rating of the Care Environment (ORCE; NICHD Early Child Care Research Network., 2005). The ORCE stimulation of cognitive development subscale was defined by ratings of high-quality stimulation provided in lessons, explanations, and activities (1 = *not at all characteristic*, 4 = *highly characteristic*). Third, cognitive stimulation in the first-grade classroom was based on the Classroom Observation System (COS; Pianta, Belsky, Houts, Morrison, & the NICHD ECCRN, 2007). The instructional quality composite ($\alpha = .70$) summed four ratings (1 = *uncharacteristic*, 7 = *extremely characteristic*): literacy, evaluative feedback, instructional conversation, and child responsibility.

To capture accumulation and configuration of environmental stimulation, these three scales needed to be categorized into levels and then combined in theoretically meaningful ways. After extensive preliminary analyses, the most stimulating contexts were identified as those scoring above the median on the HOME, ORCE, and COS. The final typology then represented the different combinations of 0–3 high-stimulation environments. Cross-classifying these binary measures created dummy variables tapping six categories of environmental consistency: (a) triple stimulation (32%), which included children above the median on all three; (b) family–child care stimulation (15%), which included children above the median on the HOME and ORCE only; (c) family–school stimulation (11%), which included children above the median on the HOME and COS only; (d) child care–school stimulation (9%), which included children above the median on the ORCE and COS only; (e) single stimulation (26%), which included children above the median on either the HOME, ORCE, or COS but not the other two; and (f) low stimulation (7%), which included children below the median on all three.

Other child and family factors. Several control variables were created to account for major observable confounds, including binary markers of gender (1 = *male*) and race (1 = *non-White*), maternal employment dummy variables (employed for pay part- or full-time, unemployed, on leave from work), and a continuous measure of school readiness at 36 months. This last measure was based on the Bracken (1984) Basic Concept Scale, a composite of five cognitive assessments of children: identifying and recognizing colors, letters, numbers, comparisons, and shapes (range = 0–61, $\alpha = .93$).

Procedure

As a first step, growth curves for reading and math test scores were estimated with free-loading latent curve models (Meredith & Tisak, 1990), which did not impose any specific trend over time but instead allowed the data to dictate it. The four WJ–R scores (54 months; Grades 1, 3, 5) served as indicators of latent variables representing the intercept and slope of the trajectory of reading or math achievement. The model was identified with constraints on the Grade 1 and 5 loadings. Specifically, the Grade 1 loading was constrained to 0 to allow the intercept to be interpreted as the mean level of achievement in Grade 1. Note that the intercept was situated at Grade 1 rather than 54 months so that the parallel learning categories (some of which contained the classroom item measured in Grade 1) could be meaningful predictors of the intercept. Next, the Grade 5 loading was constrained to 1 to allow the slope to be interpreted as the change in achievement between Grades 1 and 5. All other loadings were freely estimated. These loadings can be interpreted as a proportion of change in reading or math test scores based on the total change between Grades 1 and 5. For example, a Grade 3 loading of .60 would indicate that 60% of the total change in reading or math test scores between Grades 1 and 5 was achieved by Grade 3.

Next, environmental stimulation categories, family SES, and the child and family controls were entered into the baseline model as predictors of the intercept and slope of reading and math achievement. Comparing how results for socioeconomic circumstances and for environmental stimulation changed with the addition of the other two sets of factors to the model assessed the extent to which the mediational or spurious arrangements held in this sample. As a final step, interactions between the family SES and environmental stimulation variables were added to the growth curve model as predictors of the intercept and slope to explore moderation.

In all models, parameter estimates were obtained with full information maximum likelihood (FIML) in Mplus (Muthén & Muthén, 2004). Models were evaluated with several fit indices: χ^2, root mean square error of approximation (RMSEA), the Tucker–Lewis index (TLI), and the comparative fit index (CFI).

Results

As a starting point, Table 2 presents mean family socioeconomic characteristics for children in the six environmental stimulation categories. As expected, children in the triple stimulation category typically had the most advantaged family backgrounds, and those in the low stimulation category typically had the least advantaged family backgrounds. Of the four other environmental stimulation categories, family–child care and family–school stimulation had higher mean levels on the family socioeconomic factors than child care–school and single stimulation. Generally speaking, then, family socioeconomic circumstances and exposure to stimulating environments increased in tandem, but, perhaps not surprisingly, the link between family socioeconomic circumstances and stimulation at home appeared especially strong.

Of course, attempts to understand relations between SES factors and environmental stimulation categories are sensitive to the potential for sparse coverage in various SES × Environmental category cells. Cross-classifying the environmental stimulation typology with a set of categories for each SES indicator (parent married to child's other parent vs. not; parent college educated vs. not; income-to-needs of 0–2, 1–3, 3+; low, medium, and high neighborhood affluence defined by standard deviation cuts) revealed that some cells contained small numbers of children (e.g., 10 or fewer). The smallest cells were for children in the low stimulation category who had college-educated parents, middle-income parents, neighborhoods of low affluence, and neighborhoods of high affluence. The case coverage in these particular cells warrants caution when interpreting null or significant results.

Differences in Reading and Math Trajectories

Before assessing differences in test scores by environmental stimulation categories and family socioeconomic circumstances, we first had to determine the functional form of the test score trajectories across elementary school. Table 3 presents the results from unconditional free-loading growth curve models for reading and math.

For these unconditional models, fit was somewhat marginal for reading and moderate for math, although fit statistics improved in later modeling iterations. As explained earlier, the mean intercept for both subjects represents the average test score in Grade 1 (even though the 54-month score was also included), and the mean slope represents the average total change in test scores between Grades 1 and 5. Thus, children scored about 450 points, on average, on the Grade 1 WJ–R test for reading and then added an additional 55 points by the end of Grade 5. The basic growth curve was similar for math, although children started off, on average, a

$^{***}p < .001$.

little higher on this WJ–R test and gained slightly fewer points over time. For both reading and math, most of the upward change in the slope occurred between Grades 1 and 3. Worth noting is that the significant variance estimates indicate that children in the sample varied significantly around the mean intercept and slope for both reading and math. Such significant variation can then potentially be explained by independent variables, including the environmental stimulation dummy variables and family socioeconomic factors. Below, we present the results for reading test scores in detail and then later summarize the findings for math test scores.

Consistent Environmental Stimulation, Family SES, and Reading

The first set of models in Table 4 (see Model 1) included the environmental stimulation dummy variables as the only predictors of the intercepts and slopes of the growth curve. The stimulation coefficients are interpretable as test point differences relative to the reference, child care–school stimulation, which was chosen because it provided the contrast with the largest number of observable significant differences among categories. Of note is that post hoc between-group comparisons were performed (based on the corresponding model-implied parameter estimates and standard errors) to catalog *all* pairwise differences among categories—not just those in relation to the reference category. Thus, the reference is important for interpreting coefficients in the tables but not important for understanding the full set of patterns analyzed.

For the reading intercept, the model coefficients and post hoc comparisons together indicated a basic rank ordering (from highest to lowest) in average Grade 1 reading scores: (a) triple stimulation, family-child-care stimulation; (b) family–school stimulation; (c) child care–school stimulation, single stimulation; (d) single stimulation, low stimulation. In this rank ordering, an environmental stimulation category that is in two separate ranks is a "bridge" between ranks. For example, the coefficient for single stimulation was not significantly different from the child care–school stimulation coefficient or the low stimulation coefficient, but the child care–school stimulation and low stimulation coefficients did differ from each other. In other words, single stimulation bridged two different ranks.

For the slope, the positive low stimulation coefficient in the table indicated that children in this environmental stimulation category had more pronounced reading gains after Grade 1 than children in the child care–school stimulation category. Post hoc comparisons revealed that they also had larger reading gains than children in *all* other environmental stimulation categories. Basically, children in the low stimulation category (i.e., those with the least exposure to stimulation overall) appeared to benefit the most from the start of formal schooling. They had the greatest uptick in reading skills after school had begun. This pattern is interesting given that the classrooms they entered once school began were not high in cognitive stimulation.

Although our environmental categorization scheme was aligned with our conceptual emphasis on accumulation and configuration, we recognized that categorizing and combining continuous variables could raise concerns about loss of scale variation. Consequently, we estimated this model (and subsequent models) with different categorization schemes (e.g., with standard deviation cut points), finding no difference in results for the largest categories. Moreover, the model was estimated with two- and three-way interactions among the continuous versions of the HOME, ORCE, and COS scales. Doing so revealed weaker associations between links among the three setting factors and

the outcomes, which was likely attributable to the nonlinear nature of the scales in combination with each other.

The second set of models in Table 4 (see Model 2) included the family socioeconomic factors as the only predictors of the intercepts and slopes of each growth curve (i.e., no environmental stimulation categories or family/child controls). All four significantly predicted the reading intercept. The difference between children with and without a college-educated parent equaled about 7.5 points on the reading test in Grade 1. The spread was .5 point for each increase in the income-to-needs and 4 points between children with and without married parents. Standardizing all four coefficients revealed that the effect size for neighborhood affluence was between the effect sizes for parent education (the biggest) and family income-to-needs (the smallest). As for the reading slope, two family socioeconomic factors had significant, negative coefficients. Children with college-educated parents and children who lived in more affluent neighborhoods had slightly less pronounced upward rates of change in achievement after Grade 1. Again, the most disadvantaged appeared to benefit the most from formal schooling.

Assessing Mediation

Mediation entails differences in child learning by family SES channeled through corresponding SES differences in environmental stimulation. One way to assess mediation is to compare associations between socioeconomic circumstances and child test scores before and after taking environmental stimulation into account. If environmental stimulation mediates the associations between socioeconomic circumstances and child test scores, then these associations should be weaker after environmental stimulation is controlled. Assessing the degree to which they are weaker gauges the degree of mediation.

The baseline associations between the four family socioeconomic circumstances and the reading achievement intercept and slope appear in Model 2 of Table 4. Model 3 reveals what happened to these baseline associations once the full set of environmental stimulation dummy variables was added to the growth curve model without any other controls.

Beginning with the previously observed association between parent education and the reading intercept, the parent education coefficient in Model 2 was attenuated by 10% with the inclusion of the environmental stimulation dummy variables in Model 3. Because triple stimulation and family-child-care stimulation were the only significant coefficients among the environmental stimulation dummy variables in Model 3, they appeared to be driving this attenuation. The corresponding levels of attenuation between intercept Models 2 and 3 were 18% for family income, 33% for parent marital status, and 16% for neighborhood affluence. Thus, some of the advantage that children from more privileged backgrounds had over their peers in reading at the start of school appeared to be related to their greater likelihood of having stimulation at home matched with stimulation in child care and/or Grade 1 classrooms.

Turning to the slope, the previously observed negative associations of parent education and neighborhood affluence with the reading slope (Model 2) were slightly attenuated by the inclusion of the environmental stimulation dummy variables. Because low stimulation was the only stimulation coefficient to achieve statistical significance in Model 3, it appeared to be driving this attenuation. Thus, the shallower reading gains that children from more privileged backgrounds exhibited across the elementary school years were, in part, related to their tendency to have stimulation in any or all settings of early childhood; in other words, to *not* be in the low stimulation category. They started off ahead and then had less to gain over time.

Model 4 added the full set of child and family controls, of which early school readiness was the only one to significantly predict both intercept and slope. More school-ready children had higher initial reading test scores but slightly less pronounced test score gains as elementary school progressed. The inclusion of the Bracken measure attenuated the associations between the family socioeconomic circumstances and the reading intercept by between an additional one half and three fourths (comparing the intercept coefficients for the socioeconomic factors in Model 3 to the corresponding coefficients in Model 4). Along with race, the inclusion of the school readiness scale also washed out the observed associations between parent education and neighborhood affluence on one hand and the reading slope on the other (comparing the slope coefficients for the socioeconomic factors in Model 3 and Model 4).

Assessing Spuriousness

Spuriousness occurs when test score differences across environmental stimulation categories are accounted for by the family socioeconomic circumstances that contribute to both environmental stimulation and test scores. One way to assess spuriousness is to compare associations between environmental stimulation categories and test scores before and after taking family socioeconomic circumstances into account. If these associations are spurious (confounded with family socioeconomic circumstances), then they should be weaker after family socioeconomic circumstances are controlled.

Again, comparing coefficients between models allows an assessment of spuriousness (see Table 4). The baseline associations between the environmental stimulation dummy variables and the reading intercepts and slopes have already been presented in Model 1. The coefficients in Model 3, which simultaneously regressed the intercept and slope of reading on the family socioeconomic circumstances and the environmental stimulation dummy variables, provide the appropriate comparison. For the reading intercept, the environmental stimulation coefficients were smaller when they were estimated simultaneously with the family SES factors (Model 3 intercept) than when estimated in isolation (Model 1 intercept). The coefficients for triple stimulation and family–child care stimulation (relative to child care–school as well as single and low stimulation) remained significant but were attenuated. The coefficients for family–school stimulation and low stimulation were reduced by almost half and became nonsignificant.

When the other child and family controls were added in Model 4, the intercept coefficients for triple and family–child care stimulation appeared somewhat robust. Of the environmental stimulation dummy variables, they were the only two to be associated with the reading intercept after both the family socioeconomic circumstances and the child and family controls were taken into account. The slope coefficient for low stimulation was also robust to controls for family socioeconomic circumstances and other child and family characteristics.

Assessing Moderation

A final aim of this study was to investigate whether family socioeconomic circumstances and environmental stimulation were related to each other in more complex, multiplicative ways. Specifically, we were interested in whether the links between environmental stimulation categories and test scores varied as a function of family socioeconomic circumstances.

To assess moderation, the family socioeconomic factors, the environmental stimulation dummy variables, and their interactions were entered into the unconditional growth curve model as predictors of the reading intercept and slope. Interactions of the environmental stimulation dummy variables with each family socioeconomic factor were examined separately. Significant interactions were graphed to determine the degree to which the associations between environmental stimulation and reading test scores varied by family SES. These models were estimated with and without the set of child and family control variables. The results of revealed that, of the four socioeconomic factors, only family income-to-needs significantly interacted with the environmental stimulation categories in any consistent way. Table 5 presents the focal results of the reading models with the family income interactions. Model 1 was the baseline (i.e., main effects and interactions only), and Model 2 added the other child and family controls.

According to the results for Model 1, all environmental stimulation categories except low stimulation (recall the small cell size for Income × Low stimulation) significantly interacted with family income-to-needs to predict the reading intercept when child care-school stimulation was the reference. All of these interactions were negative in sign. To interpret these interactions, we calculated predicted intercept values for children in each environmental stimulation category (including the omitted category of child care–school stimulation) who came from low-income families (income-to-needs = 1) or high-income families (income-to-needs = 5), with all other variables held to their sample means (see Figure 1).

For high-income children, only triple stimulation was associated with a significantly higher reading intercept than the child care–school category reference. The difference between the two was 3 points, equaling 19% of a standard deviation in Grade 1 test scores (the time point that served as the intercept in the growth curve). The difference between triple stimulation and the other two environmental stimulation categories (family–school, family–child care) was 5 points (32% *SD*), although these two other categories did not significantly differ from the child care–school category. More differences across environmental categories were detected, however, for low-income children. For example, the predicted reading intercept for children with child care–school stimulation (444), the category without high family stimulation, was significantly lower than for children with family–school stimulation (3 points, 19% standard deviation) and family–child care stimulation (4, 26%). In turn, the predicted

Note. Model 1 included the other SES indicators. Model 2 added the child and family factors. Chi-square/*df* = 236.78/57*** (M1), 224.24/67*** (M2); TLI = 0.94 (M1), 0.95 (M2); CFI = 0.88 (M1), 0.90 (M2); RSMEA = 0.05 (M1), 0.05 (M2); 90% CI = 0.042–0.055 (M1), 0.047–0.060 (M2).
**p* < .05. ****p* < .001.

intercept for children in these latter two categories, which tapped double stimulation when at least one stimulating environment was the home, was significantly lower than for children in the triple stimulation category (4 and 5 points, respectively, at 26% and 32% *SD*). Indeed, the biggest within-income difference in Figure 1 was between low-income children with child care–school stimulation and children with triple stimulation (8 points, 51% *SD*). Thus, among low-income children, each environmental stimulation category involving stimulation at home was associated with higher reading intercepts than child care–school stimulation.

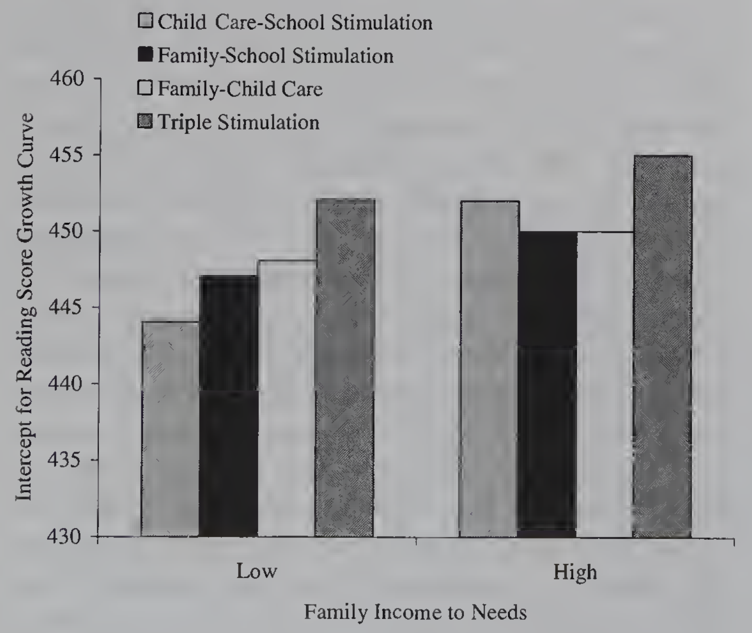

Figure 1. Reading scores at intercept, by family income and environmental stimulation category.

When the full set of child and family controls was included (see Model 2 in Table 5), this basic pattern of moderation held only for the family–school environmental stimulation category. In other words, the observed "benefits" of having triple stimulation or family–child care stimulation were equal for low-income and high-income children of similar levels of early school readiness, but low-income children appeared to benefit more from linking stimulation at home and school than high-income but similarly school-ready peers.

Summary of Math Findings

In general, the results from the math models were similar to those for reading (Table 6). In terms of the associations between environmental stimulation and test scores, one major distinction (see Table 4) emerged. It involved the math intercept.

Table 6

**p* < .05. ***p* < .01. ****p* < .001.

Children in the triple and family–child care stimulation categories had significantly higher scores in Grade 1 than children in all other categories. Moreover, in addition to the same low stimulation association seen in the reading models, triple stimulation also predicted the math slope. Children in this category had less pronounced gains in math after Grade 1 relative to those in the child care–school stimulation category and indeed relative to all other categories (according to post hoc comparisons).

Overall, the results of models examining the associations between family socioeconomic advantages and children's math trajectories were quite similar to the reading results in Table 4, with the one exception being that the association between parent education and the math slope was nonsignificant. Looking at mediation, the baseline associations between the family socioeconomic circumstances and the math intercept and slope were partially accounted for by the inclusion of the environmental stimulation dummy variables (family–child care and low stimulation for the intercept, low stimulation for the slope) and substantially mediated by the inclusion of the school readiness scale, as was the case for reading.

The only difference in the results of the spuriousness analyses for reading and math was that family–child care stimulation was the one environmental stimulation dummy variable to be associated with the math intercept before *and* after controlling for family socioeconomic circumstances and other child and family characteristics. Recall that, for reading, both the triple stimulation and family–child care stimulation demonstrated this pattern (see Table 4).

Finally, the results of math models testing for moderation (not presented but available upon request) were similar to the reading results presented in Table 5, except that family income also interacted significantly with single stimulation to predict the slope of the growth curve. Basically, the apparent "benefit" of stimulation in two or three early settings relative to only one was more pronounced for low-income children than high-income children, both when school readiness was and was not taken into account.

Discussion

At first glance, the findings of this study seem unsurprising. High-SES children had more exposure to stimulating environments that promote learning. On closer inspection, however, the findings highlight important qualifiers to established patterns in the literature. First, they address tradeoffs between additive (or cumulative) and configuration (or typology) approaches to environmental effects on children's learning. Second, they qualify for whom different types of resources matter. Both the number and configuration of early sources of cognitive stimulation were critical for children's early reading and math trajectories. Children who experienced cognitive stimulation in multiple settings of early childhood had higher rates of learning than their peers early in school, but only when one of these settings was the home. As elementary school unfolded, all children typically had similar rates of progress from their unequal starting points. Although children with the least cognitive stimulation across settings had slightly higher increases in learning from Grades 1 to 5 compared to their peers with more consistent stimulation, this advantage was small relative to the large gap that existed between them when school began. Thus, early learning disparities across environmental stimulation categories generally persisted over time.

Overall, linking stimulation in the family to stimulation in any other early childhood contexts—in child care and/or school for reading, in child care for math—seemed beneficial for children's learning. This means that the family is the first, but not the only, ingredient in early learning. Parents, after all, spend the most (and most consistent) time with their children across early childhood and play a leading role in preparing children for school (Hart & Risley, 1995; Lareau, 2004). Of course, this pattern reflects the consideration of *single* dimensions of family, child care, and school settings. At the same time, we acknowledge that the home environment and the selection of more formal settings for children may be capturing genetic relatedness between parents and their children. Still, these findings are noteworthy for several reasons.

In general, the results of this study suggest that targeting single settings as a means of improving children's learning might not be sufficiently powerful for establishing or deflecting trajectories of early achievement. Specifically, policies that focus solely on one setting, such as parenting programs, preschool interventions, or school standards movements, are unlikely to be as efficacious as those targeting consistency across multiple settings. This conclusion supports the tenets of contextual systems theory contending that multisetting approaches will add value to policy efforts, especially those aimed at at-risk populations. It also suggests that efforts to facilitate children's transitions between home and school should be deliberately expanded to include early child care and preschool. Doing so seems especially crucial for math achievement, for which cognitively stimulating child care more than stimulating entry-level school classrooms was what was needed to match with stimulating home environments to promote early learning.

A major component of this study concerned the multifaceted linkages among socioeconomic stratification and consistency of environmental stimulation. Findings revealed that children from more advantaged families started school with more developed skills than their more disadvantaged peers and that these disparities persisted through elementary school. Beyond replicating this well-documented phenomenon (Magnuson, Meyers, Ruhm, & Waldfogel, 2004), we also sought to elucidate whether consistent environmental stimulation explained the link between family SES and child learning (mediation), family SES accounted for the association between consistent stimulation and child learning (spuriousness), or some combination of both processes was occurring. The motivation for comparing these theoretical pathways was that policy efforts that seek to reduce academic disparities typically attempt to remedy the mechanisms through which socioeconomic advantages are thought to operate in the educational system rather than directly addressing family SES itself. Along these lines, having stimulation at home along with stimulation in one or two other early settings partially explained why higher SES children had higher overall skill levels. These findings generally concur with past research exploring the contextual resources through which family SES is associated with child learning (Brooks-Gunn & Duncan, 1997; Entwisle et al., 1997). Yet, this study extends that research by incorporating the broader constellation of settings through which SES has its reach rather than focusing on single settings or on multiple settings in an isolated way.

Importantly, evidence of spurious associations between configurations of stimulating settings and children's trajectories also emerged. That is, the consistency of environmental stimulation that children experienced around the transition into school was a proxy for socioeconomic circumstances more powerfully related to their learning. Yet, several exceptions existed. Triple stimulation (for reading) and family–child care stimulation (for reading and math) had potentially additive effects. Perhaps more importantly, moderation analyses revealed that the tendency for consistent environmental stimulation to simply be a proxy for family SES appeared to be less strong for children from low-income families. They appeared to gain more than high-income peers through school when early stimulation in extrafamilial settings was consistent with early stimulation at home. These findings are comparable to intervention efforts documenting higher achievement gains when at-risk children experienced more concentrated stimulation across contexts rather than in a single setting (Burchinal et al., 1997; Wasik et al., 1990). That low-income children benefited the most from stimulation at home in combination with other early childhood settings (especially entry-level school classrooms) is also in line with the intervention literature pointing to differential efficacy as a function of risk status (Burchinal et al., 1997; Winsler et al., 2008). Moreover, it is promising news for large-scale policy efforts targeting this population, including Head Start, public Pre-K, and No Child Left Behind.

In addition to those we have already discussed, several limitations of this study need to be addressed. Methodologically, although we examined family SES as a potential source of omitted variable bias in the association between consistency of environmental stimulation and children's learning, other unobserved factors, including parental efficacy and genetic traits, may account for these links. More sophisticated strategies to address unobservable confound should be utilized in the future if this line of research is to effectively inform policy intervention (Winship & Morgan, 1999). On a more conceptual level, our interest in connections among different early childhood settings focused on indirect, temporally spaced transactions rather than direct engagement between actors across settings. A comprehensive examination should include both direct and indirect forms and compare these two approaches to conceptualizing transactions among different settings of the early ecology. Finally, although the sample used in this study had many advantages for our study aims, it was not nationally representative. The generalizability of these findings, therefore, needs to be assessed in the future.

In sum, our results suggest that family socioeconomic advantages were a driving force behind children's exposure to cognitive stimulation in various settings and in their learning. Although this conclusion echoes criticisms of more direct parental involvement strategies in schools, it does not imply that policies should not have environmental foci, particularly in the case of low-income children.

Indeed, in the SECCYD, these children uniquely benefited from the accumulation of stimulating settings. Clearly, altering environmental stimulation through preschools (e.g., Head Start, public pre-K) and schools (e.g., No Child Left Behind), while challenging, is likely more feasible than policies to reduce family socioeconomic disparities, at least in the short term. Efforts to address academic differentials need to include families (not just educational contexts), should be coordinated, and should start before children enter school.

Parent Involvement and Children's Academic and Social Development in Elementary School

Nermeen E. El Nokali, Heather J. Bachman, and Elizabeth Votruba-Drzal
University of Pittsburgh

Data from the National Institute of Child Health and Human Development (NICHD) Study of Early Childcare and Youth Development (N = 1,364) were used to investigate children's trajectories of academic and social development across 1st, 3rd, and 5th grades. Hierarchical linear modeling was used to examine within- and between-child associations among maternal and teacher reports of parent involvement and children's standardized achievement scores, social skills, and problem behaviors. Findings suggest that within-child improvements in parent involvement predict declines in problem behaviors and improvements in social skills but do not predict changes in achievement. Between-child analyses demonstrated that children with highly involved parents had enhanced social functioning and fewer behavior problems. Similar patterns of findings emerged for teacher and parent reports of parent involvement. Implications for policy and practice are discussed.

A recent report by Herrold and O'Donnell (2008) from the National Center for Education Statistics found that over 90% of parents of elementary school children reported attending general school meetings, like those for the PTA or PTO, as well as participating in regularly scheduled parent teacher meetings throughout the school year. Roughly 80% of parents in the nationally representative sample reported attending school events and about 60% reported volunteering in the classroom. Parent involvement is often considered a pathway through which schools enhance the achievement of underperforming children (Berger, 1991). Consequently, parent involvement is encouraged by teachers, child-care providers, policy makers, parents, and researchers (Duch, 2005; Sheldon & Epstein, 2005). Moreover, parent involvement is a key component of early childhood education programs, such as Head Start. These programs encourage parent involvement by inviting parents to participate in activities at school and facilitating parent–teacher communication.

Over the years, a large literature has documented the importance of parent involvement for young children. The role of parent involvement in the later years of schooling has received less attention. Past research on parent involvement has also been more heavily focused on associations with student achievement, with less attention to social and emotional domains of children's development. This propensity may be attributed to the academic nature of many of the behaviors defined as parent involvement like helping with homework. Such activities should prompt more enrichment at home and attunement to a child's academic progress. However, teachers and parents may discuss children's behavior in the classroom as well, since behavior problems and social functioning may have immediate consequences for the classroom environment and teachers' instructional efforts. The aim of this study is to extend past research by examining within- and between-child associations among parent involvement and children's academic and socioemotional trajectories during elementary school.

This research was supported by a grant to Heather J. Bachman and Elizabeth Votruba-Drzal from the National Institute of Child Health and Human Development (NICHD; 1RO3HD056019-01A1). This study was conducted by the NICHD Early Child Care Research Network supported by NICHD through a cooperative agreement that calls for scientific collaboration between the grantees and the NICHD staff. An earlier version of this article was presented at the 2009 SRCD Conference.

We would like to thank our discussant, Eric Dearing, as well as the anonymous referees for their comments. The content is solely the responsibility of the authors and does not necessarily reflect the views of the NICHD. We would also like to thank Roli Mohan, Stephanie Davis, and Carolina Maldonado-Carreño for their assistance with data management. A special thanks is also extended to the children and families who participated in the NICHD Study of Early Child Care and Youth Development.

Parent Involvement in Early Childhood

Parent involvement typically involves parents' behaviors in home and school settings meant to support their children's educational progress. Measures of parent involvement commonly include the quality and frequency of communication with teachers as well as participation in school functions and activities (Dearing, Kreider, Simpkins, & Weiss, 2006; Dearing, McCartney, Weiss, Kreider, & Simpkins, 2004; Machen, Wilson, & Notar, 2004). Parent involvement also characterizes parents' values and attitudes regarding education and the aspirations they hold for their children (Catsambis, 2001; Englund, Luckner, Whaley, & Egeland, 2004). Although values and attitudes may not directly influence academic outcomes, they may enhance academic achievement indirectly by promoting children's motivation and persistence in challenging educational tasks.

Parent involvement bridges two key contexts in children's early development, namely, the home and school settings. Within an ecological framework (Bronfenbrenner & Ceci, 1994), the home and school contexts are characterized as autonomous microsystems and parent involvement is conceptualized as a mesosystem, which is made up of interactions between key microsystems. Although each setting can independently influence a child, together the home and school contexts interact to offer a unique influence. In this study parent involvement is conceptualized as a product of the interaction between the influences of school and home settings by providing continuity between the two environments. For example, if parents are aware of a teacher's instructional goals, they may provide resources and support for those learning aims at home. Similarly, in terms of social development, parent involvement may facilitate the development of consistent disciplinary approaches across home and school. Accumulating evidence suggests that these parenting practices are associated with higher academic success in the early grades, although links to socioemotional outcomes remain less clear.

Academic Achievement

Past research on parent involvement and children's academic skills is mixed (Fan & Chen, 2001). Some studies have found no significant association between parent involvement and academic achievement (Keith, Reimers, Fehrmann, Pottebaum, & Aubey, 1986; Okpala, Okpala, & Smith, 2001; Reynolds, 1992; White, Taylor, & Moss, 1992) and a few have even detected negative associations (Milne, Myers, Rosenthal, & Ginsburg, 1986; Sui-Chu & Willms, 1996). Yet, positive associations between parent involvement and academic achievement have been demonstrated repeatedly in the literature. A recent meta-analysis by Fan and Chen (2001) finds moderate associations between parent involvement and an array of learning-related or academic skills, such as achievement motivation, task persistence, and receptive vocabulary, during preschool and kindergarten. With a predominant research focus on parent involvement and achievement in either preschool and kindergarten or high school, the potentially supportive role of parent involvement during middle childhood remains understudied.

Past nonexperimental research on parent involvement commonly investigates contemporaneous associations between parent involvement and academic achievement. These studies typically examine within-grade associations of parent involvement and academic skills (Fantuzzo, McWayne, & Perry, 2004; Gonzalez-DeHass, Willems, & Holbein, 2005; McWayne, Hampton, Fantuzzo, Cohen, & Sekino, 2004). Other work incorporates contemporaneous research in the early grades with longitudinal follow-up data later in elementary school or beyond (Englund et al., 2004; Izzo, Weissberg, Kasprow, & Fendrich, 1999; Miedel & Reynolds, 1999). For example, Miedel and Reynolds (1999) detected positive associations between parent involvement in preschool and kindergarten and reading achievement in kindergarten and in eighth grade. Izzo et al. (1999) also found significant positive associations between average parent involvement in early elementary school and socioemotional development and achievement in later elementary school. Such studies reflect the common practice of considering parent involvement as a static predictor of concurrent achievement or educational outcomes in later school years. A notable exception is a study by Dearing et al. (2006) that employed longitudinal data on parent involvement and reading achievement to examine within- and between-family associations of parent involvement and literacy across elementary school. Findings suggested that differences in levels of parent involvement between families and changes in parent involvement within families were both predictive of children's literacy skills, and increasing parent involvement during elementary school improved literacy growth.

Socioemotional Development

Parent involvement is generally thought of as an avenue for promoting academic performance. However, parent involvement may also enhance children's behavior at home and in the classroom as parents and teachers work together to enhance social functioning and address problem behaviors. A growing literature has demonstrated benefits of parent involvement for social functioning (Izzo et al., 1999; McWayne et al., 2004; Reynolds, 1989; Rimm-Kaufman, Pianta, Cox, & Bradley, 2003; Supplee, Shaw, Hailstones, & Hartman, 2004). For example, a recent study of Head Start students revealed that parent involvement was associated with lower conduct problems (Fantuzzo et al., 2004). Such findings are also evident in adolescence (Hill et al., 2004). However, studies addressing parent involvement's links to socioemotional skills have typically focused on early childhood and utilized cross-sectional designs.

Research Questions

The aim of the current study is to extend past research by examining within- and between-child associations among parent involvement and academic and socioemotional trajectories during elementary school. In doing so, this investigation addresses the heavy reliance on contemporaneous, within-grade research during early childhood in the past literature by examining associations between parent involvement and academic and socioemotional functioning longitudinally throughout middle childhood.

Analytic Strategy

A major challenge facing researchers is determining whether parent involvement itself is actually beneficial to children or whether parents who are more engaged and involved in children's schooling also differ in key selection characteristics (e.g., motivation, cognitive competence) from less involved parents. If the most competent parents with developmentally advanced children are more likely to be involved in school, this could lead to an upward bias of the effect of parent involvement, thereby making it appear to be disproportionately beneficial to children. In contrast, if parents of the most struggling children are more likely to be involved, a downward bias in the influence of parent involvement may emerge, indicating that parent involvement is less beneficial for children than is actually the case. Between-child analyses are susceptible to these sorts of endogeneity or selection biases (Duncan, Magnuson, & Ludwig, 2004). One approach for addressing these biases is conducting within-individual analyses linking changes in parent involvement to changes in academic or behavioral functioning (Allison, 1990).

The present study considers between- and within-child associations between parent involvement and children's development using two-level hierarchical learn models that were estimated using full information maximum likelihood techniques in HLM 6.06. (Scientific Software International, Lincolnwood, IL). Our analysis began with the estimation of unconditional growth models to establish appropriate model specifications for our conditional analytic models (Raudenbush & Bryk, 2002). Next, a series of conditional models were estimated to address the study's aims. Level 1 contained repeated measures of achievement scores and behavior ratings taken at first, third, and fifth grades, which were nested within individual children at Level 2. Parent involvement within each grade was specified as a Level 1, along with time-varying child, family, and classroom characteristics. The Level 1 model is shown in Equation 1:

$$\begin{aligned} Y_{it} = {} & \pi_{0i} + \pi_{1i}(\mathrm{AGE}_{it} - \overline{\mathrm{AGE}_{i.}}) \\ & + \pi_{2i}(\mathrm{PINV}_{it} - \overline{\mathrm{PINV}_{i.}}) + \pi_{3i}(\mathrm{FAM}_{it} - \overline{\mathrm{FAM}_{i.}}) \\ & + \pi(\mathrm{CLASS}_{it} - \overline{\mathrm{CLASS}_{i.}}) + \varepsilon_{it.} \qquad (1) \end{aligned}$$

Achievement and social skills for child i at time t were modeled as a function of time-varying measures of age (AGE_{it}) and parent involvement (PINV_{it}), as well as family (FAM_{it}) and classroom (CLASS_{it}) characteristics. All of the predictors at Level 1 were group-mean centered, also known as within-person centering (Raudenbush & Bryk, 2002; Singer & Willett, 2003). The intercept represents each individual's average level of achievement or social skills during middle childhood, while the coefficient on AGE_{it} represents growth in achievement or social skills per month increase in age from first through fifth grade. Coefficients on the Level 1 predictors represent within-child associations over time and test whether within-child changes in parent involvement promote changes in achievement and socioemotional development. Group-mean centering is an important technique for addressing bias due to unobserved heterogeneity or unmeasured factors that vary across individuals and have a consistent effect over time. However, that these predictors are still susceptible to time-varying omitted variable bias. Between-child associations between average parent involvement and children's average level and growth of academic and socioemotional functioning were considered at Level 2. Variability in the intercept and the linear growth terms in the Level 1 equations were modeled using Equations 2 and 3:

$$\begin{aligned}\pi_{0i} = \beta_{00} &+ \beta_{01}(\text{AvPINV}_i - \overline{\text{AvPINV}}..)\\ &+ \beta_{02}(\text{EFAM}_i - \overline{\text{EFAM}}..)\\ &+ \beta_{03}(\text{CHILD}_i - \overline{\text{CHILD}}..)\\ &+ \beta_{04}(\text{AvFAM}_i - \overline{\text{AvFAM}}..)\\ &+ \beta_{05}(\text{AvCLASS}_i - \overline{\text{AvCLASS}}..) + r_{0it} \quad (2)\end{aligned}$$

$$\begin{aligned}\pi_{1i} = \beta_{10} &+ \beta_{11}(\text{AvPINV}_i - \overline{\text{AvPINV}}..)\\ &+ \beta_{12}(\text{EFAM}_i - \overline{\text{EFAM}}..)\\ &+ \beta_{13}(\text{CHILD}_i - \overline{\text{CHILD}}..)\\ &+ \beta_{14}(\text{AvFAM}_i - \overline{\text{AvFAM}}..)\\ &+ \beta_{15}(\text{AvCLASS}_i - \overline{\text{AvCLASS}}..) + r_{1it}. \quad (3)\end{aligned}$$

Variation in mean levels of achievement and social skills (π_{0i}) and in the growth of performance on these measures over time (π_{1i}) was explained with individual-level averages from middle childhood for parent involvement (AvPINV_i), family (AvFAM_i) and classroom (AvCLASS_i) characteristics. Time-invariant measures of early family and demographic (EFAM_i) characteristics from birth through 54 months, as well as time-invariant child characteristics and 54-month scores on each of the child outcomes (CHILD_i) were included as covariates. In the Level 2 equations, all predictors were grand-mean centered. These models capture both between- and within-child variation. The Level 1 coefficient on parent involvement examines whether within-child changes in parent involvement are associated with improvements in academic and social development. The Level 2 coefficients on parent involvement consider whether children with parents who have higher average levels of involvement in school display better average levels of academic and social skills as well as greater improvement in these domains over time.

Method

Sample

Data for this study are drawn from the National Institute of Child Health and Human Development Study of Early Child Care and Youth Development (NICHD SECCYD), an ongoing longitudinal, multimethod study of 1,364 children and their primary caregivers from 10 U.S. data collection sites (NICHD Early Child Care Research Network [ECCRN], 1993). Sampling for the NICHD SEYCCD was conditionally random and excluded mothers younger than 18 years of age at the time of the participating child's birth, families not intending to remain within proximity of the data collection sites for at least 3 years, children with obvious disabilities at birth or who remained in the hospital more than 7 days after birth, and mothers who would have significant problems conversing in English (NICHD ECCRN, 2004). The NICHD SECCYD contains a wide range of academic and socioemotional skills from observational and standardized assessments and parent and teacher reports, as well as parent and teacher reports of parent involvement in elementary school.

Data from birth (1991) to fifth grade were utilized in the present study. Although the initial sample comprised 1,364 children, as described in past research, ethnic minority families with lower educational levels were less likely to remain in the study over time and 137 children were lost within the first phase (1–36 months) to selective attrition (Duncan & Gibson-Davis, 2006; NICHD ECCRN, 2003). By first grade, an additional 94 children withdrew from the study, resulting in 231 attrition cases. Independent samples *t* tests and chi-square tests were conducted to examine whether the children and families in the attrition group ($n = 231$) were systematically different from the remaining sample who continued to participate during elementary school ($n = 1{,}133$). Results revealed few differences between these two groups. The retained and attrition samples did not significantly differ in maternal age, maternal cognitive ability, or child sex. However, the retained sample comprised fewer non-Hispanic Black children (11.6%; $\chi^2 = 6.44$, $p < .05$) than the attrition sample (17.7%). Mothers in this sample had more years of education ($M = 14.4$; $\chi^2 = 55.08$, $p < .001$) and were more likely to have been married when their child was born (78.6%; $\chi^2 = 349.97$, $p < .001$) than mothers in the attrition sample ($M = 13.3$ and 66.7%, respectively). Income-to-needs ratios were significantly higher among families in the retained ($M = 3.60$) than attrition ($M = 2.94$; $t = 2.76$, $p < .01$) samples.

Traditional approaches to handling missing data, such as listwise deletion or mean imputation, have been criticized for biasing estimates, misrepresenting statistical power, and leading to invalid conclusions (Acock, 2005; Rubin, 1987; Widaman, 2006). Missing data patterns were carefully analyzed and Little's MCAR tests indicated that the missing data were not missing completely at random (MCAR; $\chi^2 = 32{,}458.01$, $p < .001$), which supported the use of missing data imputation (Little, 1988). Missing data were imputed using multiple imputations by chained equations, which was implemented in Stata 10 (Royston, 2005). Currently, there is disagreement in the literature about whether missing data on dependent variables should be imputed. Some argue that imputed values for dependent variables should be deleted postimputation (von Hippel, 2007), while others maintain that the nature of missing values for independent and dependent variables are fundamentally equal and should be treated accordingly (Allison, 2008; Schafer & Graham, 2002). In the present study, imputations were performed on independent and dependent variables and imputed dependent variables were retained after imputation. Multiple imputations were performed in Stata, and based on the relative efficiency calculation by Rubin (1987), five imputations were deemed sufficient for the level of missing data in our study, resulting in a final sample of 1,364 children. The analyses for this study were performed using HLM 6.06 (Raudenbush, Bryk, Cheong, Congdon, & du Toit, 2004). Following imputation, the five data sets were imported into HLM, which was then used to conduct separate analyses for each set of plausible values. Parameter estimates were averaged and standard errors were computed in HLM 6.06 using standard techniques described by Raudenbush et al. (2004).

Measures and Procedures

Parent Involvement

Information on parent involvement was obtained from parents and teachers in first, third, and fifth grades using modified versions of the Parent–Teacher Involvement Questionnaire (Miller-Johnson, Maumary-Gremaud, & the Conduct Disorders Research Group, 1995). These questionnaires included items regarding the frequency and the quality of parents' involvement in children's educational progress in school and at home. A 5-point Likert-type response scale was employed with responses ranging from (1) *not at all* to (5) *a great deal*. Our composite measures of parent involvement include items reflecting teachers' and parents' reports of parental encouragement of education (e.g., ''How often does this parent volunteer or visit at school?''), parental investment (e.g., ''How important is education in this family?''), and educational attitudes (e.g., ''How much do you feel this parent has the same goals for his or her child that the school does?''). Parent and teacher parent involvement composites comprised 12 items and 10 items, respectively, with higher scores indicating more parent involvement. In addition, the parent involvement composites were highly reliable within each first, third, and fifth grades (parents' Cronbach's αs = .85–.86; teachers' Cronbach's αs = .89–.93). It is important to note that items selected to create the mother and teacher composites were identical for each reporter across the first, third, and fifth grade years. Parents' and teachers' reports were both analyzed in separate models rather than relying on a single reporter (see Table 1). Average levels of parent involvement were comparable across grades (see Table 1).

Outcomes

Academic achievement. Academic achievement was assessed at 54 months (prior to kindergarten entry), and first, third, and fifth grades using three subtests from the Woodcock–Johnson Psycho-Educational Battery–Revised (WJ–R; Woodcock & Johnson, 1989, 1990), which was administered to participants in a laboratory setting. Early childhood scores were included as an additional preventative measure against omitted variable bias.

Picture Vocabulary tested comprehension, knowledge and receptive vocabulary, Letter–Word Identification assessed symbolic learning and reading skills, and Applied Problems tested mathematical skills. The scores used in the current study's analyses were *W* scores, a special transformation of the Rasch ability scale, which ease interpretation of performance and facilitate analyses of change over time. Generally, high internal consistency estimates have been found in standardized samples (Woodcock & Johnson, 1989, 1990). Internal consistencies have been reported ranging from .70 to .82 for the Picture Vocabulary test with test–retest reliabilities ranging from .63 to 0.78. Internal consistencies for Letter–Word Identification and Applied problems have been quite high, ranging from .94 to .98 with test–retest reliabilities of .80–.87 (Woodcock & Johnson, 1989, 1990).

Socioemotional development. Socioemotional development was assessed during first, third, and fifth grades using two standardized measures. Parents completed the Child Behavior Checklist (CBCL; Achenbach, 1991a) and teachers completed the

Note. N = 1,364. SSRS = Social Skills Rating System; CBCL = Child Behavior Checklist; PPVT = Peabody Picture Vocabulary Test; HOME = Home Observation for Measure of the Environment.
[a]Data treated as time invariant. [b]Data averaged across first, third, and fifth grades.

Teacher Report Form (TRF), a slightly modified version of the CBCL, to measure children's social competence and behavior problems (Achenbach, 1991a). As with the achievement outcomes, early ratings from the 54-month time of social skills and problem behaviors were included in the between-child analyses when predicting later problem behaviors. Reporters rated how true the behaviors are to a child on a 3-point scale (0 = *not true*, 1 = *sometimes or somewhat true*, 2 = *very true or often true*). Higher overall scores reflect more social or behavioral problems. In the present analyses, a total behavior problem standardized t score, comprising two subscale scores of externalizing and internalizing problems, was utilized. Externalizing problems include aggressive or delinquent behavior, and internalizing problems comprised withdrawn, anxious, or depressed behaviors. The CBCL and TRF are widely accepted as reliable and internally consistent (Achenbach, 1991b). Parents' and teachers' reports of problem behaviors were highly reliable at each time point (parents' Cronbach's αs: = .93–.95; teachers' Cronbach's αs: = .95–.96).

In first, third, and fifth grades, parents and teachers also completed the Social Skills Rating System (SSRS; Gresham & Elliott, 1990), which comprised two subscales examining children's social skills and academic competence. Parents also completed the SSRS at 54 months. This score was used to control for social skills prior to school entry in the between-child analyses. The current study focused solely on the social skills subscale which assesses cooperation, assertion and self-control. Cooperation includes behaviors such as paying attention to the teacher's instruction and putting away work materials properly. Assertion comprised initiating behaviors, such as starting conversations with peers and helping peers with classroom tasks. Self-control includes behaviors that emerge in conflict situations, such as responding to teasing or peer pressure appropriately, receiving criticisms well, and controlling temper. Parents and teachers assessed the frequency of a social behavior on a 3-point scale (0 = *never*, 1 = *sometimes*, 2 = *very often*). Additionally, the reporters rated how important the behavior is for classroom success, again on a 3-point scale (0 = *not important*, 2 = *important*, 3 = *critical*). The scores from all three of these subscales were summed to create a total SSRS score for each child. These scores were standardized with higher scores reflecting better social adjustment. The validity of the SSRS is well documented and the scale has also been found to be highly correlated with other well established measures of social functioning such as the CBCL (Achenbach, 1991a, 1991b; Gresham & Elliott, 1990). Parents' and teachers' reports of social skills were highly reliable at each time point (parents' Cronbach's αs = .92–.94; teachers' Cronbach's αs = .93–.94).

Covariates

Child characteristics. A number of important background characteristics were included as covariates of child outcomes and parent involvement (see Table 1). Child demographic information was obtained from periodic parent interviews from the child's 1st month of life through fifth grade. At 1 month, mothers reported on child sex (*0 = female, 1 = male*) and ethnicity (non-Hispanic White, Hispanic, non-Hispanic Black, and Other).

Classroom characteristics. Teacher ratings were included to measure parent involvement, children's social skills and their behavior problems. Thus, it was important to control for background characteristics of teachers, such as teaching experience as well as general teacher practices that may influence their ratings or children's academic or social progress throughout school. In the fall of each school year, first-, third-, and fifth-grade teachers reported on their years of teaching experience in a Teacher Questionnaire that was modified from the Schools and Staffing Survey (National Center for Educational Statistics, 1994). Across elementary school, teachers had comparable levels of teaching experience (see Table 1).

Additionally, teacher practices were observed to measure the classroom environment as a control for classroom quality. Scores for positive emotional climate in the classroom were obtained from the qualitative rating portion of the Classroom Observation System (COS; NICHD ECCRN, 2002). This scale was chosen due to its consistent use across first, third, and fifth grades. Ratings were obtained during 2-hr classroom observations of which 30 min were dedicated to qualitative ratings. These 30 min were divided into three 10-min qualitative segments during which coders rated the teacher, the child and the classroom. Scores on the ratings used in the current study ranged from 1 to 7 and represented a global impression of the overall enthusiasm, warmth and positive regard expressed by the teacher and students in the classroom. First-, third-, and fifth-grade ratings were entered in the Level 1 models and also averaged into a single covariate and included in the Level 2 models. Classroom quality scores were comparable across first ($M = 5.32$, $SD = 1.29$), third ($M = 5.05$, $SD = 0.78$), and fifth ($M = 5.10$, $SD = 0.71$) grades.

Family characteristics. Family demographic information was also obtained from parent interviews from the child's birth through fifth grade. These characteristics include maternal age, the number of years of education completed before the birth of the study child, and the number of children in the household in first, third, and fifth grades. Mothers also reported on their marital status (0 = *married*, 1 = *unmarried*) and hours of employment at first, third, and fifth grades.

Income data were frequently collected from families participating in the NICHD SECCYD. Income-to-needs ratios were calculated by taking pretax household income for a given year and dividing it by the poverty threshold for a household, which takes into account the year the income was earned, the number of individuals in the home, and the number of children in the home. Income-to-needs ratios from first, third, and fifth grades were used in estimating within-child effects of parent involvement on achievement and social skills. A composite variable of the average income-to-needs ratio across the three grades was also used in estimating between-child effects of parent involvement on levels and changes in children's academic and social skills. An average early income-to-needs ratio composite was computed using income data from

6, 15, 24, 36, and 54 months as another covariate in the between-child analysis.

Maternal scores on the Peabody Picture Vocabulary Test–Revised (PPVT–R, Dunn & Dunn, 1981) from a laboratory assessment at the 36-month time point were used to assess maternal cognitive competence. Split-half correlations for reliability ranged from .80 to .83 in a standardization sample (Dunn & Dunn, 1981). Since maternal cognitive ability has the potential to influence child academic and socioemotional outcomes, and therefore confound associations between parent involvement and these outcomes, the PPVT–R was used as time-invariant covariate in the Level 2 models.

The Home Observation for Measure of the Environment (HOME; Caldwell & Bradley, 1984) was used to represent each child's early home environment. The HOME is a widely used assessment tool which integrates investigator observation and parental interview components to examine the physical environment, responsiveness, and academically stimulating characteristics of a home. Composite scores from age-specific versions of the HOME were obtained at 15, 36, and 54 months. These scores were transformed into z scores and then averaged to create a single early childhood home environment composite.

Results

Descriptive statistics regarding the sample and outcomes are listed in Table 1. Females comprised 52% of the current sample and 78% of the children were non-Hispanic White. On average, mothers were in their late 20s ($M = 28.11$, ages ranged from 18 to 46) with some college education ($M = 14.23$, values ranged from 7 to 21 years) and most mothers reported being stably married between the first and fifth grades ($M = 0.72$, values ranged from 0 to 1). The mean income-to-needs ratio was generally high and increased during school.

As shown in Table 2, achievement scores improved significantly across elementary school from first to fifth grade between children, as well as parent SSRS and CBCL ratings. Teacher ratings on the CBCL ($M = 50.54$, values ranged from 49.91 to 51.43) and their ratings on the SSRS ($M = 102.93$, values ranged from 102.30 to 103.36) did not change significantly across grades. On average, parent involvement was rated comparably across grades for parent reports ($M = 4.56$–4.63). Teachers rated parent involvement the highest in the third grade ($M = 3.74$ vs. 4.22 vs. 3.55, respectively). Mean comparisons using simple t tests revealed that parents rated parent involvement higher than teachers at each grade ($p < .001$).

We began our analysis by estimating unconditional growth models, which revealed significant variability in the intercepts and slopes of the trajectories for our outcome variables (see Table 2). The only exception was that the age parameter for teachers' reports of social skills and behavior problems demonstrated low reliability and chi-square tests showed no variability in this parameter, so we fixed the linear growth terms in the Level 2 models predicting teachers' reports of social skills and behavior problems. Since all of the other outcomes demonstrated significant reliability of and variability on the age parameter, both their intercepts and

linear growth terms were estimated as random effects at Level 2. As the slope terms suggest, children's reading, math, vocabulary skills, as well as their parent-rated social skills increased over time, while their problem behaviors declined.

Predicting Academic Trajectories

Within-Child Effects

Tables 3 and 4 present results of the HLM analyses predicting achievement over time with mother or teacher reports of parent involvement. The first panel of Table 3 shows the coefficients from the Level 1 model, which assessed whether within-person changes in maternal reports of parent involvement predicted within-child changes in reading, math and vocabulary scores during elementary school, controlling for changes in other child, family and school characteristics as well as between-person differences in all of these factors. Table 4 displays the same set of results for models using teacher reports of parent involvement. Increases in parent involvement were largely unrelated to individual growth in academic skills, regardless of whether parents or teachers reported on parent involvement practices. One exception emerged for reading skills. Increases in teacher-reported parent involvement were related to declines in children's reading scores (see Table 4).

$^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

More specifically, a standard deviation improvement in teacher-reported parent involvement was associated with a .03 *SD* decline in reading skills. The only other variable that consistently, significantly predicted within-child changes in achievement was classroom quality. Increases in the emotional quality of a child's classroom were associated with small declines (ranging from .01 to .05 *SD*) in each of the achievement domains.

Between-Child Effects

The second panel of Table 3 shows results from the Level 2 models that consider between-child associations of average levels of parent involvement with average level of achievement (intercept) and achievement growth over time (slope). Parent-reported parent involvement, when averaged across elementary school, was not significantly associated with children's average reading, math, and vocabulary achievement scores. Results also showed that there were no significant associations between average levels of parent-reported parent involvement and growth in achievement over time. The second panel of Table 4 shows a similar pattern emerged when teachers reported on parent involvement. Overall, few significant relations emerged between parent involvement and achievement; specifically, no between-child associations were detected and small within-child associations were evident only for reading skills when teachers reported on parent involvement.

In contrast, several child, family and classroom characteristics were linked to between-child differences in achievement, and similar patterns were revealed for both maternal and teacher reports of parent involvement. Maternal cognitive competence was associated with higher average levels of reading, math and vocabulary. Male children had lower average achievement scores in math and vocabulary than females, but no gender differences were detected for reading. Earlier scores from the 54-month time point on each of the achievement tests were positively related to average level scores in elementary school. In regards to the growth of academic skills over time, children in less emotionally supportive classes experienced greater achievement gains over time.

Predicting Social Skill Trajectories

Within-Child Effects

Table 5 presents results of the HLM analysis predicting children's social skills over time with maternal reports of parent involvement. The first panel of Table 5 displays the coefficients from the Level 1 model, within-child changes in mother-reported parent involvement predicting within-child changes in parent- and teacher-reported social skills and problem behaviors during elementary school. Within-child increases in parent involvement across elementary school were related to improvements in teacher-reported social skills. A standard deviation increase in parent involvement was linked to a modest increase of 0.22 *SD* in teacher-reported social skills, and small reductions in problem behaviors over time: 0.12 *SD* in teacher-rated problem behaviors and 0.08 *SD* mother-rated problem behaviors. In contrast, within-child changes in maternal reports of parent involvement were not linked to changes in maternal reports of child social skills.

Table 6 presents results of the HLM analysis predicting social skills over time with teachers' reports of parent involvement. The first panel of Table 6 displays the coefficients from the Level 1 model. Within-child increases in teacher-reported parent involvement were related to 0.12 *SD* improvement in teacher-reported social skills and 0.08 *SD* decrease in teacher-reported behavior problems. In contrast, enhancements in teacher-reported parent involvement were not associated with changes in maternal reports of child social skills or behavior problems.

Between-Child Effects

The second panel of Table 5 shows results from the Level 2 model examining between-child associations of parent-reported parent involvement with average levels of social skills (intercept) and behavior problems as well as growth in social skills and behavior problem over time (slope). Higher average levels of maternal-reported parent involvement across elementary school were related to better social functioning across parent and teacher SSRS reports. When compared to children whose parents' involvement in school was at the sample average, children whose parents scored a standard deviation above average displayed social skills levels that were 0.09 and 0.15 *SD* higher based on teacher and mother reports, respectively. In contrast, higher levels of maternal-reported parent involvement were not significantly associated with maternal- or teacher-rated problem behaviors on the CBCL. In summary, between-individual differences in average parent involvement across elementary school predicted higher average social functioning but not problem behaviors problems. Finally, average levels of maternal-reported parent involvement did not predict growth in social skills and problem behaviors over time.

As with the achievement findings, several child, family, and school characteristics were also linked to between-child differences in social skills and problem behaviors when parent involvement was reported by parents. Earlier ratings of social skills and problem behaviors from the 54-month time point were associated with average level scores in their corresponding subsequent ratings except for teacher-reported social skills. Higher classroom quality and teacher experience promoted higher average levels of teacher-rated social skills and were linked to lower average levels in the teacher- and maternal-rated problem behaviors.

The second panel of Table 6 show results from the Level 2 model examining between-child associations between teacher-reported parent involvement and trajectories of social skills and problem behaviors over time. Higher average levels of teacher-reported parent involvement were related to better social functioning and lower rates of behavior problems based on parent- and teacher reports. When compared to children whose parents' involvement in school was at the sample average, children whose parents scored a standard

deviation above average displayed social skills levels that were 0.43 and 0.21 *SD* higher based on teacher and mother reports, respectively. Higher levels of teacher-reported parent involvement were also associated with fewer teacher-reported behaviors problems in children. Specifically, children whose parents scored a standard deviation above average displayed problem behaviors that were lower by 0.36 *SD* higher based on teacher reports. In sum, between-individual differences in average parent involvement across elementary school predicted higher social functioning and lower teacher-reported behavior problems on average from first through fifth grades. Finally, average levels of teacher-reported parent involvement did not predict growth in social skills and problem behaviors over time.

As in the maternal report models, several child, family and school characteristics were also linked to between-child differences in social skills and problem behaviors. Earlier ratings of social skills and problem behaviors from the 54-month time point were associated with average level scores in their corresponding subsequent ratings except for teacher-reported SSRS ratings. The number of minors in a household was positively linked with average levels of teacher-rated social skills and negatively related to maternal reports of behavior problems. Higher classroom quality was positively related to teacher-rated social skills and negatively related to both maternal- and teacher-reported behavior problems. More teacher experience was related to higher average teacher-rated social skills and lower average levels of teacher-rated problem behaviors.

Discussion

The purpose of this study was to consider the benefits of parent involvement for academic and social development in elementary school. In doing so, we aimed to address the current literature's reliance on cross-sectional designs and draw attention to these processes during middle childhood, which has been previously understudied. The results of the between-child analyses suggested that higher parent involvement, as reported by mothers and teachers, promotes better social skills, fewer problem behaviors, and is unrelated to average achievement across elementary school. However, between-child variation in the average levels of parent involvement was generally not predictive of growth in achievement and socioemotional functioning across elementary school. The exception was a finding that increases in average levels of teacher-reported parent involvement are related to less growth in reading scores. Our within-child analyses linked increases in maternal-rated parent involvement to improved teacher-rated social skills and declines in maternal- and teacher-rated problem behaviors. Increases in teacher-rated parent involvement were also related to enhancements in teacher-rated social skills and declines in problem behaviors. In contrast, within-child growth in achievement was not related to changes in either measure of parent involvement.

Achievement and Parent Involvement

Overall, the between- and within-child analyses of parent involvement and achievement revealed consistent findings. Greater engagement in a variety of parent involvement practices was largely unrelated to academic achievement, and improvements in parent involvement did not predict gains in any of the standardized achievement measures, except one possibly spurious finding between changes in teacher-reported parent involvement and decreased reading growth. Other past work has not detected significant associations between parent involvement and achievement (e.g., Keith et al., 1986; Okpala et al., 2001; Reynolds, 1992; White et al., 1992). Past findings of positive between-child associations of parent involvement and achievement may be artifacts of selection bias, whereby involved parents differed from less involved parents in a variety of ways such as in their motivation and beliefs about parenting, education, and their children's development.

Another potential explanation for this lack of association concerns the breadth of our measure of parent involvement. The current study used a measure containing widely accepted dimensions of parent involvement, such as the value parents place on education and the frequency with which they visit their child's school. However, Sheldon and Epstein (2005) suggested that parental involvement is most efficacious when it is subject specific, such that parents need to be involved within whichever domain they are targeting for improvement. Likewise, in past experimental work that linked significant increases in parent involvement with growth in literacy skills, the targeted parent involvement strategies focused specifically on promoting reading skills such as learning sight words and letter–sound recognition (DeCusati & Johnson, 2004). A recent meta-analysis found that parental expectations and aspirations were the factors most highly related to achievement (Fan & Chen, 2001). In the current study, parents were surveyed about their feelings and thoughts about education, but these items may have been too general or few in number to sensitively detect change in children's achievement. Another possibility is that parent involvement is more globally beneficial for children's academic performance in school (e.g., average grades, homework completion) but does not specifically promote achievement in any particular domain. Fan and Chen (2001) examined 25 studies of parent involvement and academic achievement and found that average correlations between parent involvement and children's grades or grade point average, both global indicators of school performance, tended to be moderate in size ($r = .33$), but average correlations between involvement and math and reading achievement scores were much lower ($r = .18$).

It should be noted that the only other study of within-child associations between parent involvement and student achievement, by Dearing et al. (2006), demonstrated a significant association between improvements in parent involvement across elementary school and improvements in literacy skills during elementary school. However, there are some notable differences in this study and ours. Dearing et al. had a much smaller ($N = 281$ vs. $N = 1{,}364$) and more socioeconomically homogenous sample, consisting only of low-income children enrolled in an intervention program. Children from low-income families face a higher likelihood of confronting multiple developmental risk factors across contexts than their more affluent counterparts (Friedman & Chase-Lansdale, 2002); thus, a positive factor, like parent involvement, may be especially protective. Moreover, Dearing and colleagues used parental reports that indicated whether or not they ever participated in certain school-based activities, whereas the current study included more detailed parent and teacher perspectives of parent involvement. Therefore, differences in the present study and the Dearing et al. study may be attributable to sample and measurement characteristics.

Additionally, the within-child negative finding in the current study among teacher reports of parent involvement and reading skills, although a weak association, is also supported by past work that has uncovered negative associations among facets of parent involvement and achievement outcomes (Milne et al., 1986; Sui-Chu & Willms, 1996). These researchers argued that parents may become increasingly involved in an effort to be proactive when their children experience academic difficulties. In the early years of elementary school, parents may tend to become more involved when their children are struggling in reading, but not math, because teachers focus substantially more on reading in first and third grades (Pianta, Belsky, Houts, Morrison, & the NICHD ECCRN, 2007). This negative association for reading growth, unlike math, may reflect teachers' attempts to elicit more parental involvement among parents of struggling readers during elementary school when classroom instruction heavily targets literacy skills.

Finally, the current study unexpectedly revealed small, negative associations between classroom quality and achievement in both the within- and between-child analyses. Pianta et al. (2008) also uncovered mixed findings between emotional climate and achievement, with the measure of emotional quality showing negative associations with literacy and math in first grade and more positive associations as elementary school progressed. Quality, which was characterized as positive emotional climate in the current study, was found to be consistently predictive of fewer problem behaviors and higher social skills between children.

Social Development and Parent Involvement

Contrary to the achievement findings, significant associations were detected repeatedly among parent involvement, social skills, and behavior problems in both between- and within-child models. In fact, increases in parents' involvement over time were related to concomitant increases in children's social skills and declines in problem behaviors for both reporters of involvement. Not only do the current findings extend past cross-sectional associations between parent involvement and socioemotional functioning, but these improvements in socioemotional skills may hold longer term implications for future academic performance and behavior (Bub, McCartney, & Willett, 2007; Li-Grining, Votruba-Drzal, & Maldonado-Carreño, under review). Additionally, these associations in the within-child models suggest that the relation between parent involvement and social skills is not merely the product of selection bias. Instead, these findings may reflect a growing consistency in social expectations across settings as children progress through school. As parents become more involved with their children's education, they may be more likely to communicate with school personnel about their child's adjustment and behavior in class. In turn, parents may become more informed about their children's social difficulties from teachers and school staff, and then subsequently address and reinforce more positive behaviors at home. Although communication among parents and teachers would be expected to benefit academic development as well, it is possible that teachers and parents discuss social and behavioral issues more frequently than academic concerns.

Limitations and Future Work

Although the present study offers many advantages with its longitudinal design and multimethod measurements, several limitations should be noted. Future studies of parent involvement could include more assessments or experimental designs to address issues of causality. The current analytic techniques limit the ability to make causal inferences, even when rigorous statistical techniques are employed. Moreover, early childhood interventions often include parent involvement as a key program component, such as the Infant Health and Development Program (McCormick, McCarton, Brooks-Gunn, Belt, & Gross, 1998), Head Start (Administration for Children and Families., 2007), and the School Development Program (Haynes, Comer, & Hamilton-Lee, 1988). However, with so many program features, it is difficult to distinguish the unique contribution of parent involvement to these gains. Future studies should more directly focus on parent involvement efforts to reduce potential confounding variables from additional experimental or intervention factors. Additionally, future parent involvement researchers should try to collect extensive and comprehensive data on a variety of the practices considered to be parent involvement. Instruments that survey a wide range of parent involvement practices may mask the parent behaviors that support growth in children's academic and social competence.

Results from the current study suggest that both maternal- and teacher-reported parent involvement have predictive value for children's social development. Although the patterns in associations across reporters were remarkably similar, there were several instances in which either parent or teacher reports predicted an outcome that the other report did not. Such findings lend support to the practice of triangulation in collecting parent involvement data.

Finally, findings from the current study are limited in their generalizability. The NICHD ECCRN and Duncan (2003) asserted that although attrition and nonrandom selection in the NICHD SECCYD sample inhibit the application of findings to broader populations, the sample also embodies unique strengths. Such strengths include the breadth of economic, ethnic, and geographic diversity embedded in the NICHD SECCYD sample.

Conclusion

Overall, the present findings suggest that parents continue to wield considerable influence on children's development as children progress through school. It is important for future work to explore parent behaviors that support children's achievement. In addition, further exploration of how parents and teachers may be jointly responding to children's social and behavioral skills could help to elucidate the potential benefits of parent involvement for social development. Investigation of the possible selection factors that motivate parent involvement would also be useful to inform policies and interventions.

The Dynamics of Free Recall and Their Relation to Rehearsal Between 8 and 10 Years of Age

Martin Lehmann and Marcus Hasselhorn
German Institute for International Educational Research, Center for Education and Development

The present study longitudinally examined changes in recall in children between the ages of 8 and 10 years. Given the increasingly sophisticated use of memory strategies during this developmental period, correspondences between study and recall dynamics were of particular interest. Seventy-six children performed free-recall tasks on 5 occasions over a 2-year period. Video and audio analyses revealed that children tended to recall items successively from nearby serial positions. This so-called lag-recency effect was particularly pronounced when items from nearby serial positions were conjunctly rehearsed during study. Implications for understanding study–recall correspondences are discussed in relation to other developmental changes of this period including memory capacity.

Over the last four decades, knowledge of children's acquisition of memory strategies has dramatically increased. Today, research on memory strategies represents one of the most important areas in the field of cognitive development and the mechanisms involved in the emergence of deliberate strategy use are assumed to be a key issue in understanding human cognitive growth during childhood. From the very beginning, empirical approaches to memory strategies have focused on both sides of strategy usage: the learning behavior or input itself and recall consequences or output. Although the relation between input and output behavior seems to be critically related to developmental changes in memory proficiency (cf. Schneider & Pressley, 1997), this relation is not yet fully understood. It is, however, not until individuals recall the memorized material, that memory strategies reveal their quality and peculiarity (Schneider & Pressley, 1997; Waters & Andreassen, 1983). In the present investigation, data from an earlier study on children's applied memory-strategy behavior during study and subsequent free recall (Lehmann & Hasselhorn, 2007) were reanalyzed and observed learning behavior was related to a measure of output order developed by Kahana (1996) in his research on adults' free recall. This enabled a direct comparison of the developing processes of rehearsal behavior and recall behavior. The main goal of our analyses was to provide a more precise description of age-related recall dynamics and their relation to children's strategic behavior than has been previously presented.

Regarding the development of rehearsal, the seminal work of Ornstein and Naus (1985; Naus & Ornstein, 1983) focused on the direct consequences of different rehearsal strategies for recall and indicated that the spontaneous use of active rehearsal behavior should emerge between the ages of 8 and 10 years following a period of passive rehearsal usage (Ornstein, Baker-Ward, & Naus, 1988; Ornstein & Naus, 1978). Passive rehearsal strategies are characterized by repeating the to-be-learned items either once (labeling) or several times (rote repetition or single-word rehearsal) but not in combination with other items. In contrast, it is the very repetition of several combined items which characterizes active rehearsal (cumulative rehearsal). With respect to the recall consequences of these strategies, passive rehearsal has been found to lead to poor recall, in particular for items from the prerecency portion of a list, that is, items from the beginning and middle of the list (Hagen & Kingsley, 1968; Hagen, Meacham, & Mesibov, 1970). In contrast, active rehearsal has been found to lead to a general increase in recall performance as well as to account for the primacy effect and hence a pronounced recall of early list items (e.g., Ornstein &

Naus, 1978). The characteristics of serial position curves (i.e., recall probabilities as a function of list position) have thus always been used as an indicator of qualitative differences in children's spontaneous strategy use.

Further demonstrations of the recall consequences of different rehearsal strategies come from studies that directly control rehearsal behavior by instruction or by predetermined rehearsal patterns. Naus and Ornstein (1983), for example, used a "reading aloud" procedure in which participants rehearsed preset item combinations by reading them aloud. This procedure allowed for the control of rehearsal activity. Again, more active rehearsal behavior and therefore a joint rehearsal of different items resulted in increased recall.

A recent longitudinal study in our own lab (Lehmann & Hasselhorn, 2007) revealed that even young children profit from using cumulative rehearsal. In this study, children between the ages of 8 and 10 years performed three trials of a free-recall task on five occasions over a period of 2 years. When working on the free-recall task, participants were instructed to "learn aloud," that is, to verbalize whatever they were doing and thinking while memorizing the items. The authors examined each interstimulus interval and were in this way able to show that children used up to four different strategies during the list-learning process. Three of these strategies comprised rehearsal strategies such as labeling, single-word rehearsal, and cumulative rehearsal, while the fourth consisted of a simple form of association and elaboration. Developmental analyses revealed a gradual shift from labeling to cumulative rehearsal with increasing age. In addition, this fine-grained analysis allowed the identification of intralist strategy changes and revealed that cumulative rehearsal was frequently used at early list positions, whereas labeling dominated for later list portions. With regard to recall, cumulative rehearsal was found to be positively correlated with recall performance from the second measurement point (beginning of third grade) onward. In contrast, the remaining rehearsal strategies were, if at all, negatively related with recall performance.

These results coincide with two suggestions made by Cuvo (1975) several decades ago. First, he suggested that large rehearsal-set sizes (mean number of different items conjunctly rehearsed between two item presentations) would allow more items to be studied jointly and therefore to be strongly associated. Second, he suggested that the repeated reentering of previously presented items should result in both a greater permanence of these items in the short-term store and the creation of various associations between different items. Both suggestions have been confirmed to occur in older (sixth graders) but not younger children (second graders; e.g., Ornstein, Naus, & Stone, 1977). With respect to the behavior shown by the children assessed by Lehmann and Hasselhorn (2007), when the children were younger, they were not able to reenter items presented earlier in the list into rehearsal sets at later list portions, a behavior that was displayed when they were older. Similarly, Rundus (1971) demonstrated that adult participants tend to more frequently repeat items from the beginning of a list throughout the learning phase than items from later list positions, a behavior that again results in a notable primacy effect. A similar finding has been described by Tan and Ward (2000; Ward, 2002; Ward & Tan, 2004) who demonstrated that the noticeably better recall of items from the beginning of a list was due to the fact that these items were reentered into later rehearsal sets.

The approaches presented so far primarily focused on the recall consequences of specific learning behavior. While the examination of cumulative rehearsal behavior during study has generally been seen as an active process resulting in both a combination of different items within rehearsal sets and a transfer of earlier list items to rehearsal sets toward the end of the learning phase, corresponding recall analyses have received less attention. Information on recall sequences is, however, particularly important for identifying potential, underlying recall processes and, in turn, clarifying the relation between study and recall (Laming, 2006). With respect to the development of increasingly proficient strategies during input, one would expect a corresponding developmental change during output that may lead to more proficient recall behavior.

Bousfield's (1953) pioneering work on subjective organization during study was one of the first approaches to explicitly allow inferences about processes that mediate input and output behavior. In this approach, recall processes during output (e.g., subjective organization of the to-be-learned material) are assumed to reflect processes during input. Bousfield's (1953; Bousfield & Bousfield, 1966) methods paved the way for an enrichment of basic theory on memory strategies and learning. However, in contrast to the vast scope of knowledge on the relation between study and recall in organization, almost nothing is known about the processes directly linking study and recall in rehearsal. This is in part due to the lack of measures covering both the direct link between input and output and a process-oriented observation of output in free recall.

This issue has, in recent years, been addressed by Howard and Kahana (1999; Kahana, 1996) who showed in young adults that the temporal proximity of items during input influences the recall order of these items during output by studying the temporal item-presentation sequence at the time of encoding and the respective item output sequence at the time of recall. They found a strong tendency for items presented at neighboring positions during the learning phase to be successively recalled during the recall phase. In contrast, no such tendency was observed for items presented at more remote positions during the learning phase. They referred to this phenomenon as the *lag-recency effect*. This lag-recency effect differs from the end-of-list recency effect. While the end-of-list recency effect seems to be based on the high activation of items presented at or "transported" to the end of a list and therefore on the temporal proximity of study and recall (Howard & Kahana, 1999; Tan & Ward, 2000), the lag-recency effect refers to the proximity or strength of association between two successively presented items. During recall, the first of these two items to be recalled can operate as a retrieval cue for the second item. The observed recall transitions thus seem to be strongly influenced by temporally defined interitem associations (Kahana, Howard, & Polyn, 2008). This influence is reflected in both recall order and interresponse times (IRTs) and respectively quantified as the conditional response probability (CRP) and the conditional response latency (CRL; Kahana, 1996). As a function of lag, CRP describes the probability of items being recalled in succession given the distance (or lag) between them during the presentation phase. As indicated earlier, lag-CRP curves show a characteristic shape: Around the starting point, which is defined by the item to have just been recalled, items from nearby list positions (lags +1 and −1) show high probabilities of subsequently being recalled. With increasing lag (i.e., increasing distance between items on the list, e.g., lags −2, −3, . . . , and +2, +3, . . .), the probability of these items subsequently being recalled substantially decreases. Based on a reanalysis of data from large free-recall experiments (Murdock, 1962; Murdock & Metcalfe, 1978; Murdock & Okada, 1970), Kahana (1996) detected three basic characteristics of lag-CRP curves: (a) After recalling a specific item, the subsequently recalled item has a high probability of coming from a nearby list position; (b) the conditional response probabilities reveal an asymmetry, with the recall of items from previous list positions being less probable than the recall of items from subsequent list positions; and (c) the probability of recalls from nearby list positions is high at the beginning of the recall phase and subsequently decreases.

On the basis of these findings, Howard and Kahana (2002) proposed a *temporal-context model* that was able to explain contiguity effects in different free-recall tasks (e.g., Howard & Kahana, 1999; Kahana & Howard, 2005). In this model, recalling an item partially reinstates the context in which the item was presented and studied. This partial reinstatement of context serves as a retrieval cue for those items that shared a similar context during study. Since items from nearby list positions are most likely to have shared a similar context (partial), retrieval of this context results in close temporal recall of these neighboring items or, in other words, in the observed contiguity effect.

As mentioned earlier, little is known about the development of the relation between study and recall dynamics in children when implementing rehearsal activities. The present study thus had two main purposes. First, we aimed to increase understanding of general developmental changes in recall dynamics within a free-recall task and, second, to particularly explore the developing relation between strategic behavior and subsequent recall dynamics. To this end, we reanalyzed data from an earlier study by Lehmann and Hasselhorn (2007) to determine whether there are developmental changes in recall dynamics and whether these recall dynamics are due to children's rehearsal behavior.

With regard to the first purpose of examining developmental changes in recall dynamics, Lehmann and Hasselhorn (2007) and Ornstein and Naus (1985; Naus & Ornstein, 1983) have both shown developmental changes in rehearsal behavior and increases in recall performance. These findings, however, were again based on an examination of recall performance as a static end product of learning behavior rather than as a dynamic process in itself. Yet the aforementioned contiguity effect (e.g., Howard & Kahana, 1999) and the influence of semantic similarity on retrieval processes (e.g., Hasselhorn, 1992; Howard & Kahana, 2002) suggest that one has to analyze recall order when it comes to understanding recall as a subject-driven process. Such an analysis allows us to identify the consequences of preceding learning behavior and developmental processes in the functioning of episodic memory. Since the ability to encode ordinal structures and sequences of single events emerges very early in childhood, we suppose that associative effects, in terms of contiguity, can be observed within children's recall behavior.

Concerning the development of recall dynamics, the processes underlying study and recall can be inferred not only from the order in which items are recalled but also from the IRTs between them (Bousfield & Sedgewick, 1944; Pollio, 1974; Pollio, Richards, & Lucas, 1969). As soon as successive item retrievals are no longer independent of one another—thus fulfilling a main assumption of the temporal-context model (Howard & Kahana, 2002)—their IRTs are also assumed to be shorter as compared to the retrieval of almost unrelated items. In other words, we suppose that the stronger the association between two items or the greater the overlap between two contexts, the shorter the interval between the output of these items.

Concerning the second main purpose of more directly exploring the relation between strategic behavior and recall dynamics, we analyzed whether the peculiarities of children's rehearsal behavior identified in the study by Lehmann and Hasselhorn (2007) had differential effects on the corresponding recall dynamics. In one of the few previous studies on rehearsal-recall correspondences, Ornstein, Naus, and Stone (1977) analyzed the relation between the joint rehearsal of several words (i.e., cumulative rehearsal) and increased recall of items from early list positions. The authors applied Pellegrino's (1971) measure of intertrial repetition for subjective organization with units of size 2 and examined whether differences in input strategies (namely, rehearsal) were associated with differences in output organization. No differences in output organization were found for either different rehearsal strategies or for different age groups. However, results of two other studies by Ornstein, Naus, and Miller (1977) and Naus, Ornstein, and Aivano (1977) suggest that the joint rehearsal of several different items becomes increasingly important when a list lacks inherent (categorical-grouping) structure. Ornstein and Naus (1978, p. 95) suppose that under these conditions, "active rehearsal may serve an organizational function." Since Lehmann and Hasselhorn used semantically unrelated items and identified large qualitative and quantitative differences between strategies during study, we assumed that different forms of learning behavior would lead to considerable differences in subsequent recall behavior. In contrast to labeling and single-word rehearsal, cumulative rehearsal was explicitly assumed to represent a memory strategy that enables different items to share a very similar learning context. This shared context should, according to the temporal-context model (Howard & Kahana, 2002), result in an increased probability of close temporal recall for items sharing this context. In addition, this effect should be even more pronounced when items frequently share the same context in terms of repeatedly being selectively rehearsed.

Finally, Lehmann and Hasselhorn (2007) found that memory capacity constituted a strong factor underpinning both qualitative and quantitative developmental changes in active rehearsal behavior (see also Guttentag, 1984, 1989). Since memory capacity is assumed to be responsible for the retrieval of previously presented items that are subsequently available for rehearsal, we hypothesized that memory capacity should propel the association of items with one another during study and recall.

Method

Participants

Participants were 76 children (48 girls and 28 boys) who were assessed on five occasions over the course of a 2-year longitudinal study. The children attended various elementary schools in the area of Göttingen in Germany. They voluntarily participated (with parental permission) and were primarily from Caucasian middle-income families. At the beginning of the study, children were currently completing the latter half of second grade (*M* age = 8.3 years, *SD* = 6 months). Following their first assessment, children were tested on a further four occasions approximately 6 months apart. At the fifth measurement point they thus attended the latter half of fourth grade (*M* age = 10.2 years, *SD* = 6 months).

Materials and Procedure

Children studied three different lists of words and subsequently completed immediate free-recall tests. With the exception of the first measurement point, which lists comprised 14 items, the lists consisted of 12 highly concrete, familiar items from different semantic categories. Each list contained only one item from each category and the three lists were parallel with regard to the number of syllables. At each measurement point the three lists were administered in an identical and predetermined order. Individual stimulus items were simultaneously presented acoustically and visually at a rate of one item every 8 s. Acoustic presentation was performed using a CD player and visual presentation using 5 × 5 cm picture cards for each item, with the name of the object printed underneath its picture. Children were tested individually and both their learning and recall behavior were videotaped and digitally recorded.

At the beginning of each of the three trials, children were informed that they would be acoustically and visually presented with a number of items that were to be memorized and subsequently recalled in any order they wished. In addition, the children were instructed to think aloud while memorizing the items and to verbalize whatever they were thinking or doing (for a similar procedure, see Guttentag, Ornstein, & Siemens, 1987). List presentation was performed from a CD and by simultaneously placing the picture cards, one at a time, in front of the children. Each card was visible for an interval of 8 s until the subsequent item was acoustically presented by the CD and the card was replaced by the subsequent picture card. Following presentation of the entire list, children were instructed to recall as many items as possible. The recall phase ended after a 1-min interval in which the child was not able to recall any more words. In order to ensure that children were able to meet task requirements and to familiarize them with the thinking-aloud procedure, three practice trials (each including six items) were conducted at the first measurement point. At subsequent measurement points, only one practice trial was administered.

Lehmann and Hasselhorn (2007) assessed children's memory capacity with a digit span backward task, similar to the Wechsler Intelligence Scale for Children (Hamburg–Wechsler Intelligenztest fuer Kinder III [HAWIK–III]; Tewes, Rossmann, & Schallberger, 1999). In this task, digit sequences of increasing length were presented, starting with sequences of 2 one-syllable digits. At each sequence length, two series were presented acoustically at a rate of one digit every second. The digit span backward score was the maximal sequence length recalled in the correct backward order. If both sequences of the same length were accurately recalled, half a point was added to the score.

Coding and Scoring

For scoring and coding of strategic behavior, Lehmann and Hasselhorn (2007) used the audio and video recordings. During each interstimulus interval, children's behavior was coded according to five different strategy classifications: the three rehearsal strategies labeling (speaking aloud the name of one item only once), single-word rehearsal (repeating the name of one item several times), and cumulative rehearsal (speaking aloud a rehearsal set containing at least two items), as well as associative and elaborative learning behavior, and *no* observable learning behavior. At each measurement occasion, the percentages of occurrence of the different strategies were calculated. Two independent raters agreed on 89%, 88%, and 94% of strategy classification of labeling, single-word rehearsal, and cumulative rehearsal, respectively.

In addition children's verbalization of the to-be-learned items was assessed and coded and scored at each rehearsal opportunity. Two independent raters agreed on about 95% of the assessment of verbalizations. The few disagreements were resolved through inspection of the recordings and discussion.

For scoring and coding of recall behavior, again audio and video recordings were used. Two independent raters agreed on about 95% of assessment of number and order of items recalled and on about 90% of assessment of the time between each recall. Again, disagreements were resolved through inspection of the recordings and discussion.

Results

The previous analyses by Lehmann and Hasselhorn (2007) showed that cumulative rehearsal primarily occurred in early portions of the list. In contrast, the highest percentages for labeling were found in later list portions. With increasing age, however, children also showed incremental use of cumulative rehearsal in later list sections. Single-word rehearsal was used in a stable manner over both the course of the list-learning process and the five measurement points. Regarding the quality of rehearsal, mean rehearsal-set size, as measured by the number of different items included in an interstimulus interval, was observed to steadily increase over the five measurement points, with mean values of 1.11 (*SD* = 0.78), 1.38 (*SD* = 0.79), 1.64 (*SD* = 1.03), 1.90 (*SD* = 1.08), and 2.00 (*SD* = 1.15) for Measurement Points 1–5, respectively. In addition, when analyzing the data of only those children who actually engaged in cumulative rehearsal maximum rehearsal sets observed at the five measurement points were 3.8, 4.0, 4.7, 4.9, and 5.0 (range = 2–8) for Measurement Points 1–5, respectively.

At the five measurement points, children recalled a mean number of 5.25 (*SD* = 1.61), 5.55

(*SD* = 1.39), 5.85 (*SD* = 1.53), 6.28 (*SD* = 1.39), and 6.81 (*SD* = 1.43) items, respectively. Due to the fact that the three lists at the first measurement point contained two more items than the lists at later measurement points, recall percentages were analyzed. Recall percentages reliably increased with age over the five measurement points (for detailed information, see Lehmann & Hasselhorn, 2007).

Finally, Lehmann and Hasselhorn (2007) identified memory capacity to constitute a strong factor for the implementation of cumulative rehearsal. Memory capacity, assessed by the Digit Span Backward, increased reliably over the course of the elementary school years at intervals of 1 year (3.79, 3.88, 4.07, 4.24, and 4.43, for Measurement Points 1–5, respectively).

According to the goals of the present study, results are presented in two sections. In line with the first purpose of the study, the first section presents results on developmental changes in recall performance. In the second section, evidence of a correspondence between recall performance and strategic learning behavior are presented. Furthermore, evidence of a relation between selective mnemonic behaviors and the dynamics of free recall are reported. Finally, the influence of memory capacity on selective rehearsal behavior is demonstrated. Unless otherwise stated, all differences were significant at the $p < .05$ level.

Recall

Conditional response probability. So far, developmental changes in recall performance have almost exclusively been described using serial position curves. Serial position curves allow a valid inspection of recall performance with regard to the characteristics of the to-be-learned material and highlight developmental changes in recall performance. However, information on recall processes and the dynamics of recall remain greatly disregarded. In contrast, CRP curves allow for the identification of recall dynamics or more precisely of sequential contiguity. CRP is defined as "the probability of recalling item y after item x, conditionalized on recall of item y" (Kahana, 1996, p. 104). CRP is plotted as a function of lag, that is, as a function of the distance between two items within the list, reinstated at the time of recall. CRP as a function of lag (or lag-CRP) is calculated by dividing the number of transitions made to that lag (numerator) by the number of transitions that could have been made to that lag (denominator). The maximum lag is thus defined by the range of the list. In addition, the final position on the list does not allow for positive transitions and the first position does not allow for negative transitions.

To give an example: At the time of test, a person recalls six items out of a list of 10 items in the subsequent order (numbers correspond to the items' position within the list): 3, 4, 7, 5, 9, and 10. Given that there is no possible transition to the first item recalled, the following lags between recalled items can be identified: +1, +3, −2, +4, and +1. Considering the order of presentation of the list items, five transitions could have been made to lag +1 (to Items 4, 7, 5, 9, and 10), five transitions to lag +3 (to Items 4, 7, 5, 9, and 10), only four transitions to lag +4 (to Items 7, 5, 9, and 10) because there was no list item that could have been transitioned four list positions forward to List Item 4, and so on. Negative lags, that is, backward transitions at the time of testing, are subject to the same restrictions as forward transitions. In the given example, a negative transition to lag −2 could have been made three times (to List Items 4, 7, and 5). A negative transition to the lag −2, however, could not have been made to List Items 9 and 10 given that there were no items positioned after List Item 10.

We inspected the recall protocols from all five measurement points and analyzed developmental changes in the lag-recency effect. In the above-mentioned analyses performed by Kahana (1996), the first three recalled items were excluded in order to analyze free-recall data which had been freed from the recency effect. In the present study, preliminary analyses revealed that at Measurement Points 1–4, the probability of first recall for items from the last list position was at least twice as high as that of first recall for items from any other list position. Under the assumption that the recency effect in the present study was restricted to the first item recalled, this item was therefore excluded from all analyses. In addition, analyses only included recalls up to the fifth output. This was due to recall performance at the first measurement point in which the mean number of items recalled was approximately equal to 5. Hence, by limiting analyses to the early recalled items, we aimed (a) to balance children's recall performances that might emerge from large interindividual recall differences and (b) to avoid confounding of recall processes. Even if the lag-recency effect is observable at later recall transitions, this effect has been shown to be considerably smaller than that found at the beginning of the recall phase (Howard & Kahana, 1999). Since we were interested in recall orders of within-list items, repetitions and intrusions were excluded from analyses.

Figure 1 shows the lag-CRP functions for each of the five measurement points. As can be seen, the quantitative levels of the functions changed with age while the basic shape of the five curves remained highly similar. After recalling an item, the children tended to recall an item from a nearby list position. In order to analyze age-related differences in the lag-recency effect, we adopted the procedure developed by Kahana, Howard, Zaromb, and Wingfield (2002) and differentiated within the five lag-CRP functions between adjacent transitions (lags of +1 and −1) and remote transitions (lags of +3, +4, +5, and −3, −4, −5). An analysis of variance (ANOVA) with measurement points (1–5) and lags (adjacent and remote) as within-subject factors revealed a significant main effect of measurement point, $F(4, 296) = 7.54$, $MSE = 0.003$, $p < .001$; a significant main effect of lag, $F(1, 74) = 55.67$, $MSE = 0.01$, $p < .001$; and a significant interaction, $F(4, 296) = 3.19$, $MSE = 0.006$. While the form of the lag-CRP functions did not undergo large age-related changes, lag-CRP functions showed incremental steepness as the children increased in age. This was especially the case for the adjacent +1 lags that showed the highest probabilities at all measurement points but increasing probability with age and a peak at Measurement Point 5. In contrast, CRP functions for more remote lags (forward and backward) remained at almost the same low level. Tukey's honestly significant difference (HSD) tests supported these observations and revealed reliably higher probabilities for adjacent than remote lags at all measurement points. More important from a developmental perspective, however, was the finding that adjacent lags were far more pronounced at Measurement Point 5 than at Measurement Points 1, 3, and 4.

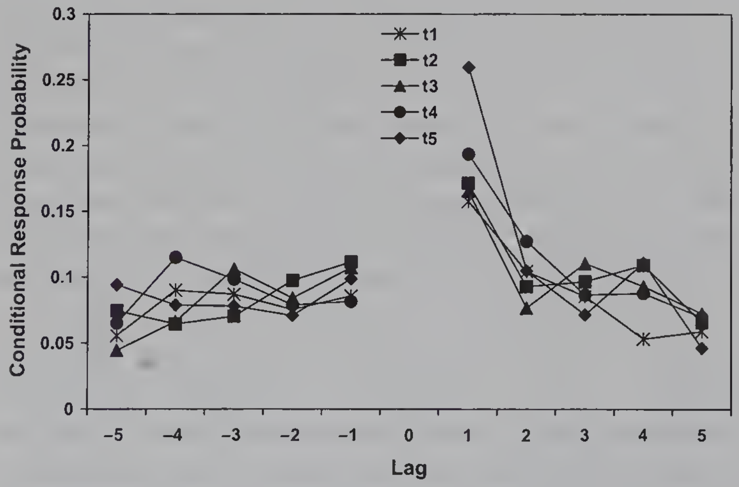

Figure 1. Conditional response probability curves as a function of lag when the children were 8.3 years (t_1), 8.9 years (t_2), 9.3 years (t_3), 9.9 years (t_4), and 10.2 years (t_5) old.

Conditional response latency. Associations between unrelated items can be formed when they share a similar episodic or rather temporally defined context. Associations are inferred by the tendency of one item evoking the other. Thus, associations between items are assumed to be responsible for recall sequences. These associations, however, not only appear to influence the order in which items are recalled but also the IRTs between them. In order to investigate this second characteristic of interitem associations, we recorded IRTs during children's recall and analyzed them conditional on recall transitions. Analyses of these so-called CRLs were comparable to those of the CRPs in that they included Output Positions 2–5 and followed the same requirements as the CRPs. IRT data were analyzed on the basis of computer-based visual display of the audio signals comprising vocalized recalls and pauses between recalls. IRTs were measured as the duration between the onset of a vocalized recall and the onset of a subsequent vocalized recall. Vocalization time was included in the IRTs given that vocalization of an item might itself overlap with children's search process for the next item. This assumption was confirmed by the tendency of some children to protract the endings of the items.

Figure 2 shows CRLs as a function of lag. An examination of these functions indicates that CRL's were shortest when successively recalled items were from nearby list positions. Quantitative analysis of the developmental latency data was again conducted by differentiating between adjacent transitions (lags +1 and −1) and remote transitions (lags +3, +4, +5, and −3, −4, −5). An ANOVA with measurement points (1–5) and lag (adjacent and remote) as within-subject factors only revealed a significant main effect of lag, $F(1, 30) = 6.71$, $MSE = 34{,}713{,}877$. Subsequent Tukey's HSD tests showed that latencies between items from adjacent input positions were shorter than those from remote input positions.

Relation Between Rehearsal Behavior and Recall Dynamics

In a reanalysis of rehearsal and recall data from a free-recall study by Murdock and Metcalfe (1978), Laming (2006, p. 1159) concluded that "recall and rehearsal result from a common underlying process." Since our CRP results reported earlier exclusively focused on the correspondence between the

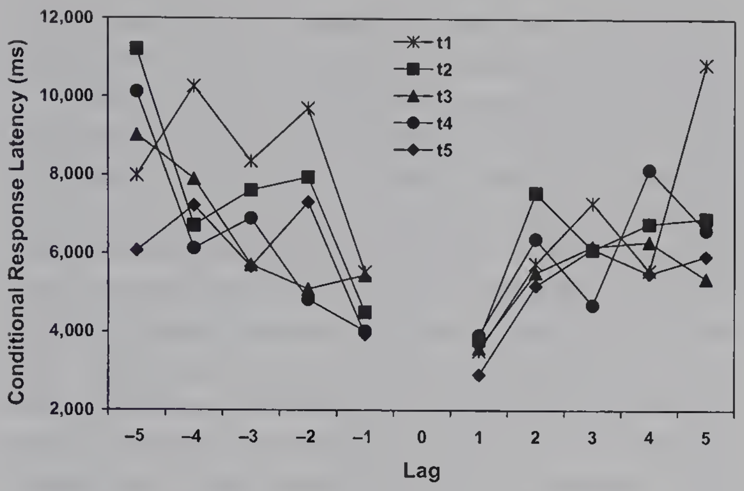

Figure 2. Conditional response latency curves as a function of lag when the children were 8.3 years (t_1), 8.9 years (t_2), 9.3 years (t_3), 9.9 years (t_4), and 10.2 years (t_5) old.

sequence of presentation and the sequence of recall, we aimed in a second step to examine whether and how learning behavior affects this correspondence. The children, who were given the possibility and even invited to actively memorize the lists of words, were observed by Lehmann and Hasselhorn (2007) to actually use three different rehearsal strategies (labeling, single-word rehearsal, and cumulative rehearsal). The following developmental analyses therefore focus on the influence of rehearsal behavior and in particular the impact of selective rehearsal of specific items or sets of items on the lag-recency effect. In the analysis of the lag-recency effect and thus also the recall order, we again differentiated between recalls from adjacent versus remote list positions.

Rehearsal behavior. Strategy development can be described in terms of both qualitative and quantitative changes (for detailed information, see Lehmann & Hasselhorn, 2007). Qualitative differences between rehearsal strategies are particularly characterized by the properties of the rehearsal sets involved, namely, rehearsal-set size. In the course of strategy development, children also show quantitative shifts in the frequency of the strategies which they apply. Specifically, children increasingly frequently and proportionally used superior strategies. In sum, advanced goal-directed strategic behavior (characterized by both qualitative and quantitative improvement) should also be reflected in resulting recall dynamics.

With respect to our data, correlation analyses revealed that mean rehearsal-set size was positively correlated with the mean probability of adjacent lags at Measurement Points 2, 3, and 4, $r(74) = .32$, $r(74) = .27$, and $r(74) = .41$, respectively. At Measurement Points 1 and 5, correlations were positive but nonsignificant, $rs(74) < .16$. Mean rehearsal-set sizes were not related to the average probability of remote lags at any of the five measurement points. Regarding quantitative aspects of rehearsal (i.e., the percentages of strategy use), the frequency of cumulative-rehearsal usage was positively related to the CRPs of adjacent lags at Measurement Points 2, 3, and 4, $r(74) = .28$, $r(74) = .28$, and $r(74) = .32$, respectively. At Measurement Points 1 and 5, correlations were again positive but nonsignificant, $rs(74) < .17$. Regarding the more passive rehearsal activities, only single-word rehearsal was positively related to the CRPs of remote lags at Measurement Point 2, $r(74) = .27$, and negatively related to the CRPs of adjacent lags, $r(74) = -.36$. As expected, proficient cumulative-rehearsal behavior during study, as characterized by rehearsal sets containing multiple items in close contiguity and high frequency in the execution of this behavior, was positively related to the recall of neighboring items. Significant relations between other rehearsal behavior and recall were only observed at Measurement Point 2, suggesting a smaller impact of other rehearsal strategies on systematic recall behavior.

The influence of selective rehearsal behavior on CRP and CRL. Selective rehearsal behavior can be defined as the selective repetition of specific items or a specific set of items. In a first step, we examined developmental changes in the occurrence of selective rehearsal behavior. In order to identify such behavior, we examined children's rehearsal protocols and classified pairs of items that were repeatedly rehearsed together. Again, we differentiated between pairs of items from adjacent list positions (lags +1 and −1) and pairs of items from remote list positions (lags +3, +4, +5, and −3, −4, −5). The first two columns in Table 1, respectively, display the number of joint repetitions of two items from nearby and remote list positions. A 2 (lag: adjacent and remote) × 5 (measurement points) ANOVA with repeated measures on both factors revealed main effects of lag, $F(1, 75) = 89.64$, $MSE = 0.28$, $p < .001$, and measurement point, $F(4, 300) = 36.00$, $MSE = 0.23$, $p < .001$. In addition, a significant Lag × Measurement Point interaction was found, $F(4, 300) = 39.43$, $MSE = 0.05$, $p < .001$. For both sets of item pairs, the mean number of joint repetitions increased as children got older. For items from adjacent serial positions, however, the mean number of joint repetitions increased more steeply than the mean number of joint rehearsals for more remote item pairs. These changes in rehearsal characteristics reflect a clear development toward increasing selective rehearsal behavior, in

Table 1

Mean Values (and Standard Deviations) for Number of Joint Rehearsals of Items From Adjacent and Remote Positions (General) and for Number of Joint Rehearsals of Items From Adjacent and Remote Positions (Effectively Recalled) at the Five Measurement Points (t_1–t_5)

	Number of joint rehearsals			
	General		Effectively recalled	
	Adjacent	Remote	Adjacent	Remote
t_1	0.04 (0.10)	0.05 (0.14)	1.33 (3.64)	0.68 (2.33)
t_2	0.44 (0.59)	0.12 (0.20)	2.86 (5.69)	0.64 (1.54)
t_3	0.63 (0.76)	0.22 (0.31)	3.76 (6.26)	1.61 (3.30)
t_4	0.82 (0.85)	0.29 (0.38)	4.51 (6.69)	1.78 (3.45)
t_5	0.91 (0.89)	0.34 (0.42)	5.95 (8.54)	1.97 (3.76)

particular in the rehearsal of items from nearby list positions. Subsequent Tukey's HSD tests confirmed this developmental pattern and revealed that with the exception of the first measurement point joint rehearsals of pairs of adjacent list items were more frequent than joint rehearsals of pairs of remote list items. Furthermore, the number of joint rehearsals of adjacent items steadily increased up to the beginning of fourth grade but not thereafter. Age-related differences with respect to the rehearsal of pairs of remote list items were only reliable in intervals of 1 year.

In order to compare processes of learning and recall, we analyzed the relation between the number of selective rehearsals and the recall order of these item pairs by once again examining children's recall protocols and differentiating between item pairs from adjacent and those from remote list positions. From Measurement Point 2 onward, a positive relation was observed between the number of rehearsals of adjacent list items and adjacent recall of these item pairs, $rs(74) > .24$. In contrast, the mean number of joint rehearsals for items from remote list positions was not related to adjacent recall of these item pairs at any of the five measurement occasions.

In a second step, we examined whether differences in the number of joint rehearsal of items affected subsequent consecutive recall of these items. Columns 3 and 4 in Table 1 present the mean number of joint rehearsals for items from adjacent and remote serial positions that were effectively recalled in succession. To control for differences in recall outcomes between adjacent and remote items, the number of joint repetitions of each adjacent and remote item pair was respectively related to the total number of recalls made for adjacent or remote item pairs. A two-way ANOVA with repeated measures on the factors lag (adjacent and remote) and measurement points (1–5) and the dependent variable "mean number of joint rehearsals of item pairs recalled" revealed main effects of lag, $F(1, 75) = 21.91$, $MSE = 47.68$, $p < .001$, and measurement point, $F(4, 300) = 13.44$, $MSE = 15.20$, $p < .001$. More importantly, however, the Lag × Measurement Point interaction also proved significant, $F(4, 296) = 4.38$, $MSE = 12.47$. With increasing age, joint rehearsal of item pairs became more and more effective. This was especially the case for items from adjacent serial positions and particularly apparent during fourth grade. Subsequent Tukey's HSD tests showed that from Measurement Point 2 onward, the mean number of joint rehearsals of effectively recalled adjacent item pairs was higher than the mean number of recalled remote item pairs. In addition, the number of joint rehearsals of effectively recalled adjacent item pairs was higher at Measurement Point 4 than at Measurement Point 1 and at Measurement Point 5 than at Measurement Points 1 and 3.

Since Lehmann and Hasselhorn (2007) reported that the percentages of cumulative-rehearsal use were not uniformly distributed across the list-learning process but were instead especially high at early- and middle-list positions, we further examined the distribution of pairs of adjacent items that were effectively recalled in succession. Given that that the group of item pairs from remote list positions was too heterogeneous to obtain an interpretable data pattern, distributions were examined for adjacent items only. At least 50 percent of successively recalled items from adjacent list positions (50%, 60%, 59%, 65%, and 68% for the five measurement occasions, respectively) were item pairs from the early list portion (i.e., Items 1–2, 2–3, 3–4, 4–5, and 5–6). Percentages for joint rehearsals of effectively recalled items from adjacent list positions were even more pronounced, with item pairs from early list positions amounting to at least 75% of the overall joint rehearsals of adjacent item pairs (75%, 79%, 90%, 79%, and 75% for the five measurement points, respectively).

We also tested the influence of joint rehearsal on recall latencies. Although most correlations were not significant, the highest correlation was interestingly found at Measurement Point 5, with the mean number of joint rehearsals of adjacent item pairs being related to short latencies between the successive recollection of these items, $r(70) = -.26$. While this latter finding should be interpreted cautiously, it suggests an increasing proficiency and effectiveness of selective rehearsal behavior at the end of Grade 4.

Memory capacity influence on selective rehearsal behavior. In the present study, additional analyses revealed positive correlations between memory capacity as measured by digit span backward and the number of joint rehearsals of items from neighboring serial positions at Measurement Points 2–5, *r*s(74) = .29, .37, .33, and .39, respectively. Correlation analyses between memory capacity and number of joint rehearsals of neighboring items that were effectively recalled in succession additionally revealed a positive relation at Measurement Points 2, 3, and 5, *r*s(74) = .33, .38, and .38, respectively. Findings for items from remote serial positions were, however, different. High memory capacity was, on the one hand, also positively correlated with the number of joint rehearsals of items from remote serial positions at Measurement Points 2–5, *r*s(74) = .36, .35, .30, and .42, respectively. On the other hand, no relation was found between memory capacity and the number of joint rehearsals of remote items that were effectively recalled in succession.

Discussion

While previous research (Lehmann & Hasselhorn, 2007; Ornstein & Naus, 1978) has highlighted the developmental changes in children's free-recall performance (age-related increase in active rehearsal leading to better recall of the to-be-learned material), the detailed method used in the present investigation yielded more insightful descriptions of recall dynamics in children and their developmental progression than those previously available. Recall dynamics are of particular interest because they offer an opportunity to relate sequential processes during study with processes during recall. In this concluding section, we thus successively consider developmental changes of sequential recall processes and the corresponding learning processes.

Sequential Effects During Recall

In the present analyses, we longitudinally examined age-related changes in recall dynamics following a list-learning process in children. Past analyses of rehearsal-recall observations have primarily focused on serial position curves that disregard sequential output positions. In contrast, the present analyses were based on a measure relating input order (i.e., the sequence of presentation during study) to output order (i.e., the sequence of recall). This detailed examination allowed us to analyze sequential dependencies across output positions and therefore revealed a much more process-oriented picture than has been yielded by previous analyses. We examined the so-called CRP that was introduced by Kahana (1996) and that gives the probability of recalling item *i* + lag after recalling item *i*. Analyses of the CRP revealed a high tendency for subsequently recalled items to come from nearby serial positions (lag-recency effect) and showed that this tendency is considerably higher for forward than for backward recalls.

In line with Kahana's (1996) findings, CRP analyses in the present study also revealed the lag-recency effect. Compared to the CRP curves generated for adults in studies by Kahana and his colleagues (Howard & Kahana, 1999; Kahana et al., 2002); however, we found a more pronounced asymmetry in the lag-recency effect in our sample of children aged between 8 and 10 years, with only small values and little variation in CRPs for backward recalls but large CRP values for forward recalls. This particularly applied to items from neighboring serial positions and much less so to items from remote serial positions. Furthermore, the present findings suggest that the lag-recency effect develops across the observed 2-year period: The effect was considerably more pronounced at the end of Grade 4 than at previous measurement points. In addition, recalls from more distant serial positions resulted in longer recall latencies and those from close serial positions in short recall latencies. In conclusion, the present findings suggest that, within a free-recall task comprising semantically unrelated material, interitem associations result from contextual or temporal proximity of the items. These interitem associations seem to result in associated items being recalled in very fast succession. The recall phenomena observed in the present study in 8- to 10-year-old children match recall phenomena in sort-recall tasks in children of the same age. Hasselhorn (1992), for example, analyzed 8- and 10-year-olds' interitem latencies in a sort-recall task and found that children's within-category latencies were shorter than their between-category latencies. Hence, recall of items sharing a similar temporal context (i.e., from adjacent serial positions) might be equated with the recall of items sharing a semantic context (i.e., from the same category) and, in turn, the recall of items from remote serial positions with the recall of items from different categories.

Relation Between Rehearsal Behavior and Recall Dynamics

Development in children's strategy use is characterized by their discovery of qualitatively novel strategies and concepts and by quantitative shifts in the frequency and efficiency with which they execute strategies (Siegler, 2006). The remarkable work of Ornstein and colleagues (e.g., Ornstein & Naus, 1978) has repeatedly shown that both the acquisition of advanced rehearsal strategies and qualitative changes in executing cumulative rehearsal (rehearsal-set size) are major contributors to recall performance and that these qualitative advancements increase with age. Recent research has further shown that quantitative improvement, that is, increasing frequency in the execution of cumulative rehearsal, also predicts recall performance (see Lehmann & Hasselhorn, 2007).

Nonetheless, previous analyses of rehearsal, have rarely addressed the issue of systematic change in recall dynamics as a consequence of developmental changes in rehearsal behavior. In allowing an assessment of sequential dependencies in retrieval, the present analyses permitted to demonstrate that both qualitative and quantitative developmental changes in rehearsal were related to sequential characteristics of recall. Specifically, increasing quality in rehearsal behavior (rehearsal-set size) and increasing frequency (percentages) of cumulative-rehearsal usage at Measurement Points 2–4 were related to the probability of recalling items from nearby serial list positions. These results suggest that, when implemented as an active goal-directed behavior, cumulative rehearsal leads to adjacent items being related during study and subsequently recalled in succession. These results differ from those reported by Ornstein, Naus, and Stone (1977) in a rehearsal-training study with second and sixth graders. Here, Pellegrino's (1971) measure of intertrial repetition for subjective units of size 2 did not yield a significant effect of rehearsal strategy on output organization for either of the two age groups. In contrast to the present study, however, Ornstein, Naus, and Stone (1977) used the same list of words with different orders across several trials. If indeed rehearsal is characterized by a process that constructs retrievable units from neighboring items, then reordering items in each trial might result in order interferences between the different trials and thus obscure subjective organization or subjective clustering.

The observed cessation of the described effects after the fourth measurement point suggests that qualitative and quantitative changes in children's rehearsal behavior beyond this developmental stage potentially might not be detected by such global measures as rehearsal-set size or the number of implemented strategies. This assumption is supported by the obvious limitations of global measures of rehearsal and in particular of rehearsal-set size. Naus et al. (1977), for example, found a clear limitation of rehearsal-set size, with sets larger than approximately three to four items failing to additionally enhance recall. Hence, even if children are able to compile large rehearsal sets, they might find it difficult to do so throughout the entire list-learning process. If children therefore find it difficult to continually and conjunctly rehearse a large number of items and additionally have the impression that they do not especially profit from large rehearsal sets during recall, then other mechanisms beyond solely compiling large rehearsal sets should come into play.

Selective Rehearsal and Its Influences on Recall Dynamics

According to the assumption that a fine-grained approach is needed to detect developmental changes in the relation between specific rehearsal behavior and specific recall behavior, we analyzed the joint rehearsal of particular items. Our aim was therefore to identify whether these sequential dependencies were due to selective and focused learning behavior with respect to these items. By analyzing the composition of rehearsal sets, we found that when children grew older (in the course of Grades 3 and 4), they showed conjunct rehearsal of items from nearby serial positions far more often than conjunct rehearsal of items from remote serial positions.

In focusing on pairs of items that were rehearsed together and subsequently recalled in succession, the present study contributed a further method for validating rehearsal-recall matches. The examination of pairs of jointly rehearsed items and their recall correspondences offers the possibility to identify study-recall patterns that include both qualitative and quantitative aspects of rehearsal behavior: The more often pairs of items are rehearsed together in different interstimulus intervals, the higher the percentage of cumulative-rehearsal usage according to its definition (cumulative rehearsal is defined as an average rehearsal set of at least two different items; e.g., Guttentag et al., 1987). In addition, the more often items (here, item pairs) are reentered into cumulative-rehearsal sets for additional study, the larger the rehearsal sets and the more frequent and various the opportunities for interitem associations become (see also Cuvo, 1975).

Examining the number of conjoint reentries in interstimulus intervals of pairs of items that were additionally effectively recalled thus allowed us to establish that successively recalled items were far more frequently studied together when they came from nearby as opposed to remote serial positions. This effect became even more pronounced with increasing age.

Implications for the Development of Rehearsal–Recall Correspondences

The current approach to examining developmental changes in study-recall behavior lead us to suggest the following study-recall processes in children when working on a free-recall task: The experimentally predetermined item presentation sequence can be seen as a kick-off for associating items presented in close proximity in terms of the temporal-context model proposed by Howard and Kahana (2002). When children are allowed to engage in strategic behavior, neighboring items are rehearsed together. This mechanism of repetition increases the interitem associations between these items as a result of which the items can be kept available for further rehearsal and more easily retrieved. This characteristic is particularly noticeable in younger children who show less proficient forms of cumulative rehearsal. In a training study by Naus et al. (1977), third graders were instructed to rehearse the currently presented item with the two previously presented items. While children were able to implement cumulative-rehearsal behavior, most of them showed a rather inflexible rehearsal pattern and rehearsed each currently presented item with the items from the first two serial positions. With increasing age, however, children's rehearsal behavior becomes more flexible. At these later stages, both a large rehearsal-set size and a high proportion of cumulative-rehearsal usage presumably lead to a continuous reentering of previously presented items into rehearsal sets and consequently, to an increase in interitem associations and an intermixture of new and old items generating various retrieval cues for later recall. This is in accordance with an observation by Ornstein, Naus, and Liberty (1975), some decades ago, who found in eighth-grade children's rehearsal protocols many previously presented items as being rehearsed together in several later rehearsal sets.

Developmental increase in memory capacity would appear to be an essential factor establishing this developmental change. Memory capacity is assumed to be responsible for the retrieval of previously presented items that are subsequently available for rehearsal and association with one another. In the present study, additional analyses revealed that memory capacity exerted its influence on both rehearsal of item pairs from adjacent and remote serial positions during study but not on rehearsal of item pairs from remote serial positions during recall. Specifically, high memory capacity was positively correlated with the ability to compile many items (from different serial positions) into rehearsal sets and to maintain the process of joint rehearsal of (associated) items over a prolonged period. Regarding the link between study and recall, however, the observed effect of memory capacity on study was only mirrored in effects on recall for items from neighboring positions. Items that are successively presented and rehearsed may therefore be strongly associated with one another and in turn be successively recalled. Recalling a specific item seems to reinstate the learning context, which serves as a retrieval cue for other items with a similar context (Kahana et al., 2008). The present study reveals that this study-recall pattern develops during childhood. More particularly, in the present sample, this correspondence was found to increase up to the age of approximately 10 years. Presumably, the high processing demands of multi-item rehearsal constrain in younger children the ability to rehearse many different items conjointly, that is, in an active, goal-directed strategic behavior that should prompt construction of retrievable units of adjacent items. However, if memory demands are reduced during study (e.g., by keeping the items visible during study) even younger children (Grade 3) are able to use cumulative rehearsal in an efficient manner and to rehearse different items together (see Guttentag et al., 1987; Ornstein, Medlin, Stone, & Naus, 1985).

Limitations and Future Research

While the results of the present study suggest a clear lag-recency effect in children that increases with age, they should be interpreted with some caution. On the one hand, the lag-recency effect is usually tested using a larger number of lists. Using three lists, as was the case in the present study, causes results to be less reliable. On the other hand, previous studies have shown the lag-recency effect to be rather robust and have demonstrated that it is still to be found in adults at late output positions (Howard & Kahana, 1999). Due to this robustness and given that the CRPs found in the present study closely resemble those reported in previous studies with adults as well as showing the same properties as described in these studies, using CRPs to assess recall processes in children appears to represent an adequate option.

The present analyses indicate that when children work on a free-recall task, processes taking place at the time of study and at the time of test seem to be compatible. However, this correspondence seems to be mediated by children's memory capacity, which itself increases with age. Employing complex memory strategies such as cumulative rehearsal requires enormous mental effort. The proficient use of cumulative rehearsal (i.e., high-quality rehearsal over a prolonged period of time) thus seems to necessitate high memory capacity. It is well established that older children have larger memory spans and are therefore able to store more information. As shown by Guttentag et al. (1987) and Lehmann and Hasselhorn (2007), smaller memory demands (e.g., by strong experience with the task) or higher memory capacity allow children to more extensively make use of cumulative rehearsal or to use it at all. However, we know very little about the sources of these capacity differences and their specific impact on rehearsal. In light of Cowan's (1997) review of several causes of developmental changes in children's memory capacity, including, for example, more storage space, faster processing speed, improved attention, and less memory loss over time, its impact on rehearsal would seem to be far from straightforward. In order to more precisely understand the factors underlying the impact of memory capacity on rehearsal processes, more detailed analyses both during study and recall are necessary. Future research should extend the present analyses by specifying the locus of capacity advantages in older children within the rehearsal process. It may, for example, be argued that differences in rehearsal rate explain why some children use and profit from an active rehearsal process while others do not (e.g., Schneider & Bjorklund, 1998). However, the assumption that the amount of time it takes to rehearse or recite the to-be-learned material represents the defining factor in explaining capacity differences does not comply with findings that emphasize the role of chunk limits in storage capacity differences (e.g., Cowan, 2001). In the present study, the identification of strongly associated neighboring items would seem to favor the latter explanation. In sum, it may prove fruitful to examine whether the assessment of different aspects of capacity reveals different aspects of rehearsal and subsequent rehearsal-recall correspondences.

Finally, the present results raise the question concerning the existence of further, qualitatively different developmental steps toward a sophisticated mastery of free-recall tasks. Addressing this question may include a search for additional internally driven sources that account for study-recall correspondences beyond memory capacity. It might, for example, be assumed that under the premise of capacity influences, children would be able to allocate their resources to control processes or behavior that additionally structures the to-be-learned material both during study and recall. The developmental changes in memory-related activities may, however, additionally be driven by external factors as experience and schooling practice. For instance, Coffman, Ornstein, McCall, and Curran (2008) showed that first-grade teachers' provision of metacognitive information and request for deliberate remembering during instruction had a critical impact on their pupils' use of mnemonic techniques and ability to generalize training in sorting and clustering strategies. Thus, from our point of view, memory capacity should be regarded as a necessary but not sufficient source for rehearsal development.

Manuscripts Accepted for Publication

Sex Differences in Salivary Cortisol, Alpha-Amylase, and Psychological Functioning Following Hurricane Katrina, Jacob Vigil, David Geary, Douglas Granger, and Mark Flinn.

Exposure to 9/11 Among Youth and Their Mothers in New York City: Enduring Associations With Mental Health and Sociopolitical Attitudes, Elizabeth Gershoff, J. Lawrence Aber, Angelica Ware, and Jennifer Kotler.

Exploring Posttraumatic Growth in Children Impacted by Hurricane Katrina: Correlates of the Phenomenon and Developmental Considerations, Ryan Kilmer and Virginia Gil-Rivas.

Sierra Leone's Former Child Soldiers: A Follow-Up Study of Psychosocial Adjustment and Community Reintegration, Theresa Betancourt, Ivelina Borisova, Timothy Phillips, Robert T. Brennan, Theodore Whitfield, Marie de la Soudiere, John Williamson, and Stephen Gilman.

Impact of Maternal Posttraumatic Stress Disorder and Depression Following Exposure to the September 11 Attacks on Preschool Children's Behavior, Claude M. Chemtob, Yoko Nomura, Khushmand Rajendran, Rachel Yehuda, Deena Schwartz, and Robert Abramovitz.

Tsunami, War, and Cumulative Risk in the Lives of Sri Lankan Schoolchildren, Claudia Catani, Abigail H. Gewirtz, Elizabeth Wieling, Elisabeth Schauer, Thomas Elbert, and Frank Neuner.

Growing Pains: The Impact of Disaster-Related and Daily Stressors on the Psychological and Psychosocial Functioning of Youth in Sri Lanka, Gaithri Fernando, Kenneth Miller, and Dale Berger.

Children With Disabilities in the Context of Disaster: A Social Vulnerability Perspective, Lori Peek and Laura M. Stough.

Typologies of Family Functioning and Children's Adjustment During the Early School Years, Melissa Sturge-Apple, Patrick Davies, and E. Mark Cummings.

Defining Best Practice in Care and Protection of Children in Crisis-Affected Settings: A Delphi Study, Alastair Ager, Lindsay Stark, Bree Akesson, and Neil Boothby.

Posttraumatic Resilience in Former Ugandan Child Soldiers, Fionna Klasen, Gabriele Oettingen, Judith Daniels, Manuela Post, Catrin Hoyer, and Hubertus Adam.

The Effects of the 1999 Turkish Earthquake on Young Children: Analyzing Traumatized Children's Completion of Short Stories, Elif Celebi Oncu and Aysegul Metindogan Wise.

The Kenyan Political Conflict and Children's Adjustment, Mumbe Kithakye, Amanda Morris, Andrew Terranova, and Sonya Myers.

An Eye for Detail: An Event-Related Potential Study of the Rapid Processing of Fearful Facial Expressions in Children, Petra Vlamings, Lisa M. Jonkman, and Chantal Kemner.

On the Progression and Stability of Adolescent Identity Formation, Wim Meeus, Rens van de Schoot, Loes Keijsers, Seth J. Schwartz, and Susan Branje.

Dogs, Bogs, Labs, and Lads: What Phonemic Generalizations Indicate About the Nature of Children's Early Word-Form Representations, Erik Thiessen and Meagan N. Yee.

Investigating the Development of Core Cognitive Skills in Autism: A 3-Year Prospective Study, Elizabeth Pellicano.

Home Media and Children's Achievement and Behavior, Sandra Hofferth.

The Effects of Maltreatment and Neuroendocrine Regulation on Memory Performance, Dante Cicchetti, Fred A. Rogosch, Mark L. Howe, and Sheree L. Toth.

Interracial and Intraracial Contact, School-Level Diversity, and Change in Racial Identity Status Among African American Adolescents, Tiffany Yip, Eleanor K. Seaton, and Robert M. Sellers.

Child Care and the Development of Behavior Problems Among Economically Disadvantaged Children in Middle Childhood, Elizabeth

Votruba-Drzal, Rebekah Coley, Carolina Maldonado Carreno, Christine Li-Grining, and P. Lindsay Chase-Lansdale.

An Ecological Approach to Promoting Early Adolescent Mental Health and Social Adaptation: Family-Centered Intervention in Public Middle Schools, Elizabeth Stormshak, Arin M. Connell, Marie-Helene Veronneau, Michael W. Myers, Thomas J. Dishion, Kathryn Kavanagh, and Allison S. Caruthers.

Assessing the Effects of a Work-Based Antipoverty Program for Parents on Youth's Future Orientation and Employment Experiences, Rachel Kaplan, Vonnie C. McLoyd, Kelly Purtell, and Aletha Huston.

Children's Classroom Engagement and School Readiness Gains in Pre-Kindergarten, Nina C. Chien, Carollee Howes, Margaret Burchinal, Robert Pianta, Sharon Ritchie, Donna Bryant, Richard Clifford, Diane Early, and Oscar Barbarin.

Early Elementary School Adjustment of Maltreated Children in Foster Care: The Roles of Inhibitory Control and Caregiver Involvement, Katherine Pears, Philip A. Fisher, Jacqueline Bruce, Hyoun K. Kim, and Karen Yoerger.

Children's Understanding of Ordinary and Extraordinary Minds, Jonathan Lane, Henry Wellman, and E. Margaret Evans.

What Paradox? Referential Cues Allow for Infant Use of Phonetic Detail in Word Learning, Christopher Fennell and Sandra R. Waxman.

Contagious Yawning in Autistic and Typical Development, Molly Helt, Inge-Marie Eigsti, Peter J. Snyder, and Deborah A. Fein.

Tolerance of Practices by Muslim Actors: An Integrative Social-Developmental Perspective, Maike Gieling, Jochem Thijs, and Maykel Verkuyten.

Structure and Strategies in Children's Educational Television: The Roles of Program Type and Learning Strategies in Children's Learning, Deborah L. Linebarger and Jessica Taylor Piotrowski.

Bridging the Gap: Solving Spatial Means–Ends Relations in a Locomotor Task, Sarah Berger, Karen E. Adolph, and Alisan E. Kavookjian.

Sex Categorization Among Preschool Children: Increasing Utilization of Sexually Dimorphic Cues, Kerri Johnson, Leah Lurye Murphy, and Louis G. Tassinary.

Gender Differences in Spatial Ability of Young Children: The Effects of Training and Processing Strategies, David Tzuriel and Gila Egozi.

Disasters, Victimization, and Children's Mental Health, Kathryn Becker-Blease, Heather Turner, and David Finkelhor.

Do Adolescents and Parents Reconstruct Memories About Their Conflict as a Function of Adolescent Attachment? Matthew Dykas, Susan S. Woodhouse, Katherine B. Ehrlich, and Jude Cassidy.

Cognitive Flexibility in Drawings of Bilingual Children, Esther Adi-Japha, Jennie Berberich-Artzi, and Afaf Libnawi.

The Contributions of Numerosity and Domain-General Abilities to School Readiness, Lynn Fuchs, David Geary, Donald Compton, Douglas Fuchs, Carol Hamlett, and Joan Bryant.

Prospective Associations Between Peer Victimization and Aggression, Jamie Ostrov.

Relations Between Physiological and Cognitive Regulatory Systems: Infant Sleep Regulation and Subsequent Executive Functioning, Annie Bernier, Stephanie M. Carlson, Stéphanie Bordeleau, and Julie Carrier.

Maternal Discussions of Mental States and Behaviors: Relations to Emotion Situation Knowledge in European American and Immigrant Chinese Children, Stacey Doan and Qi Wang.

Reading Minds: The Relation Between Children's Mental State Knowledge and Their Metaknowledge About Reading, Serena Lecce, Silvia Zocchi, Adriano Pagnin, Paola Palladino, and Mele Taumoepeau.

Do Black and Hispanic Children Benefit More From Preschool? Understanding Differences in Preschool Effects Across Racial Groups, Daphna Bassok.

Adolescents' Development of Skills for Agency in Youth Programs: Learning to Think Strategically, Reed Larson and Rachel Angus.

Preverbal Infants Anticipate That Food Will Be Brought to the Mouth: An Eye Tracking Study of Manual Feeding and Flying Spoons, Olga Kochukhova and Gustaf Gredebäck.

Race Salience and Essentialist Thinking in Racial Stereotype Development, Kristin Pauker, Nalini Ambady, and Evan Apfelbaum.

Differing Levels of Gender Salience in Preschool Classrooms: Effects on Children's Gender Attitudes and Intergroup Bias, Lacey J. Hilliard and Lynn S. Liben.

Comprehension of Infrequent Subject–Verb Agreement Forms: Evidence From French-Learning Children, Geraldine Legendre, Isabelle Barriere, Louise Goyet, and Thierry Nazzi.

Two-Year-Olds Use the Generic/Nongeneric Distinction to Guide Their Inferences About Novel Kinds, Susan Graham, Samantha Nayer, and Susan Gelman.

Goal Neglect and Working Memory Capacity in 4- to 6-Year-Old Children, Stuart Marcovitch, Janet J. Boseovski, Robin J. Knapp, and Michael J. Kane.

The Social Costs of Academic Success Across Ethnic Groups, Thomas E. Fuller-Rowell and Stacey N. Doan.

Children's Reasoning About Disclosing Adult Transgressions: Effects of Maltreatment, Child Age, and Adult Edentity, Thomas Lyon, Elizabeth A. Ahern, Lindsay A. Malloy, and Jodi A. Quas.

A Developmental Perspective on Executive Function, John R. Best and Patricia Miller.

Pathways to Mathematics: Longitudinal Predictors of Performance, Jo-Anne LeFevre, Lisa Fast, Sheri-Lynn Skwarchuk, Brenda Smith-Chant, Jeffrey Bisanz, Deepthi Kamawar, and Marcie Penner-Wilger.

Development in Children's Comprehension of Linguistic Register, Laura Wagner, Maia Greene-Havas, and Rebecca Gillespie.

How 15 Hundred Is Like 15 Cherries: Effect of Progressive Alignment on Representational Changes in Numerical Cognition, Clarissa Thompson and John Opfer.

Toddlers' Prosocial Behavior: From Instrumental to Empathic to Altruistic Helping, Margarita Svetlova, Sara R. Nichols, and Celia A. Brownell.

Movement Planning Reflects Skill Level and Age Changes in Toddlers, Yu-ping Chen, Rachel Keen, Kerstin Rosander, and Claes von Hofsten.

Young Children Selectively Avoid Helping People With Harmful Intentions, Amrisha Vaish, Malinda Carpenter, and Michael Tomasello.

Danish Majority Children's Reasoning About Exclusion Based on Gender and Ethnicity, Signe Juhl Moller and Harriet Tenenbaum.

How Does It Look? Level 2 Perspective Taking at 36 Months of Age, Henrike Moll and Andrew Meltzoff.

Emotion Discourse, Social Cognition, and Social Skills in Children With and Without Developmental Delays, Rachel M. Fenning, Bruce L. Baker, and Jaana Juvonen.

A Monozygotic Twin Differences Study of Friends' Aggression and Children's Adjustment Problems, Frank Vitaro, Mara Brendgen, Michel Boivin, Stephane Cantin, Ginette Dionne, Richard E. Tremblay, Alain Girard, and Daniel Perusse.

Children of Katrina: Lessons Learned About Post-Disaster Symptoms and Recover Partners, Mindy Kronenberg, Tonya Hansel, Adrianne Brennan, Beverly Lawrason, Howard Osofsky, and Joy Osofsky.

Teacher–Child Relationships and the Development of Academic and Behavioral Skills During Elementary School: A Within- and Between-Child Analysis, Carolina Maldonado-Carreño and Elizabeth Votruba-Drzal.

Object Similarity Bootstraps Young Children to Action-Based Verb Extensions, Etsuko Haryu, Mutsumi Imai, and Hiroyuki Okada.

Can Maltreated Children Inhibit True and False Memories for Emotional Information? Mark Howe, Sheree Toth, and Dante Cicchetti.

Child Development, May/June 2010, Volume 81, Number 3, Page 1024

Errata

Steinberg, L., Graham, S., O'Brien, L., Woolard, J., Cauffman, E., & Banich, M. (2009). Age differences in future orientation and delay discounting. *Child Development*, *80*, 28–44.

On page 44 in the Appendix of the article, the first sentence of the scoring instructions should read: ''Reverse score items 1, 3, 4, 6, 8, 11, 13, and 15, so that higher scores indicate a stronger future orientation.''

Lagattuta, K. H., Nucci, L., & Bosacki, S. L. (2010). Bridging theory of mind and the personal domain: Children's reasoning about resistance to parental control. *Child Development*, *81*, 616–635.

This article contained an error in the presentation of Figures 6 and 7 on pages 628–629. Although the figure captions are correct, they do not correspond to the accompanying bar graphs. The bar graph in Figure 7 (not Figure 6) displays data for identity-related explanations, and the bar graph in Figure 6 (not Figure 7) presents data for moral-evaluative explanations.

JOURNAL OF
Clinical Psychology

Edited by
BEVERLY E. THORN

Founded in 1945, the ***Journal of Clinical Psychology*** is a peer-reviewed forum devoted to research, assessment, and practice. Published eight times a year, the ***Journal*** includes research studies; articles on contemporary professional issues, single case research; brief reports (including dissertations in brief); notes from the field; and news and notes. In addition to papers on psychopathology, psychodiagnostics, and the psychotherapeutic process, the journal welcomes articles focusing on psychotherapy effectiveness research, psychological assessment and treatment matching, clinical outcomes, clinical health psychology, and behavioral medicine.

From time to time, the ***Journal*** publishes Special Sections, featuring a selection of articles related to a single particularly timely or important theme; individuals interested in Guest Editing a Special Section are encouraged to contact the Editors.

Journal of SOCIAL ISSUES
Rick H. Hoyle, PhD
EDITOR

Unexpected Educational Pathways
Issue Editors: Stephen C. Peck, Leon Feinstein, and Jacquelynne S. Eccles

A Journal of the Society for the Psychological Study of Social Issues

Journal of
SOCIAL
ISSUES

Edited by
SHERI R. LEVY

Published on behalf of The Society for the Psychological Study of Social Issues (SPSSI)

Journal of Social Issues (JSI) brings behavioral and social science theory, empirical evidence, and practice to bear on human and social problems. Each issue of the journal focuses on a single topic — recent issues, for example, have addressed poverty, housing, and health; privacy as a social and psychological concern; youth and violence; and the impact of social class on education.

A subscription to ***JSI*** also includes a full subscription to SPSSI's two other journals, ***Analyses of Social Issues and Public Policy (ASAP)*** and ***Social Issues and Police Review (SIPR)***.

Notice to Contributors

S1U8

Child Development publishes empirical, theoretical, review, applied, and policy articles reporting research on child development. Published by the interdisciplinary Society for Research in Child Development (SRCD), the journal welcomes relevant submissions from all disciplines. Further information is available at http://www.srcd.org/cd.html.

Types of Articles

Child Development considers manuscripts in formats described below. Inquiries concerning alternative formats should be addressed to the Editor prior to submission. All submissions are expected to be no more than 40 manuscript pages, including tables, references, and figures (but excluding appendices). Authors should provide a justification if the submission is substantially longer. Unless the editor finds that justification compelling, the submission will be returned to the author for shortening prior to editorial review.

Empirical articles comprise the major portion of the journal. To be accepted, empirical articles must be judged as being high in scientific quality, contributing to the empirical base of child development, and having important theoretical, practical, or interdisciplinary implications. Reports of multiple studies, methods, or settings are encouraged, but single-study reports are also considered. Empirical articles will thus vary considerably in length, but should be no longer than 40 manuscript pages; text and graphics should be as concise as material permits. All modes of empirical research are welcome.

Empirical reports are reserved for short cutting-edge empirical papers that are no longer than 4,000 words in length (including text, tables, footnotes, appendices), which advance research and knowledge in an area through noteworthy findings and/or new methods. For manuscripts that require longer descriptions of methods and results, authors should use the Empirical article format.

Reviews focus on past empirical and/or on conceptual and theoretical work. They are expected to synthesize or evaluate a topic or issue relevant to child development, should appeal to a broad audience, and may be followed by a small number of solicited commentaries.

Essays describe original concepts, methods, trends, applications, and theories; these may also be accompanied by solicited commentaries.

Child Development and … are articles that provide readers with tutorials about some new concept or academic specialty pertinent to research in child development. These papers should review the major definitions, methods, and findings of the concept or specialty and discuss past or potential links to child development.

From another perspective is a format in which papers on a focal topic, written by different authors, are published simultaneously. Papers represent diverse perspectives (e.g., authors whose work represents different populations; different disciplines; different theories, methods, or analytic tools). In some cases, calls for submissions on particular topics will be disseminated through SRCD (via e-mail or SRCD publications), and submissions will undergo normal editorial review. In some cases, a submitted manuscript (e.g., an empirical article) may be selected as a lead article for this format, with invited commentaries providing additional perspectives. The editors also welcome suggestions from readers for topics for this format.

Manuscript Submission

Child Development invites for consideration manuscripts that are neither identical to nor substantially similar to work published or under review elsewhere. In the submission cover letter, please provide details about other published or submitted papers having substantial overlap (including data sets) with the new CD submission to enable editors to judge whether the new submission is sufficiently distinct from other work to warrant consideration. Please note if the paper is posted on a website, see http://www. srcd.org/web posting. html. Editors retain the right to reject manuscripts that do not meet established ethical standards for research or dissemination.

Manuscripts should be submitted electronically to the Child Development Online Submission Site at www.srcd.org /CDsubmit/ as a Word or WordPerfect file. Please also submit a cover letter that contains the name(s) of the author(s) and affiliation(s), and the street address, telephone, fax, and electronic mail address of the corresponding author. A corresponding author's submission to *Child Development* implies that all coauthors have agreed to the content and form of the manuscript and that the ethical standards of SRCD have been followed (see the *Child Development* website or pp. 283–284 of the 2000 SRCD Directory). Any financial interest or conflict of interest must be explained to the Editor in the cover letter. The corresponding author is responsible for informing all coauthors, in a timely manner, of manuscript submission, editorial decisions, reviews, and revisions. Please note that if your submission (or its revision) is accepted for publication, each author must submit a signed Exclusive License Form (http://www.srcd.org/Documents/Publications/CD/cdcopyright.pdf) before the manuscript can enter production. Planning ahead to meet this requirement is especially important for manuscripts with multiple authors.

The manuscript file should be formatted with double-spaced, 12-point type, and should include a single paragraph abstract of 100–120 words. Please follow all guidelines on format, style, and ethics provided in the Publication Manual (6th ed.) of the American Psychological Association. Figures included with initial submissions will not be returned. Therefore, please submit only electronic files or copies of figures. If color artwork is submitted, and the authors believe color art is necessary to the presentation of their work, the submissions letter should indicate that one or more authors or their institutions are prepared to pay the substantial costs associated with color art reproduction. Authors should keep a copy of all correspondence, files, and figures to guard against loss.

Manuscript Review

If you have any questions about your submission, please inquire at cdev@srcd.org or call (734) 926-0615. Each manuscript is handled by the Editor or an Associate Editor who consults with one or more Consulting Editors and/or ad hoc reviewers who have relevant expertise. To ensure blind review, cover sheets are removed before review; authors should avoid including any other information about identity or affiliation in submissions. Copies of the submission and associated correspondence are retained in the SRCD archives. For accepted manuscripts, authors are required to prepare a 300–500 layperson's summary for public dissemination purposes. Details are provided to authors as part of final processing.

There is no charge for publication in *Child Development* unless tabular or graphic materials exceed 10% of the total number of pages. Charges are also levied for changes in proofs other than correction of printer's errors. Any inquiries relating to charges or business matters (including reprint orders) should be addressed to Wiley-Blackwell, *Child Development*, Production Coordinator, 350 Main Street, Malden, MA 02148, (781) 388-8200.

Inquiries and suggestions regarding editorial policy may be addressed to: Dr. Jeffrey J. Lockman, Editor, *Child Development*, Department of Psychology, Tulane University, 2007 Percival Stern Hall, New Orleans, LA 70118-5698, lockman@tulane.edu. *Please do not send electronic or paper manuscripts to the above address.* Doing so will delay the processing of your manuscript.

Note to NIH Grantees

Pursuant to NIH mandate, Society through Wiley-Blackwell will post the accepted version of Contributions authored by NIH grantholders to PubMed Central upon acceptance. This accepted version will be made publicly available 12 months after publication. For further information, see www.wiley.com/go/nihmandate.

MONOGRAPHS OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT

Recent

DEPRIVATION-SPECIFIC PSYCHOLOGICAL PATTERNS: EFFECTS OF INSTITUTIONAL DEPRIVATION
- *Michael Rutter, Edmund J. Sonuga-Barke, Celia Beckett, Jennifer Castle, Jana Kreppner, Robert Kumsta, Wolff Schlotz, Suzanne Stevens, and Christopher A. Bell* (Serial Na. 295, 2010).

A DYNAMIC CASCADE MODEL OF THE DEVELOPMENT OF SUBSTANCE-USE ONSET
- *Kenneth A. Dodge, Patrick S. Malone, Jennifer E. Lansford, Shari Miller, Gregory S. Pettit, and John E. Bates* (Serial Na. 294, 2009).

FLEXIBILITY IN EARLY VERB USE: EVIDENCE FROM A MULTIPLE-*N* DIARY STUDY
- *Letitia R. Naigles, Erika Hoff, and Donna Vear* (Serial Na. 293, 2009).

MARITAL CONFLICT AND CHILDREN'S EXTERNALIZING BEHAVIOR: INTERACTIONS BETWEEN PARASYMPATHETIC AND SYMPATHETIC NERVOUS SYSTEM ACTIVITY
- *Mona El-Sheikh et al.* (Serial Na. 292, 2009).

THE EFFECTS OF EARLY SOCIAL-EMOTIONAL AND RELATIONSHIP EXPERIENCE ON THE DEVELOPMENT OF YOUNG ORPHANAGE CHILDREN
- *The St. Petersburg–USA Orphanage Research Team* (Serial Na. 291, 2008).

UNDERSTANDING MOTHER-ADOLESCENT CONFLICT DISCUSSIONS: CONCURRENT AND ACROSS-TIME PREDICTION FROM YOUTHS' DISPOSITIONS AND PARENTING
- *Nancy Eisenberg et al.* (Serial Na. 290, 2008).

DEVELOPING OBJECT CONCEPTS IN INFANCY: AN ASSOCIATIVE LEARNING PERSPECTIVE
- *David H. Rakison and Gary Lupyan* (Serial Na. 289, 2008).

THE GENETIC AND ENVIRONMENTAL ORIGINS OF LEARNING ABILITIES AND DISABILITIES IN THE EARLY SCHOOL YEARS
- *Yulia Kovas, Claire M. A. Haworth, Philip S. Dale, and Robert Plomin* (Serial Na. 288, 2007).

THE PRESERVATION OF TWO INFANT TEMPERAMENTS INTO ADOLESCENCE
- *Jerome Kagan, Nancy Snidman, Vali Kahn, and Sara Towsley* (Serial No. 287, 2007).

CHILDREN'S QUESTIONS: A MECHANISM FOR COGNITIVE DEVELOPMENT
- *Michelle M. Chouinard* (Serial Na. 286, 2007).

BEST PRACTICES IN QUANTITATIVE METHODS FOR DEVELOPMENTALISTS
- *Kathleen McCartney, Margaret R. Burchinal, and Kristen L. Bub* (Serial No. 285, 2006).

FOUNDATIONS OF SELF-AWARENESS: AN EXPLORATION THROUGH AUTISM
- *R. Peter Hobson, Gayathri Chidambi, Anthony Lee, and Jessica Meyer* (Serial No. 284, 2006).

OUR CHILDREN TOO: A HISTORY OF THE BLACK CAUCUS
OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT, 1973–1997
- *Diana T. Slaughter-Defoe, Aline M. Garrett, and Algea O. Harrison-Hale* (Serial Na. 283, 2006).

PARENTAL SUPPORT, PSYCHOLOGICAL CONTROL, AND BEHAVIORAL CONTROL:
ASSESSING RELEVANCE ACROSS TIME, CULTURE, AND METHOD
- *Brian K. Barber, Heidi E. Stolz, and Joseph A. Olsen* (Serial Na. 282, 2005).

BEING HURT AND HURTING OTHERS: CHILDREN'S NARRATIVE ACCOUNTS
AND MORAL JUDGMENTS OF THEIR OWN INTERPERSONAL CONFLICTS
- *Cecilia Wainryb, Beverly A. Brenl, and Sonia Matwin* (Serial Na. 281, 2005).

CHILDHOOD SEXUAL ASSAULT VICTIMS: LONG-TERM OUTCOMES AFTER TESTIFYING IN CRIMINAL COURT
- *Jodi A. Quas, Gail S. Goodman, Simona Ghetti, Kristen Weede Alexander, Robin Edelstein, Allison D. Redlich, Ingrid M. Cordon, and David P. H. Jones* (Serial Na. 280, 2005).

THE EMERGENCE OF SOCIAL COGNITION IN THREE YOUNG CHIMPANZEES
- *Michael Tomasello and Malinda Carpenter* (Serial Na. 279, 2005).

TRAJECTORIES OF PHYSICAL AGGRESSION FROM TODDLERHOOD TO MIDDLE CHILDHOOD:
PREDICTORS, CORRELATES, AND OUTCOMES
- *NICHD Early Child Care Research Network* (Serial No. 278, 2004).

CONSTRAINTS ON CONCEPTUAL DEVELOPMENT: A CASE STUDY OF THE ACQUISITION OF
FOLKBIOLOGICAL AND FOLKSOCIOLOGICAL KNOWLEDGE IN MADAGASCAR
- *Rita Astuti, Gregg E. A. Solomon, and Susan Carey* (Serial No. 277, 2004).

ORIGINS AND EARLY DEVELOPMENT OF HUMAN BODY KNOWLEDGE
- *Virginia Slaughter, Michelle Heron, Linda Jenkins, and Elizabeth Tilse* (Serial Na. 276, 2004).

MOTHER CHILD CONVERSATIONS ABOUT GENDER: UNDERSTANDING THE ACQUISITION OF ESSENTIALIST BELIEFS
- *Susan A. Gelman, Marianne G. Taylor, and Simone P. Nguyen* (Serial Na. 275, 2004).
